about 20% of first attacks occur in adults, with arthritis being the predominant feature. Symptoms in all age groups typically begin 2 to 3 weeks after streptococcal infection and are heralded by fever and migratory polyarthritis—one large joint after another becomes painful and swollen for a period of days, followed by spontaneous resolution with no residual disability. Although cultures are negative for streptococci at the time of symptom onset, serum titers of antibodies against one or more streptococcal antigens (e.g., streptolysin O or DNAase) usually are elevated. The clinical signs of carditis include pericardial friction rubs and arrhythmias; myocarditis may be sufficiently severe to cause cardiac dilation and resultant functional mitral insufficiency and CHF. Nevertheless, less than 1% of patients die of acute rheumatic fever.

The diagnosis of acute rheumatic fever is made based on serologic evidence of previous streptococcal infection in conjunction with two or more of the *Jones criteria:* (1) carditis; (2) migratory polyarthritis of large joints; (3) subcutaneous nodules; (4) erythematous annular rash (erythema marginatum) in the skin; and (5) Sydenham chorea, a neurologic disorder characterized by involuntary purposeless, rapid movements (also called *St. Vitus dance*). Minor criteria such as fever, arthralgias, EKG changes, or elevated acute phase reactants also can help support the diagnosis.

After an initial attack and the generation of immunologic memory, patients are increasingly vulnerable to disease reactivation with any subsequent streptococcal infections. Carditis is likely to worsen with each recurrence, and the damage is cumulative. However, *chronic rheumatic carditis* usually is not clinically evident until years or even decades after the initial episode of rheumatic fever. At that time, the signs and symptoms of valvular disease depend on which cardiac valve(s) is involved. In addition to various cardiac murmurs, cardiac hypertrophy and dilation, and CHF, patients with chronic rheumatic heart disease often have arrhythmias (particularly atrial fibrillation in the setting of mitral stenosis), and thromboembolic complications due to atrial mural thrombi. In addition, scarred and deformed valves are more susceptible to infective endocarditis. The long-term prognosis is highly variable. In some cases, a relentless cycle of valvular deformity ensues, yielding hemodynamic abnormality, which begets further

deforming fibrosis. Surgical repair or replacement of diseased valves—mitral valvuloplasty—has greatly improved the outlook for patients with rheumatic heart disease.

Infective Endocarditis

Infective endocarditis (IE) is a microbial infection of the heart valves or the mural endocardium that leads to the formation of *vegetations* composed of thrombotic debris and organisms, often associated with destruction of the underlying cardiac tissues. The aorta, aneurysmal sacs, other blood vessels, and prosthetic devices also may become infected. Although fungi, rickettsiae (agents of Q fever), and chlamydial species can cause endocarditis, the vast majority of cases are caused by extracellular bacteria.

Infective endocarditis is classified into *acute* and *subacute* forms based on the tempo and severity of the clinical course; the distinctions are related to the virulence of the responsible microbe and whether underlying cardiac disease is present. Of note, a clear delineation between acute and subacute endocarditis is not always possible, and many cases fall somewhere along the spectrum between the two forms.

- *Acute endocarditis* refers to tumultuous, destructive infections, frequently involving a highly virulent organism attacking a previously normal valve. It is associated with of substantial morbidity and mortality, even with appropriate antibiotic therapy and/or surgery.
- *Subacute endocarditis* refers to infections by organisms of low virulence affecting a previously abnormal heart, especially scarred or deformed valves. The disease typically appears insidiously and—even if untreated—follows a protracted course of weeks to months; most patients recover after appropriate antibiotic therapy.

Pathogenesis

Infective endocarditis can develop on previously normal valves, but cardiac abnormalities predispose to such infections; rheumatic heart disease, mitral valve prolapse, bicuspid aortic valves, and calcific valvular stenosis are all common substrates. Prosthetic heart valves (discussed later) now account for 10% to 20% of all cases of IE. Sterile platelet-fibrin deposits at sites of pacemaker lines, indwelling vascular catheters, or endocardium damage by flow "jets" stemming from preexisting cardiac disease all can be foci for bacterial seeding and development of endocarditis. Host factors such as neutropenia, immunodeficiency, malignancy, diabetes mellitus, and alcohol or intravenous drug abuse also increase the risk for IE and adversely affect outcomes.

The causative organisms differ depending on the underlying risk factors; 50% to 60% of cases occurring on damaged or deformed valves are caused by *Streptococcus viridans,* a relatively banal group of normal oral flora. By contrast, the more virulent *S. aureus* (common to skin) can attack healthy as well as deformed valves and is responsible for 10% to 20% of cases overall; it also is the major offender in infections occurring in intravenous drug abusers. Additional bacterial agents include enterococci and the so-called "HACEK group" (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella*), all commensal in the oral cavity. More rarely, gram-negative bacilli and fungi are involved. In about 10% of all cases of endocarditis, no organism is isolated from the blood ("culture-negative" endocarditis) because of previous antibiotic therapy, difficulty in isolating the offending agent, or because deeply embedded organisms within the enlarging vegetation are not readily released into the blood.

Foremost among the factors predisposing to endocarditis is seeding of the blood with microbes. The mechanism or portal of entry of the agent into the bloodstream may be an obvious infection elsewhere, a dental or surgical procedure that causes a transient bacteremia, injection of contaminated material directly into the bloodstream by intravenous drug abusers, an occult source from the gut, or oral cavity, or trivial injuries. Recognition of predisposing anatomic substrates and clinical conditions causing bacteremia allows appropriate antibiotic prophylaxis.

MORPHOLOGY

In both acute and subacute forms of the disease, friable, bulky, and potentially destructive vegetations containing fibrin, inflammatory cells, and microorganisms are present on the heart valves (Figs. 11.20 and 11.21). **The aortic and mitral valves are the most common sites of infection, although the tricuspid valve is a frequent target in the setting of intravenous drug abuse.** Vegetations may be single or multiple and may involve more than one valve; they can sometimes erode into the underlying myocardium to produce an abscess cavity **(ring abscess)** (Fig. 11.21B). Shedding of **emboli** is common because of the friable nature of the vegetations. Since the fragmented vegetations contain large numbers of organisms, abscesses often develop at the sites where emboli lodge, leading to development of **septic infarcts** and aneurysms resulting from bacterial infection of the arterial wall **(mycotic aneurysms).**

Subacute endocarditis typically causes less valvular destruction than acute endocarditis. On microscopic examination, the vegetations of subacute endocarditis often have granulation tissue at their bases (suggesting chronicity), promoting development of chronic inflammatory infiltrates, fibrosis, and calcification over time.

Clinical Features

Fever is the most consistent sign of infective endocarditis. However, in subacute disease (particularly in older adults), fever may be absent, and the only manifestations may be nonspecific fatigue, weight loss, and a flulike syndrome; splenomegaly also is common in subacute cases. By contrast, acute endocarditis often manifests with rapidly developing fever, chills, weakness, and lassitude. Murmurs are present in 90% of patients with left-sided lesions. In those who are not treated promptly, microemboli are formed, which can give rise to petechia, nail bed *(splinter)* hemorrhages, retinal hemorrhages *(Roth spots),* painless palm or sole erythematous lesions *(Janeway lesions),* or painful fingertip nodules *(Osler nodes)*; diagnosis is confirmed by positive blood cultures and echocardiographic findings.

Prognosis depends on the infecting organism and the development of complications. Adverse sequelae generally begin within the first weeks after onset of the infectious process and can include glomerulonephritis due to glomerular trapping of antigen-antibody complexes, with

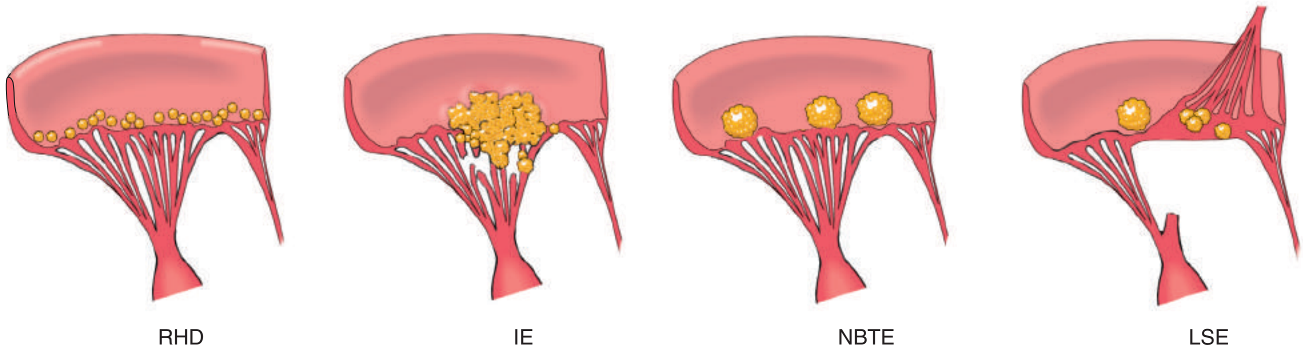

Fig. 11.20 Major forms of vegetative endocarditis. The acute rheumatic fever phase of rheumatic heart disease (RHD) is marked by the appearance of small, warty, inflammatory vegetations along the lines of valve closure; as the inflammation resolves, substantial scarring can result. Infective endocarditis (IE) is characterized by large, irregular, often destructive masses that can extend from valve leaflets onto adjacent structures (e.g., chordae or myocardium). Nonbacterial thrombotic endocarditis (NBTE) typically manifests with small- to medium-sized, bland, nondestructive vegetations at the line of valve closure. Libman-Sacks endocarditis (LSE) is characterized by small- to medium-sized inflammatory vegetations that can be attached on either side of the valve leaflets; these heal with scarring.

hematuria, albuminuria, or renal failure (Chapter 14). Clinical features of septicemia, arrhythmias (suggesting extension to underlying myocardium and conduction system), and systemic embolization bode ill for the patient. Left untreated, IE generally is fatal. However, with appropriate long-term (6 weeks or more) antibiotic therapy and/or valve replacement, mortality is reduced. For infections with low-virulence organisms (e.g., *Streptococcus viridans* or *Streptococcus bovis*), the cure rate is 98%, and for enterococci and *Staphylococcus aureus* infections, cure rates range from 60% to 90%; however, infections with aerobic gram-negative bacilli or fungi are associated with fatality rate of approximately 50%.

Noninfected Vegetations

Nonbacterial Thrombotic Endocarditis

Nonbacterial thrombotic endocarditis (NBTE) is characterized by the deposition of sterile thrombi on cardiac valves, typically in those with an underlying hypercoagulable state. Although NBTE can occur in otherwise healthy individuals, a wide variety of diseases associated with general debility or wasting are associated with an increased risk for NBTE—hence the alternate term *marantic endocarditis*. In contrast to infective endocarditis, the sterile valvular lesions of NBTE are nondestructive (Fig. 11.22).

The vegetations in NBTE are typically small (1 to 5 mm in diameter) and valvular damage is not a prerequisite. Indeed, the condition usually occurs on previously normal valves. Rather, hypercoagulable states are the usual precursor to NBTE; such conditions include chronic disseminated intravascular coagulation, hyperestrogenic states, and those associated with underlying malignancy, particularly mucinous adenocarcinomas. This last association probably relates to the procoagulant effect of circulating mucin and/or tissue factor elaborated by these tumors. Endocardial trauma, such as from an indwelling catheter, also is a well-recognized predisposing condition.

Although the local effect on the valve usually is trivial, NBTE lesions can become clinically significant by giving rise to emboli that can cause infarcts in the brain, heart, and other organs. NBTE also can serve as a potential nidus for bacterial colonization and the consequent development of infective endocarditis.

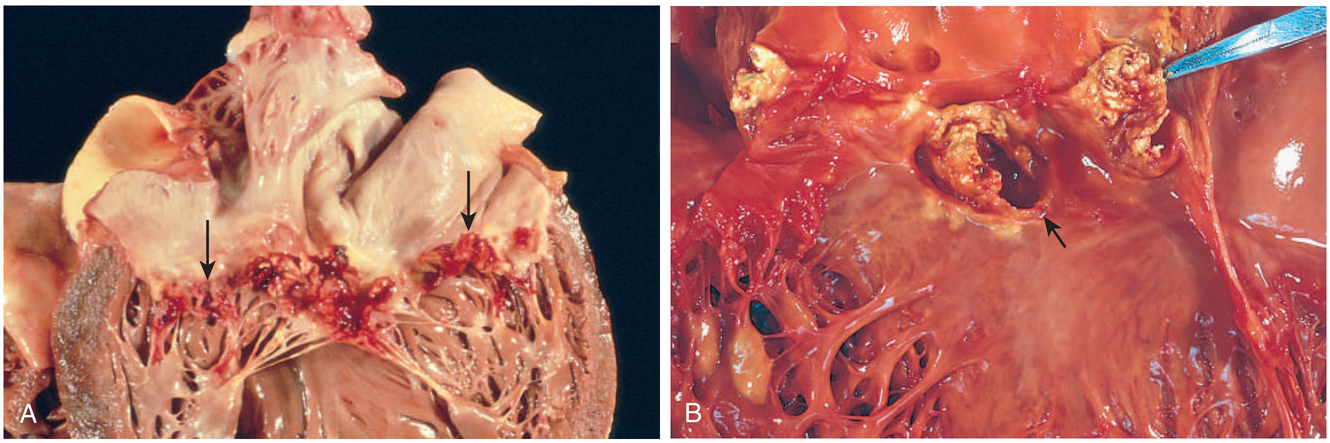

Fig. 11.21 Infective endocarditis. (A) Subacute endocarditis caused by *Streptococcus viridans* on a previously myxomatous mitral valve. The large, friable vegetations are denoted by *arrows*. (B) Acute endocarditis caused by *Staphylococcus aureus* on a congenitally bicuspid aortic valve with extensive cuspal destruction and ring abscess *(arrow)*.

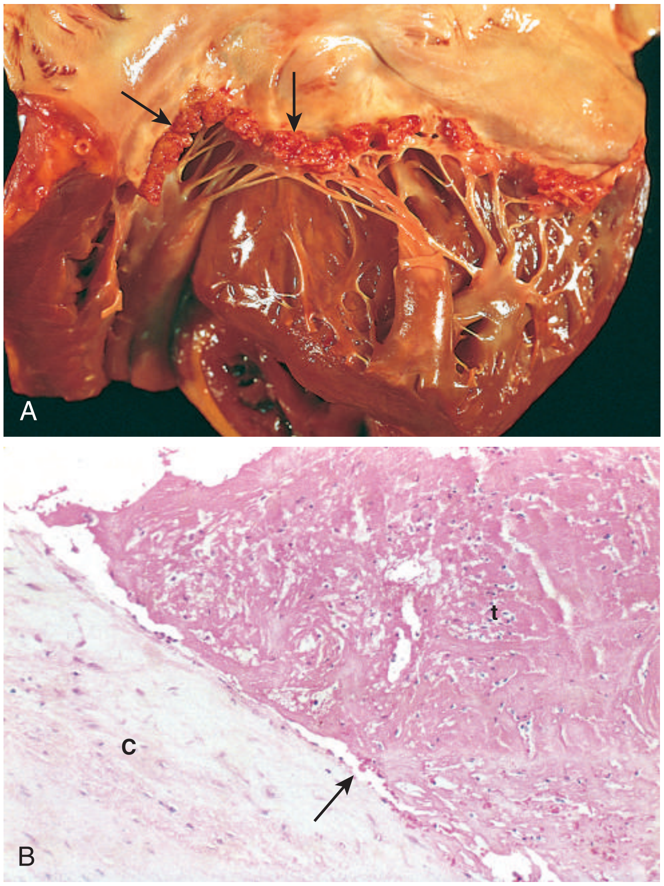

Fig. 11.22 Nonbacterial thrombotic endocarditis (NBTE). (A) Small thrombotic vegetations along the line of closure of the mitral valve leaflets *(arrows)*. (B) Photomicrograph of NBTE lesion, showing bland thrombus, with virtually no inflammation in the valve cusp *(C)* or the thrombotic deposit *(t)*. The thrombus is only loosely attached to the cusp *(arrow)*.

Endocarditis in Systemic Lupus Erythematosus: Libman-Sacks Endocarditis

Libman-Sacks endocarditis is characterized by the presence of sterile vegetations on the valves of patients with systemic lupus erythematosus. It occurs in about 10% of patients with SLE. The lesions probably develop as a consequence of immune complex deposition and thus exhibit associated inflammation, often with fibrinoid necrosis of the valve adjacent to the vegetation; subsequent fibrosis and serious deformity can result in lesions that resemble chronic rheumatic heart disease. These can occur anywhere on the valve surface, on the cords, or even on the atrial or ventricular endocardium (see Fig. 11.20). Similar lesions can occur in the setting of anti-phospholipid antibody syndrome (Chapter 4).

SUMMARY

VALVULAR HEART DISEASE

- Valve pathology can lead to occlusion *(stenosis)* and/or regurgitation *(insufficiency)*; acquired aortic or mitral valve stenosis accounts for approximately two thirds of all valve disease.
- Valve calcification typically results in stenosis; abnormal matrix synthesis and turnover leads to myxomatous degeneration and insufficiency.
- Inflammatory valve diseases cause postinflammatory neovascularization and scarring. Rheumatic heart disease results from anti-streptococcal antibodies that cross-react with cardiac tissues; it most commonly affects the mitral valve and is responsible for almost all cases of acquired mitral stenosis.
- Infective endocarditis can rapidly destroy normal valves, or can be indolent and minimally destructive of previously abnormal valves. Systemic embolization can produce septic infarcts.
- Nonbacterial thrombotic endocarditis occurs on previously normal valves as a result of hypercoagulable states; embolization is an important complication.

CARDIOMYOPATHIES AND MYOCARDITIS

Cardiac diseases due to intrinsic myocardial dysfunction are termed *cardiomyopathies* (literally, "heart muscle diseases"); these can be primary—that is, principally confined to the myocardium—or secondary presenting as the cardiac manifestation of a systemic disorder. Cardiomyopathies are thus a diverse group that includes inflammatory disorders (e.g., myocarditis), immunologic diseases (e.g., sarcoidosis), systemic metabolic disorders (e.g., hemochromatosis), muscular dystrophies, and genetic disorders of myocardial fibers. In many cases, the cardiomyopathy is of unknown etiology and thus is termed idiopathic; however, a number of previously "idiopathic" cardiomyopathies have been shown to be the consequence of specific genetic abnormalities in cardiac energy metabolism or in structural and contractile proteins.

Cardiomyopathies can be classified according to a variety of criteria, including the underlying genetic basis of dysfunction; indeed, some of the arrhythmia-inducing channelopathies that are included in some classifications of cardiomyopathy were alluded to earlier. For purposes of general diagnosis and therapy, however, three time-honored clinical, functional, and pathologic patterns are recognized (Fig. 11.23 and Table 11.5):

- Dilated cardiomyopathy (DCM) (including arrhythmogenic right ventricular cardiomyopathy)
- Hypertrophic cardiomyopathy (HCM)
- Restrictive cardiomyopathy

Of the three major patterns, DCM is most common (90% of cases), and restrictive cardiomyopathy is the least frequent. Within each pattern, there is a spectrum of clinical severity, and in some cases clinical features overlap among the groups. In addition, each of these patterns can be caused by a specific identifiable cause, or can be idiopathic (see Table 11.5).

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is characterized by progressive cardiac dilation and contractile (systolic) dysfunction, usually with concurrent hypertrophy; regardless of the cause, the clinicopathologic patterns are similar.

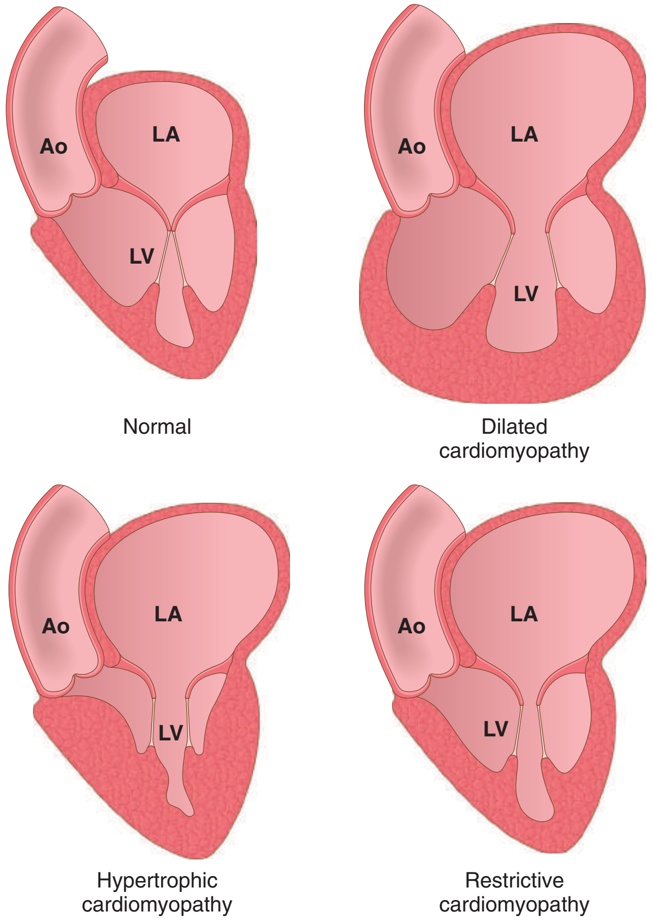

Fig. 11.23 The three major forms of cardiomyopathy. Dilated cardiomyopathy leads primarily to systolic dysfunction, whereas restrictive and hypertrophic cardiomyopathies result in diastolic dysfunction. Note the changes in atrial and/or ventricular dilation and in ventricular wall thickness. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

Pathogenesis

Although many individuals with DCM have a familial (genetic) form, DCM can also result from various acquired myocardial insults. These include the following:

- *Myocarditis* (an inflammatory disorder that precedes the development of cardiomyopathy in at least some cases, and is sometimes caused by viral infections)
- *Toxicities,* including adverse effects of chemotherapeutic agents and chronic alcoholism, a history of which can be elicited in 10% to 20% of patients
- *Pregnancy,* so-called "peripartum cardiomyopathy"
- *Stress-provoked*
- *Tachycardia-induced*

By the time it is diagnosed, DCM has frequently already progressed to end-stage disease; the heart is dilated and poorly contractile, and at autopsy or cardiac transplant, fails to reveal any specific pathologic features. Nevertheless, genetic and epidemiologic studies suggest that at least five general pathways can lead to end-stage DCM (Fig. 11.24):

- *Genetic causes.* DCM has a hereditary basis in 20% to 50% of cases. Over 50 genes are known to be mutated in this form of cardiomyopathy, with autosomal dominant inheritance being the predominant pattern; mutations affecting cytoskeletal proteins or proteins that link the sarcomere to the cytoskeleton (e.g., α-cardiac actin) are most commonly involved. X-linked DCM is most frequently associated with mutatons in dystrophin, a cell membrane protein that physically couples the intracellular cytoskeleton to the ECM (Chapter 22). Uncommon forms of DCM are caused by mutations of mitochondrial proteins involved in oxidative phosphorylation or fatty acid β-oxidation, presumably leading to defective ATP generation. Other genetic forms of DCM include those with mutations in cytoskeletal proteins such as desmin (the principal intermediate filament protein in cardiac myocytes), and the nuclear lamins A and C. Since contractile myocytes and conduction fibers share a common developmental pathway, congenital conduction abnormalities also can be a feature of inherited forms of DCM.
- *Infection.* The nucleic acid "footprints" of coxsackievirus B and other enteroviruses can occasionally be detected in the myocardium from late-stage DCM patients. Moreover, sequential endomyocardial biopsies have documented instances in which infectious myocarditis progressed to DCM. Simply finding viral transcripts or demonstrating elevated anti-viral antibody titers may be sufficient to invoke a myocarditis that was "missed" in its early stages. Consequently, many cases of DCM are attributed to viral infections, even though inflammation is absent from the end-stage heart.
- *Alcohol or other toxic exposure.* Alcohol abuse is strongly associated with the development of DCM. Alcohol and

Table 11.5 Cardiomyopathies: Functional Patterns, Causes

Functional Pattern	Left Ventricular Ejection Fraction*	Mechanisms of Heart Failure	Causes	Secondary Myocardial Dysfunction (Mimicking Cardiomyopathy)
Dilated	<40%	Impairment of contractility (systolic dysfunction)	Genetic; alcohol; peripartum; myocarditis; hemochromatosis; chronic anemia; doxorubicin (Adriamycin); sarcoidosis; idiopathic	Ischemic heart disease; valvular heart disease; hypertensive heart disease; congenital heart disease
Hypertrophic	50%–80%	Impairment of compliance (diastolic dysfunction)	Genetic; Friedreich ataxia; storage diseases; infants of diabetic mothers	Hypertensive heart disease; aortic stenosis
Restrictive	45%–90%	Impairment of compliance (diastolic dysfunction)	Amyloidosis; radiation-induced fibrosis; idiopathic	Pericardial constriction

*Range of normal values is approximately 50% to 65%.

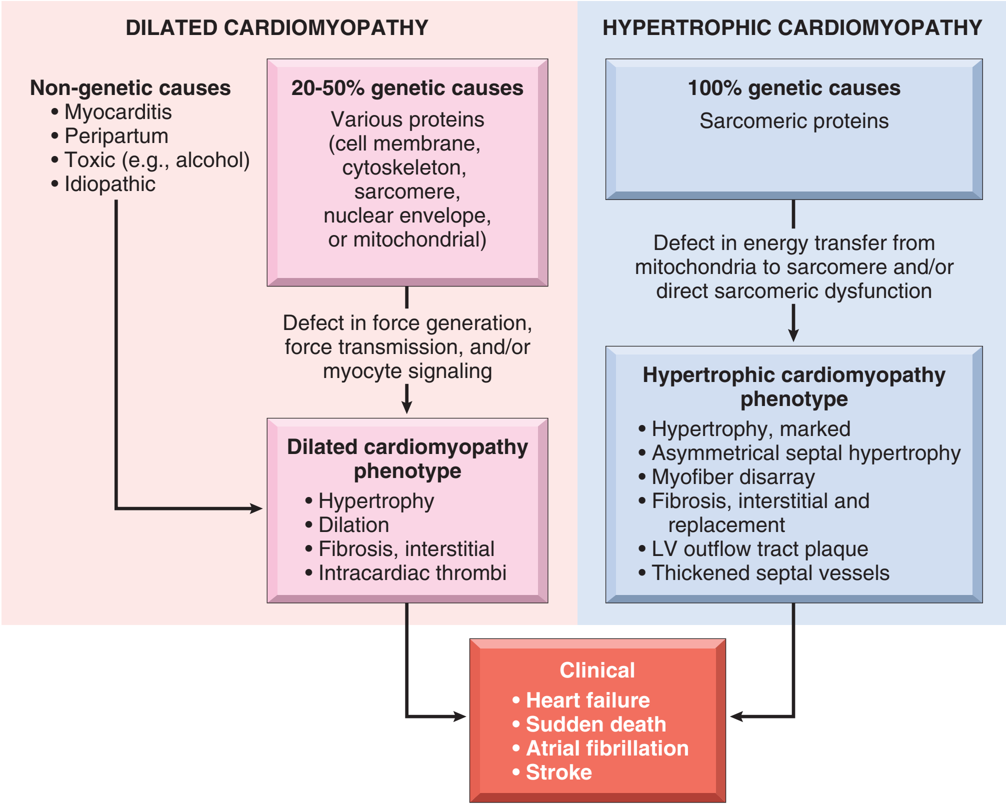

Fig. 11.24 Causes and consequences of dilated and hypertrophic cardiomyopathy. A significant fraction of dilated cardiomyopathies—and virtually all hypertrophic cardiomyopathies—have a genetic origin. Dilated cardiomyopathies can be caused by mutations in cytoskeletal, sarcomeric, nuclear envelope, or mitochondrial proteins; hypertrophic cardiomyopathies typically are caused by sarcomeric protein mutations. Although the two forms of cardiomyopathy differ in cause and morphology, they have common clinical end points. *LV,* Left ventricle.

its metabolites (especially acetaldehyde) have a direct toxic effect on the myocardium. Moreover, chronic alcoholism can be associated with thiamine deficiency, introducing an element of beriberi heart disease (Chapter 8). DCM also can develop after exposure to other toxic agents, such as cobalt, and particularly doxorubicin (Adriamycin), a chemotherapeutic drug.

- *Peripartum cardiomyopathy* occurs late in gestation or several weeks to months postpartum. The etiology is multifactorial, including pregnancy-associated hypertension, volume overload, nutritional deficiency, metabolic derangements (e.g., gestational diabetes), and/or immunologic responses. Recent work suggests that the primary defect is impaired angiogenesis within the myocardium leading to ischemic injury. Antiangiogenic cleavage products of the hormone prolactin (which rises late in pregnancy) and placental-derived antagonists to the VEGF have been implicated. Fortunately, approximately one half of these patients spontaneously recover normal function.
- *Iron overload* in the heart can result either from hereditary hemochromatosis (Chapter 16) or from multiple transfusions. Iron overload also can cause restrictive cardiomyopathy due to interstitial fibrosis, but DCM is the most common manifestation; it has been attributed to interference with metal-dependent enzyme systems or to injury caused by iron-mediated production of reactive oxygen species.

MORPHOLOGY

The heart in DCM characteristically is enlarged (up to two to three times the normal weight) and **flabby,** with dilation of all chambers (Fig. 11.25). Because of the wall thinning that accompanies dilation, the ventricular thickness may be less than, equal to, or greater than normal. **Mural thrombi** are often present and may be a source of thromboemboli. By definition, valvular and vascular lesions (e.g., atherosclerotic coronary artery disease) that can cause cardiac dilation secondarily are absent.

The characteristic histologic abnormalities in DCM are nonspecific. Most myocytes exhibit **hypertrophy** with enlarged nuclei, but many are attenuated, stretched, and irregular. There is also variable interstitial and endocardial fibrosis, with scattered areas of replacement fibrosis; the latter mark previous myocyte ischemic necrosis caused by hypoperfusion, or they may be the footprints of a previous "missed" myocarditis.

In DCM secondary to iron overload, there is a marked accumulation of intramyocardial hemosiderin, which is demonstrable by staining with Prussian blue.

Clinical Features

The fundamental defect in DCM is ineffective contraction. Thus, in end-stage DCM, the cardiac ejection fraction typically is less than 25% (normal is 50% to 65%). Secondary mitral regurgitation and abnormal cardiac rhythms are

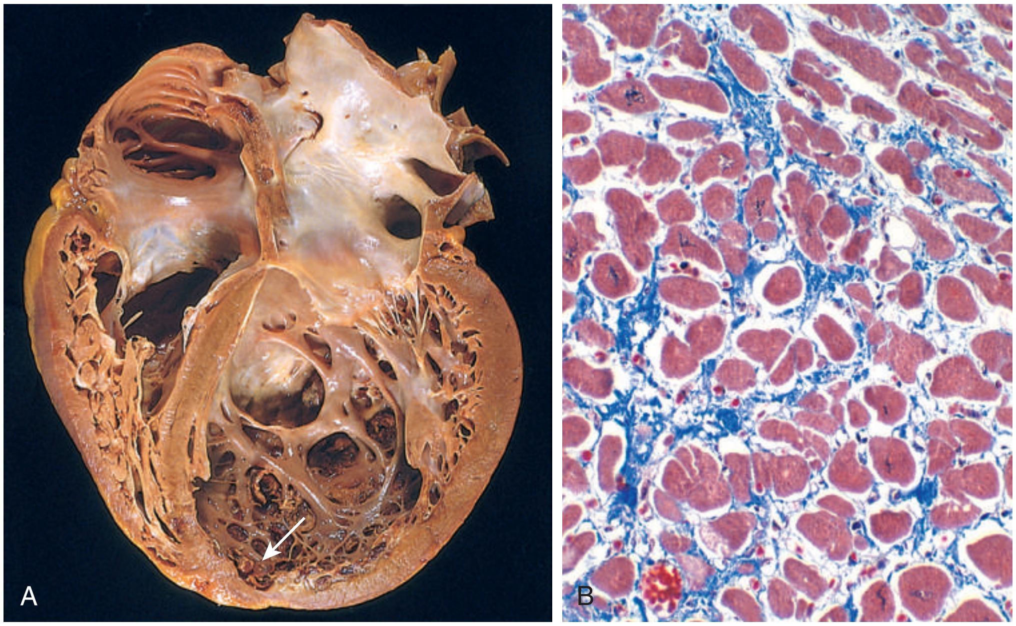

Fig. 11.25 Dilated cardiomyopathy (DCM). (A) Four-chamber dilation and hypertrophy are evident. A small mural thrombus can be seen at the apex of the left ventricle *(arrow)*. (B) The nonspecific histologic picture in typical DCM, with myocyte hypertrophy and interstitial fibrosis. (Collagen is *blue* in this Masson trichrome–stained preparation.)

common, and embolism from intracardiac (mural) thrombi can occur. DCM most commonly is diagnosed between 20 and 50 years of age. It typically manifests with signs of slowly progressive CHF, including dyspnea, easy fatigability, and poor exertional capacity. One half of patients die within 2 years and only 25% survive longer than 5 years; death is usually due to progressive cardiac failure or arrhythmia. Cardiac transplantation is the only definitive treatment, although implantation of long-term ventricular assist devices is increasingly utilized; in some patients, a course of mechanical assistance can produce durable regression of cardiac dysfunction.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy is an autosomal dominant disorder that classically manifests with right-sided heart failure and rhythm disturbances, which can cause sudden cardiac death. Its prevalence in the general adult population is close to 1 in 5000 in a study from Italy. Similar prevalence is likely in the US where it seems to be under reported. Almost 10% of cases of sudden deaths in athletes have been ascribed to this entity. Morphologically, the right ventricular wall is severely thinned owing to myocyte replacement by fatty infiltration and lesser amounts of fibrosis (Fig. 11.26). Many of the causative mutations involve genes encoding desmosomal junctional proteins at the intercalated disk (e.g., plakoglobin), as well as proteins that interact with the desmosome (e.g., the intermediate filament desmin). It's thought that myocyte death is caused by desmosomal detachment, particularly during strenuous exercise.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is characterized by myocardial hypertrophy, defective diastolic filling, and— in one third of cases—ventricular outflow obstruction. The heart is thick-walled, heavy, and hypercontractile, in striking contrast to the flabby, poorly contractile heart in DCM. Systolic function usually is preserved in HCM, but the myocardium does not relax and therefore exhibits primary diastolic dysfunction. HCM needs to be distinguished clinically from disorders causing ventricular stiffness (e.g., amyloid deposition) and ventricular hypertrophy (e.g., aortic stenosis and hypertension).

Pathogenesis

Most cases of HCM are caused by missense mutations in one of several genes encoding proteins that form the contractile apparatus. The usual pattern of transmission is autosomal dominant, with variable expression. Although more than 400 causative mutations in nine different genes have been identified, all have one unifying feature: they all affect sarcomeric proteins and increase myofilament function. This results in myocyte hypercontractility, increased energy use, and a net negative energy balance. Of the various sarcomeric proteins, β-myosin heavy chain is most frequently involved, followed by myosin-binding protein C and troponin T. Mutations in these three genes account for 70% to 80% of all cases of HCM.

Some of the genes mutated in HCM also are mutated in DCM (e.g., beta-myosin), but in DCM the mutations depress motor function as opposed to the gain of function seen in HCM.

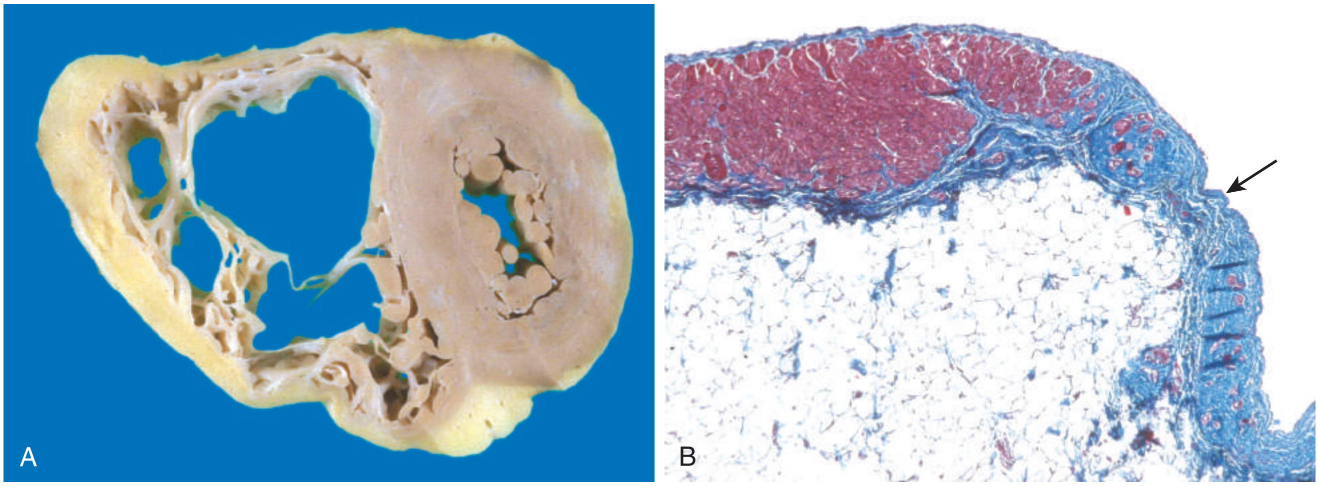

Fig. 11.26 Arrhythmogenic right ventricular cardiomyopathy. (A) The right ventricle is markedly dilated with focal, almost transmural replacement of the free wall by adipose tissue and fibrosis. The left ventricle has a grossly normal appearance in this heart; it can be involved (albeit to a lesser extent) in some instances. (B) The right ventricular myocardium *(red)* is focally replaced by fibrous connective tissue *(blue, arrow)* and fat (Masson trichrome stain).

MORPHOLOGY

Hypertrophic cardiomyopathy is marked by massive myocardial hypertrophy without ventricular dilation (Fig. 11.27A). Classically, there is disproportionate thickening of the ventricular septum relative to the left ventricle free wall (so-called ***asymmetric septal hypertrophy***); nevertheless, in about 10% of cases of HCM, concentric hypertrophy is seen. On longitudinal sectioning, the ventricular cavity loses its usual round-to-ovoid shape and is compressed into a "banana-like" configuration. The anterior mitral leaflet contacts the septum during ventricular systole, producing a plaque in the left ventricular outflow tract and thickening of the mitral leaflet; these changes correlate with functional left ventricular outflow tract obstruction due to systolic anterior motion of the mitral valve.

The characteristic histologic features in HCM are marked myocyte hypertrophy, haphazard **myocyte** (and myofiber) **disarray,** and interstitial fibrosis (Fig. 11.27B).

Clinical Features

Although HCM can present at any age, it typically manifests during the postpubertal growth spurt. The clinical symptoms can be best understood in the context of the functional abnormalities. It is characterized by massive left ventricular hypertorphy associated with (paradoxically) a markedly reduced stroke volume. This latter occurs as a consequence of impaired diastolic filling and overall smaller chamber size. In addition, roughly 25% of patients have dynamic obstruction to the left ventricular outflow by the anterior leaflet of the mitral valve. Reduced cardiac output and a secondary increase in pulmonary venous pressure cause exertional dyspnea, with a *harsh systolic ejection murmur.* A combination of massive hypertrophy, high left ventricular pressures, and compromised intramural arteries frequently leads to myocardial ischemia (with angina), even in the absence of concomitant CAD. Major clinical problems include atrial fibrillation with mural thrombus formation, ventricular fibrillation leading to sudden cardiac death, infectious endocarditis of the mitral valve, and CHF. Most patients' symptoms are improved by therapy that promotes ventricular relaxation; partial surgical excision or controlled alcohol-induced infarction of septal muscle also can relieve the outflow tract obstruction. As mentioned earlier, HCM is an important cause of sudden cardiac death. In almost one third of cases of sudden cardiac death in athletes younger than 35 years of age, the underlying cause is HCM.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is characterized by a primary decrease in ventricular compliance, resulting in impaired ventricular filling during diastole (simply put, the wall is ***stiffer***). This form of cardiomyopathy may be idiopathic or may be associated with systemic diseases that affect the myocardium, for example, radiation fibrosis, amyloidosis, sarcoidosis, or products of inborn errors of metabolism.

Three forms of restrictive cardiomyopathy merit brief mention:

- *Amyloidosis* is caused by the deposition of extracellular proteins with a predilection for forming insoluble β-pleated sheets (Chapter 5). Cardiac amyloidosis can occur in the setting of systemic amyloidosis (e.g., multiple myeloma) or can be predominantly restricted to the heart (e.g., senile cardiac amyloidosis). In the latter case, deposition of normal (or mutant) forms of transthyretin (a liver-synthesized circulating protein that transports thyroxine and retinol) in the hearts of older adult patients results in a restrictive cardiomyopathy. Four percent of African Americans carry a specific mutation of transthyretin that increases the risk of cardiac amyloidosis in that population over fourfold. Besides depositing as amyloid, immunoglobulin light-chains in AL-type amyloid also are directly cardiotoxic and can induce myocardial dysfunction.
- *Endomyocardial fibrosis* is principally a disease of children and young adults in Africa and other tropical areas. It is

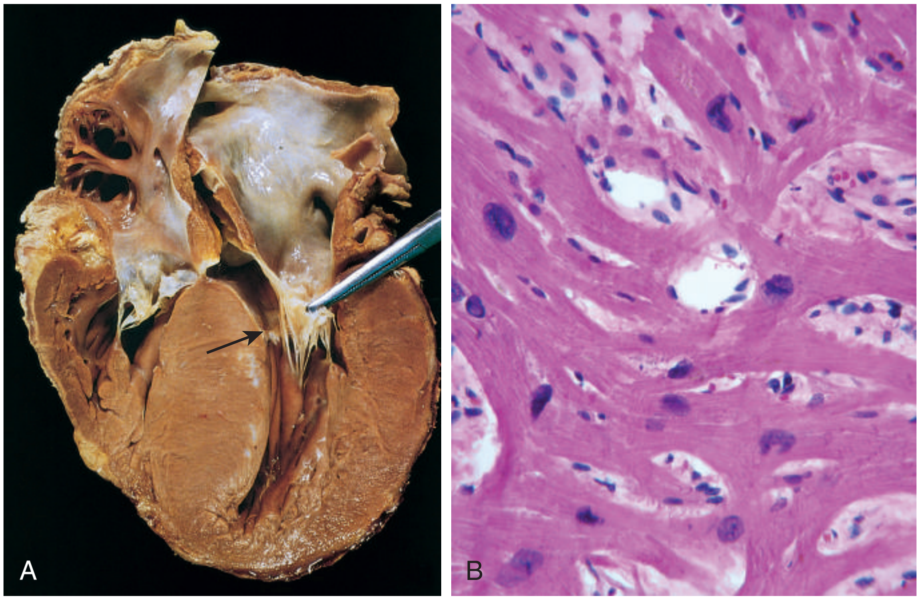

Fig. 11.27 Hypertrophic cardiomyopathy with asymmetric septal hypertrophy. (A) The septal muscle bulges into the left ventricular outflow tract, giving rise to a "banana-shaped" ventricular lumen, and the left atrium is enlarged. The anterior mitral leaflet has been moved away from the septum to reveal a fibrous endocardial plaque *(arrow)* (see text). (B) Histologic appearance demonstrating disarray, extreme hypertrophy, and characteristic branching of myocytes, as well as interstitial fibrosis.

characterized by dense diffuse fibrosis of the ventricular endocardium and subendocardium, often involving the tricuspid and mitral valves. The fibrous tissue markedly diminishes the volume and compliance of affected chambers, resulting in a restrictive physiology. Endomyocardial fibrosis has been linked to nutritional deficiencies and/or inflammation related to helminthic infections (e.g., hypereosinophilia); worldwide, it is the most common form of restrictive cardiomyopathy.

- *Loeffler endomyocarditis* also exhibits endocardial fibrosis, typically associated with formation of large mural thrombi. It has no geographic or population predilection. It is characterized by peripheral hypereosinophilia and eosinophilic tissue infiltrates; release of eosinophil granule contents, especially major basic protein, probably engenders endocardial and myocardial necrosis, followed by scarring, layering of the endocardium by thrombus, and finally thrombus organization. Of interest, some patients have an underlying hypereosinophilic myeloproliferative neoplasm driven by gene rearrangements that lead to expression of constitutively active tyrosine kinases (Chapter 12). Treatment of such patients with tyrosine kinase inhibitors can result in hematologic remission and reversal of the endomyocardial lesions.

MORPHOLOGY

In restrictive cardiomyopathy, the ventricles are of approximately normal size or only slightly enlarged, the cavities are not dilated, and the myocardium is firm. However, both atria are typically dilated as a consequence of restricted ventricular filling and pressure overloads. Microscopic examination reveals variable degrees of interstitial fibrosis. Although gross morphologic findings are similar for restrictive cardiomyopathy of disparate causes, endomyocardial biopsy often can reveal a specific etiology.

Myocarditis

Myocarditis encompasses a diverse group of clinical entities in which infectious agents and/or inflammatory processes target the myocardium. It is important to distinguish myocarditis from conditions such as IHD, where the inflammatory process is secondary to some other cause of myocardial injury.

Pathogenesis

In the United States, viral infections are the most common cause of myocarditis, with coxsackieviruses A and B and other enteroviruses accounting for a majority of the cases. Cytomegalovirus (CMV), human immunodeficiency virus (HIV), influenza virus, and others are less common pathogens. Offending agents can be identified by serologic studies that show rising antibody titers or through molecular diagnostic techniques using infected tissues. While some viruses cause direct cell death, in most cases the injury results from an immune response directed against virally infected cells; this is analogous to the damage inflicted by virus-specific T cells on hepatitis virus–infected liver cells (Chapter 16). In some cases, viruses trigger a reaction against cross-reacting proteins such as myosin heavy chain.

The nonviral infectious causes of myocarditis run the entire gamut of the microbial world. The protozoan *Trypanosoma cruzi* is the agent of Chagas disease. Although uncommon in the northern hemisphere, Chagas disease affects up to one half of the population in endemic areas of South America, with myocardial involvement in the vast majority. About 10% of the patients die during an acute attack; others can enter a chronic immune-mediated phase with development of progressive signs of CHF and arrhythmia 10 to 20 years later. *Toxoplasma gondii* (household cats are the most common vector) also can cause myocarditis, particularly in immunocompromised individuals.

Trichinosis is the most common helminthic disease associated with cardiac involvement.

Myocarditis occurs in approximately 5% of patients with Lyme disease, a systemic illness caused by the bacterial spirochete *Borrelia burgdorferi* (Chapter 9). Lyme myocarditis manifests primarily as self-limited conduction system disease, frequently requiring temporary pacemaker insertion.

Noninfectious causes of myocarditis include systemic diseases of immune origin, such as systemic lupus erythematosus and polymyositis. Drug hypersensitivity reactions affecting the heart (hypersensitivity myocarditis) may occur with exposure to a wide range of agents; such reactions typically are benign and only in rare circumstances lead to CHF or sudden death.

MORPHOLOGY

In acute myocarditis, the heart may appear normal or dilated; in advanced stages, the myocardium typically is flabby and often mottled with pale and hemorrhagic areas. Mural thrombi may be present.

Microscopically, myocarditis is characterized by edema, interstitial inflammatory infiltrates, and myocyte injury (Fig. 11.28). A diffuse lymphocytic infiltrate is most common (see Fig. 11.28A), although the inflammatory involvement is often patchy and can be "missed" on endomyocardial biopsy. If the patient survives the acute phase of myocarditis, lesions may resolve without significant sequelae or heal by progressive fibrosis.

In **hypersensitivity myocarditis,** interstitial and perivascular infiltrates are composed of lymphocytes, macrophages, and a high proportion of eosinophils (Fig. 11.28B). **Giant cell myocarditis** is a morphologically distinctive entity characterized by widespread inflammatory cell infiltrates containing multinucleate giant cells (formed by macrophage fusion). Giant cell myocarditis probably represents the aggressive end of the spectrum of lymphocytic myocarditis, and there is at least focal—and frequently extensive—necrosis (Fig. 11.28C). This variant carries a poor prognosis.

Chagas myocarditis is characterized by the parasitization of scattered myofibers by trypanosomes accompanied by an inflammatory infiltrate of neutrophils, lymphocytes, macrophages, and occasional eosinophils (Fig. 11.28D).

Clinical Features

The clinical spectrum of myocarditis is broad; at one end, the disease is asymptomatic, and patients recover without sequelae. At the other extreme is the precipitous onset of heart failure or arrhythmias, occasionally with sudden death. Between these extremes are many levels of involvement associated with a variety of signs and symptoms, including fatigue, dyspnea, palpitations, pain, and fever. The clinical features of myocarditis can mimic those of acute MI. Clinical progression from myocarditis to DCM occasionally is seen.

Other Causes of Myocardial Disease

Cardiotoxic Drugs

Cardiac complications of cancer therapy are an important clinical problem. Cardiotoxicity can be associated with conventional chemotherapeutic agents, targeted drugs such as tyrosine kinase inhibitors, and certain forms of immunotherapy (e.g., immune checkpoint blockade for cancer). The anthracyclines doxorubicin and daunorubicin are the chemotherapeutic agents that are most frequently associated with toxic myocardial injury, which often takes the form of a dilated cardiomyopathy and heart failure. Anthracycline toxicity is dose-dependent (cardiotoxicity becomes progressively more frequent above a total dose of 500 mg/m^2) and is attributed primarily to peroxidation of lipids in myocyte membranes.

Many other agents, such as lithium, phenothiazines, and chloroquine, have been implicated in myocardial injury and sometimes sudden death. Common findings in hearts injured by many of these chemicals and drugs (including diphtheria exotoxin and doxorubicin) are myofiber swelling, cytoplasmic vacuolization, and fatty change. Discontinuing such agents can lead to complete resolution, with no apparent sequelae. Sometimes, however, more extensive damage produces myocyte necrosis and leads to a dilated cardiomyopathy.

Catecholamines

Foci of myocardial necrosis with contraction bands, often associated with a sparse mononuclear inflammatory infiltrate (mostly macrophages), can occur in individuals with pheochromocytoma, a tumor that elaborates catecholamines (Chapter 20). Similar changes can occur with a variety of agents—endogenous or exogenous—under the rubric of "catecholamine effect." These include cocaine, high doses of ephedrine (an adrenergic agent in many cold and allergy formulations), intense autonomic stimulation secondary to intracranial lesions, or vasopressor agents such as dopamine. The mechanism of catecholamine cardiotoxicity is uncertain, but seems to relate either to a direct toxicity of catecholamines on cardiac myocytes via calcium overload or to vasoconstriction in the face of an increased heart rate. The mononuclear cell infiltrate is probably a reaction to microscopic foci of myocyte cell death.

SUMMARY

CARDIOMYOPATHIES AND MYOCARDITIS

- *Cardiomyopathy* refers to intrinsic cardiac muscle disease; there may be specific causes, or it may be idiopathic.
- The three general pathophysiologic categories of cardiomyopathy are *dilated* (accounting for 90% of the cases), *hypertrophic*, and *restrictive* (least common).
- DCM results in systolic (contractile) dysfunction. Causes include myocarditis, toxic exposures (e.g., alcohol), and pregnancy. In 20% to 50% of cases, mutations affecting cytoskeletal proteins are responsible.
- HCM results in diastolic (relaxation) dysfunction. Virtually all cases are due to autosomal dominant mutations in the proteins that make up the contractile apparatus, in particular β-myosin heavy chain.
- Restrictive cardiomyopathy results in a stiff, noncompliant myocardium and can be due to depositions (e.g., amyloid), increased interstitial fibrosis (e.g., due to radiation), or endomyocardial scarring.

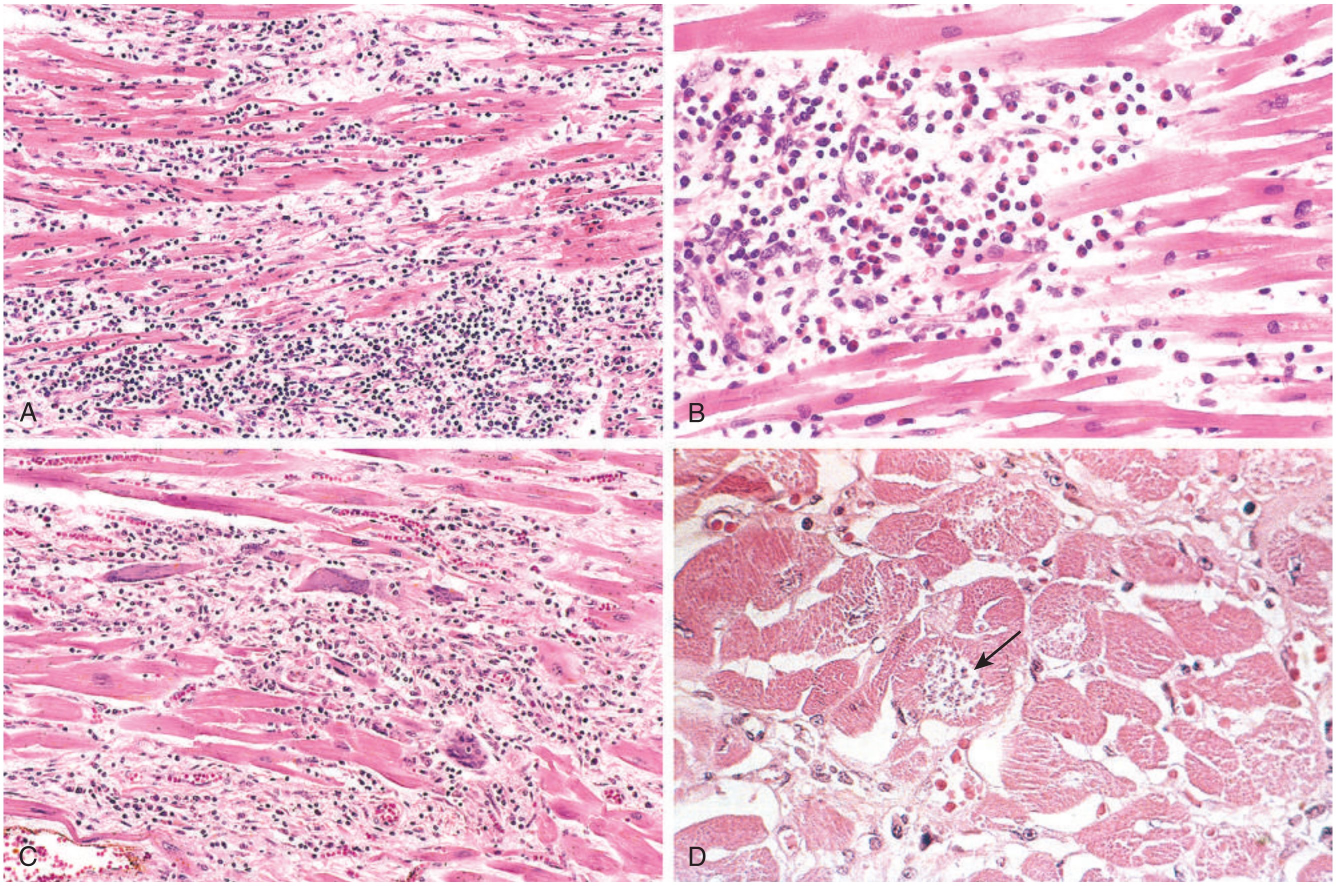

Fig. 11.28 Myocarditis. (A) Lymphocytic myocarditis, with edema and associated myocyte injury. (B) Hypersensitivity myocarditis, characterized by perivascular eosinophil-rich inflammatory infiltrates. (C) Giant cell myocarditis, with lymphocyte and macrophage infiltrates, extensive myocyte damage, and multinucleate giant cells. (D) Chagas myocarditis. A myofiber distended with trypanosomes *(arrow)* is present, along with mononuclear inflammation and myofiber necrosis.

- Arrhythmogenic right ventricular cardiomyopathy is an autosomal dominant disorder of cardiac muscle that manifests with right-sided heart failure and rhythm disturbances that can cause sudden cardiac death in athletes.
- Myocarditis is an inflammatory disorder caused by infections or immune reactions. Coxsackieviruses A and B are the most common pathogens in the United States. Clinically, myocarditis may be asymptomatic, give rise to acute heart failure, or evolve to DCM.

PERICARDIAL DISEASE

Pericardial lesions typically are associated with a pathologic process elsewhere in the heart or surrounding structures, or are secondary to a systemic disorder. Pericardial disorders include effusions and inflammatory conditions, sometimes resulting in fibrous constriction.

Pericardial Effusion and Hemopericardium

Normally, the pericardial sac contains less than 50 cc of thin, clear, straw-colored fluid. Under various circumstances, the pericardial sac may be distended by accumulations of serous fluid *(pericardial effusion),* blood *(hemopericardium),* or pus *(purulent pericarditis).*

Pericardial effusions and their causes include the following:

- *Serous*: Congestive heart failure, hypoalbuminemia of any cause
- *Serosanguineous*: Blunt chest trauma, malignancy, ruptured MI, or aortic dissection
- *Chylous:* Mediastinal lymphatic obstruction

With long-standing cardiac enlargement or with slowly accumulating fluid, the pericardium has time to dilate. This permits chronic pericardial effusions to become quite large without interfering with cardiac function. Thus, with chronic effusions of less than 500 cc in volume, the only clinical significance is a characteristic globular enlargement of the heart shadow on chest radiograph. In contrast, rapidly developing fluid collections of as little as 200 to 300 cc (e.g., due to hemopericardium caused by a ruptured MI or aortic dissection) can produce clinically devastating compression of the thin-walled atria and venae cavae, or the ventricles themselves; cardiac filling is thereby restricted, producing potentially fatal *cardiac tamponade*.

Pericarditis

Primary pericarditis is uncommon. It is typically due to viral infection (often with concurrent myocarditis),

although bacteria, fungi, or parasites may also be involved. In most cases, pericarditis is secondary to acute MI or cardiac surgery (so-called "Dressler's syndrome"), radiation to the mediastinum, or processes involving other thoracic structures (e.g., pneumonia or pleuritis). *Uremia* is the most common systemic disorder associated with pericarditis. Less common secondary causes include rheumatic fever, systemic lupus erythematosus, and metastatic malignancies. Pericarditis can (1) cause immediate hemodynamic complications if it elicits a large effusion (resulting in cardiac *tamponade*), (2) resolve without significant sequelae, or 3) progress to a chronic fibrosing process.

MORPHOLOGY

In patients with acute viral pericarditis or uremia**,** the exudate typically is fibrinous, imparting an irregular, shaggy appearance to the pericardial surface (so-called "bread and butter" pericarditis). In acute bacterial pericarditis**,** the exudate is fibrinopurulent (suppurative), often with areas of frank pus (Fig. 11.29); tuberculous pericarditis can exhibit areas of caseation. Pericarditis due to malignancy often is associated with an exuberant, shaggy fibrinous exudate and a bloody effusion; metastases can be grossly evident as irregular excrescences or may be grossly inapparent, especially in the case of leukemia. In most cases, acute fibrinous or fibrinopurulent pericarditis resolves without any sequelae. With extensive suppuration or caseation, however, healing can result in fibrosis (chronic pericarditis).

Chronic pericarditis may be associated with delicate adhesions or dense, fibrotic scars that obliterate the pericardial space. In extreme cases, the heart is so completely encased by dense fibrosis that it cannot expand normally during diastole—resulting in the condition known as **constrictive pericarditis.**

Clinical Features

Pericarditis classically manifests with atypical chest pain (not related to exertion and worse in recumbency), and a prominent friction rub. When associated with significant fluid accumulation, acute pericarditis can cause cardiac *tamponade,* which leads to declining cardiac output and consequent shock. Chronic constrictive pericarditis produces a combination of right-sided venous distention and low cardiac output, similar to the clinical picture in restrictive cardiomyopathy.

CARDIAC TUMORS

Primary Neoplasms

Primary cardiac tumors are uncommon; moreover, most also are (fortunately) benign. The five most common have no malignant potential and account for 80% to 90% of all primary heart tumors. In descending order of frequency, these are myxomas, fibromas, lipomas, papillary fibroelastomas, and rhabdomyomas. Angiosarcomas constitute the most common primary *malignant* tumor of the heart. Only the myxomas and rhabdomyomas merit further mention here.

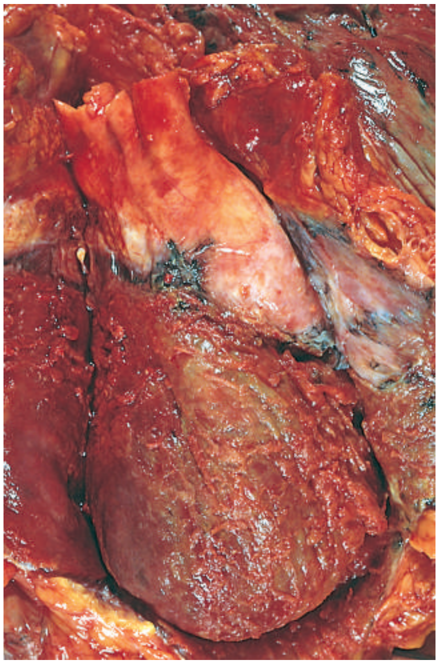

Fig. 11.29 Acute suppurative (purulent, exudative) pericarditis, caused by extension from a pneumonia.

Myxomas are the most common primary tumors of the adult heart (Fig. 11.30). Roughly 90% are atrial, with the left atrium accounting for 80% of those.

Rhabdomyomas are the most frequent primary tumors of the heart in infants and children; they frequently are discovered owing to valvular or outflow obstruction. Cardiac rhabdomyomas occur with high frequency in patients with tuberous sclerosis caused by mutations in the *TSC1* or *TSC2* tumor suppressor genes; loss of TSC-1 and TSC-2 activity leads to myocyte overgrowth. Because they often regress spontaneously (for unknown reasons), rhabdomyomas are sometimes considered to be hamartomas rather than true neoplasms. In keeping with this not all cardiac rhabdomyomas that occur in patients with tuberous sclerosis are clonal.

MORPHOLOGY

Myxomas are almost always single, classically arising in the region of the fossa ovalis (atrial septum). They can be small (less than 1 cm in diameter) or massive (up to 10 cm across), sessile or pedunculated masses (Fig. 11.30A), most often manifesting as soft, translucent, villous lesions with a gelatinous appearance. Pedunculated forms often are sufficiently mobile to swing into the mitral or tricuspid valve during systole, causing intermittent obstruction or exerting a "wrecking ball" effect that damages the valve leaflets.

Histologically, myxomas are composed of stellate, frequently multinucleated myxoma cells (typically with hyperchromatic nuclei), admixed with cells showing endothelial, smooth muscle, and/or fibroblastic differentiation; all of the cell types arise from differentiation of multipotential mesenchymal tumor cells. The cells are embedded in an abundant acid mucopolysaccharide ground substance (Fig. 11.30B). Hemorrhage, poorly organizing thrombus, and mononuclear inflammation also are usually present.

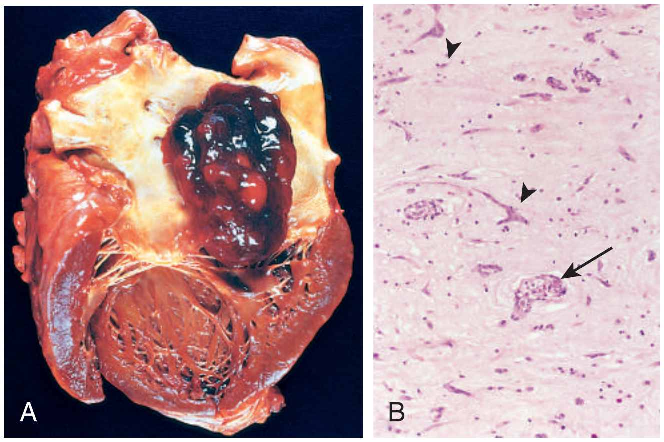

Fig. 11.30 Atrial myxoma. (A) A large pedunculated lesion arises from the region of the fossa ovalis and extends into the mitral valve orifice. (B) Abundant amorphous extracellular matrix contains scattered multinucleate myxoma cells *(arrowheads)* in various groupings, including abnormal vascular formations *(arrow)*.

Rhabdomyomas are gray-white masses up to several centimeters in diameter that protrude into the ventricular chambers. Histologic examination shows a mixed population of cells; most characteristic, however, are large, rounded, or polygonal cells containing numerous glycogen-laden vacuoles separated by strands of cytoplasm running from the plasma membrane to the centrally located nucleus, so-called "spider cells".

Clinical Features

The major clinical manifestations of myxomas are due to valvular "ball-valve" obstruction, embolization, or a syndrome of constitutional signs and symptoms including fever and malaise. This syndrome is caused by elaboration of the cytokine interleukin-6 by the tumor cells, a major mediator of the acute-phase response. Echocardiography is the diagnostic modality of choice, and surgical resection is almost uniformly curative.

Cardiac Effects of Noncardiac Neoplasms

With enhanced patient survival due to diagnostic and therapeutic advances, significant cardiovascular effects of noncardiac neoplasms and their therapy are increasingly encountered (Table 11.6). The pathologic consequences include direct tumor metastasis or infiltration, effects of circulating mediators, and therapeutic complications.

The most frequent metastatic tumors involving the heart are carcinomas of the lung and breast, melanomas, leukemias, and lymphomas. Metastases can reach the heart and pericardium by retrograde lymphatic extension (carcinomas), by hematogenous seeding (many tumors), by direct contiguous extension (primary carcinoma of the lung, breast, or esophagus), or by venous extension (tumors of the kidney or liver). Clinical symptoms are most often associated with pericardial spread, which can cause symptomatic pericardial effusions or a mass-effect that is sufficient to restrict cardiac filling. Bronchogenic carcinoma or malignant lymphoma may infiltrate the mediastinum extensively, causing encasement, compression, or invasion of the superior vena cava and obstruction to blood flow from the head and upper extremities *(superior vena cava syndrome)*. Renal cell carcinoma often invades the renal vein and may grow as a continuous column of tumor up the inferior vena cava and into the right atrium, blocking venous return to the heart.

Noncardiac tumors also may affect cardiac function indirectly, sometimes via circulating tumor-derived substances. The consequences include nonbacterial thrombotic endocarditis, carcinoid heart disease, pheochromocytoma-associated myocardial damage, and myeloma-associated AL-type amyloidosis.

Complications of chemotherapy were discussed earlier in this chapter. Radiation used to treat breast, lung, or mediastinal neoplasms can cause pericarditis, pericardial effusion, myocardial fibrosis, and chronic pericardial disorders. Other cardiac effects of radiation therapy include accelerated coronary artery disease and mural and valvular endocardial fibrosis.

Carcinoid Heart Disease

The carcinoid syndrome results from bioactive compounds such as serotonin released by carcinoid tumors (Chapter 15); systemic manifestations include flushing, diarrhea, dermatitis, and bronchoconstriction. *Carcinoid heart disease* refers to the cardiac manifestation caused by the bioactive compounds and occurs in one half of patients in whom the systemic syndrome develops. Cardiac lesions typically do not occur until there is a massive hepatic metastatic burden, since the liver normally inactivates circulating mediators before they can affect the heart. Classically, endocardium and valves of the right heart are primarily affected since they are the first cardiac tissues bathed by the mediators released by gastrointestinal carcinoid tumors. The left side of the heart is afforded some measure of protection because the pulmonary vascular bed degrades the mediators. However, left-sided heart carcinoid lesions can occur in the setting of atrial or ventricular septal defects and right-to-left flow, or they can arise in association with primary pulmonary carcinoid tumors.

Table 11.6 Cardiovascular Effects of Noncardiac Neoplasms

Direct Consequences of Tumor
Pericardial and myocardial metastases
Large vessel obstruction
Pulmonary tumor emboli
Indirect Consequences of Tumor (Complications of Circulating Mediators)
Nonbacterial thrombotic endocarditis
Carcinoid heart disease
Pheochromocytoma-associated heart disease
Myeloma-associated amyloidosis
Effects of Tumor Therapy
Chemotherapy
Radiation therapy

Modified from Schoen FJ, et al: Cardiac effects of non-cardiac neoplasms, *Cardiol Clin* 2:657, 1984.

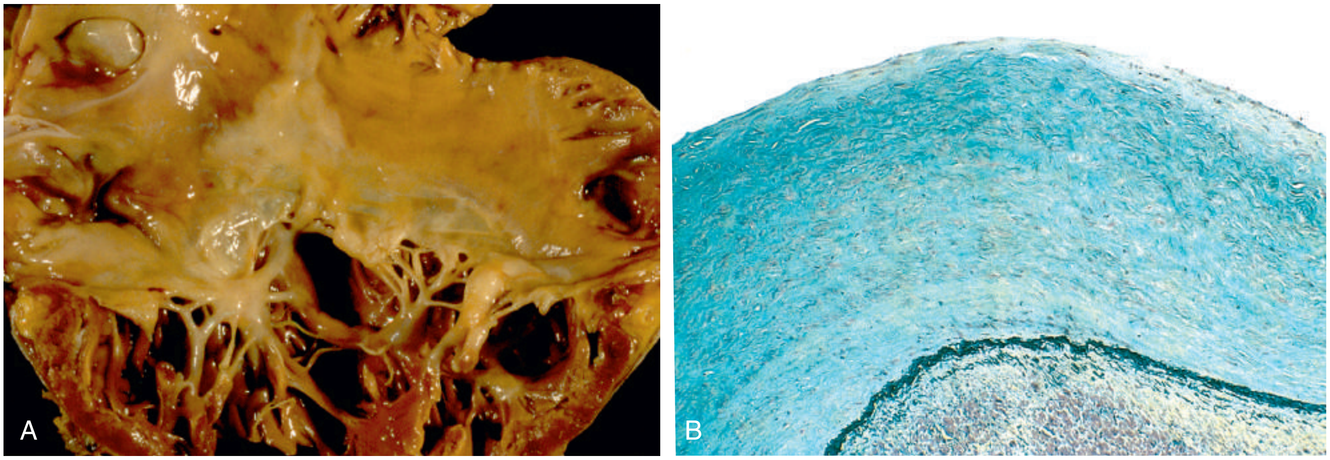

Fig. 11.31 Carcinoid heart disease. (A) Characteristic endocardial fibrotic *(light gray)* lesion "coating" the right ventricle and tricuspid valve, and extending onto the chordae tendineae. (B) Microscopic appearance of the thickened endocardium, which contains smooth muscle cells and abundant acid mucopolysaccharides (blue-green in this Movat stain, which colors the underlying endocardial elastic tissue black).

Pathogenesis

The mediators elaborated by carcinoid tumors include serotonin (5-hydroxytryptamine), kallikrein, bradykinin, histamine, prostaglandins, and tachykinins. Although it is not clear which of these is causative, plasma levels of serotonin and urinary excretion of the serotonin metabolite 5-hydroxyindoleacetic acid correlate with the severity of right-sided heart lesions. The valvular plaques in carcinoid syndrome also are similar to lesions that occur with the administration of fenfluramine (an appetite suppressant) or ergot alkaloids (for migraine headaches); of interest, these agents either affect systemic serotonin metabolism or directly bind to hydroxytryptamine receptors on heart valves.

MORPHOLOGY

The cardiovascular lesions associated with the carcinoid syndrome are distinctive, glistening white, intimal, plaquelike thickenings on the endocardial surfaces of the cardiac chambers and valve leaflets (Fig. 11.31). The lesions are composed of smooth muscle cells and sparse collagen fibers embedded in an acid mucopolysaccharide–rich matrix. Underlying structures are intact. With right-sided involvement, typical findings are tricuspid insufficiency and pulmonic stenosis.

CARDIAC TRANSPLANTATION

Although permanent ventricular assist device implantation is increasingly an option for management of end-stage heart disease, cardiac transplantation remains the treatment of choice for patients with intractable heart failure. Without transplantation, medically managed end-stage heart failure carries a 50% 1-year mortality rate, and less than 10% of patients survive 5 years. Over 5000 heart transplantation procedures are performed annually worldwide, mostly for DCM and IHD.

The major complications of cardiac transplantation are acute cardiac rejection and allograft arteriopathy. The immunosuppression required for allograft survival also increases the risk for opportunistic infections and certain malignancies (e.g., Epstein-Barr virus–associated lymphoma).

- *Rejection* is characterized by interstitial lymphocytic inflammation, myocyte damage and a histologic pattern similar to that seen in viral myocarditis. Both T cell- and antibody responses to the allograft are involved in the rejection reaction.
- *Allograft arteriopathy* is the single most important long-term limitation for cardiac transplantation. It is marked by late, progressive, diffusely stenosing intimal proliferation in the coronary arteries, leading to ischemic injury.

Despite these problems, the outlook for transplant recipients generally is good, with a 1-year survival rate of 90% and a 5-year survival rate of more than 70%.

CHAPTER

Hematopoietic and Lymphoid Systems 12

CHAPTER OUTLINE

The hematopoietic and lymphoid systems are affected by a wide spectrum of diseases. One useful way to organize these disorders is based on whether they primarily affect red cells, white cells, or the coagulation system, which includes platelets and clotting factors. The most common red cell disorders are those that lead to *anemia,* a state of red cell deficiency. White cell disorders, by contrast, are most often associated with excessive proliferation resulting from malignant transformation. Derangements in blood coagulation may result in hemorrhagic diatheses (bleeding disorders). Finally, splenomegaly, a feature of numerous diseases, is discussed at the end of the chapter, as are tumors of the thymus.

Although these divisions are useful, in reality the production, function, and destruction of red cells, white cells, and components of the hemostatic system are closely linked, and derangements primarily affecting one cell type or component of the system often lead to alterations in others. For example, in certain conditions B cells make autoantibodies against components of the red cell membrane. The opsonized red cells are recognized and destroyed by phagocytes in the spleen, which becomes enlarged. The increased red cell destruction causes anemia, which in turn drives a compensatory hyperplasia of red cell progenitors in the bone marrow.

Other levels of interplay and complexity stem from the anatomically dispersed nature of the hematolymphoid system and the capacity of both normal and malignant white cells to "traffic" between various compartments. Hence, a patient who is diagnosed with lymphoma by lymph node biopsy also may be found to have neoplastic lymphoid cells in the bone marrow and blood. The malignant clone of lymphoid cells in the marrow may suppress hematopoiesis, giving rise to low blood cell counts (cytopenias), and the dissemination of tumor cells to the liver and spleen may lead to organomegaly. Thus, in both benign and malignant hematolymphoid disorders, a single underlying abnormality can result in diverse systemic manifestations. Keeping these complexities in mind, we will use the time-honored classification of hematolymphoid disorders based on predominant involvement of red cells, white cells, and the hemostatic system.

Red Cell Disorders

Disorders of red cells can result in anemia or, less commonly, polycythemia (an increase in red cells also known as erythrocytosis). *Anemia* is defined as a reduction in the oxygen-transporting capacity of blood, resulting from a decrease in the red cell mass to subnormal levels.

Anemia can stem from bleeding, increased red cell destruction, or decreased red cell production. These mechanisms serve as one basis for classifying anemia (Table 12.1). In some entities overlap occurs, for example in thalassemia, where both reduced red cell production and early destruction contribute to anemia. With the exception of anemia caused by chronic renal failure or chronic inflammation (described later), the decrease in tissue oxygen tension that accompanies anemia triggers increased production of the growth factor *erythropoietin* from specialized cells in the kidney. This in turn drives a compensatory hyperplasia of erythroid precursors in the bone marrow and, in severe anemia, the appearance of *extramedullary hematopoiesis* within the secondary hematopoietic organs (the liver, spleen, and lymph nodes). In well-nourished persons who become anemic because of acute bleeding or increased red cell destruction (hemolysis), the compensatory response can increase the production of red cells fivefold to eightfold. The rise in marrow output is signaled by the appearance of increased numbers of newly formed red cells *(reticulocytes)* in the peripheral blood. By contrast, anemia caused by decreased red cell production (aregenerative anemia) is associated with subnormal reticulocyte counts (reticulocytopenia).

Table 12.1 Classification of Anemia According to Underlying Mechanism

Blood Loss
Acute: trauma
Chronic: gastrointestinal tract lesions, gynecologic disturbances
Increased Destruction (Hemolytic Anemias)
Intrinsic (Intracorpuscular) Abnormalities
Hereditary
Membrane abnormalities
Membrane skeleton proteins: spherocytosis, elliptocytosis
Membrane lipids: abetalipoproteinemia
Enzyme deficiencies
Enzymes of hexose monophosphate shunt: glucose-6-phosphate dehydrogenase, glutathione synthetase
Glycolytic enzymes: pyruvate kinase, hexokinase
Disorders of hemoglobin synthesis
Structurally abnormal globin synthesis (hemoglobinopathies): sickle cell anemia, unstable hemoglobins
Deficient globin synthesis: thalassemia syndromes
Acquired
Membrane defect: paroxysmal nocturnal hemoglobinuria
Extrinsic (Extracorpuscular) Abnormalities
Antibody-mediated
Isohemagglutinins: transfusion reactions, immune hydrops (Rh disease of the newborn)
Autoantibodies: idiopathic (primary), drug-associated, systemic lupus erythematosus
Mechanical trauma to red cells
Microangiopathic hemolytic anemias: thrombotic thrombocytopenic purpura, disseminated intravascular coagulation
Defective cardiac valves
Infections: malaria
Impaired Red Cell Production
Disturbed proliferation and differentiation of stem cells: aplastic anemia, pure red cell aplasia
Disturbed proliferation and maturation of erythroblasts
Defective DNA synthesis: deficiency or impaired use of vitamin B_{12} and folic acid (megaloblastic anemias)
Anemia of renal failure (erythropoietin deficiency)
Anemia of chronic disease (iron sequestration, relative erythropoietin deficiency)
Anemia of endocrine disorders
Defective hemoglobin synthesis
Deficient heme synthesis: iron deficiency, sideroblastic anemias
Deficient globin synthesis: thalassemias
Marrow replacement: primary hematopoietic neoplasms (acute leukemia, myelodysplastic syndromes)
Marrow infiltration (myelophthisic anemia): metastatic neoplasms, granulomatous disease

Anemia also can be classified on the basis of red cell morphology, which often points to particular causes. Features that provide etiologic clues include the size, color, and shape of the red cells. These are judged subjectively by visual inspection of peripheral smears and also are expressed quantitatively using the following indices:

- *Mean cell volume* (MCV): the average volume per red cell, expressed in femtoliters (cubic microns)
- *Mean cell hemoglobin* (MCH): the average mass of hemoglobin per red cell, expressed in picograms
- *Mean cell hemoglobin concentration* (MCHC): the average concentration of hemoglobin in a given volume of packed red cells, expressed in grams per deciliter
- *Red cell distribution width* (RDW): the coefficient of variation of red cell volume

Red cell indices are directly measured or automatically calculated by specialized instruments in clinical laboratories. The same instruments also determine the *reticulocyte count,* a simple measure that distinguishes between hemolytic and aregenerative anemia. Adult reference ranges for these tests are shown in Table 12.2. Depending on the differential diagnosis, a number of other blood tests also may be performed to evaluate anemia, including (1) *serum iron indices* (iron levels, iron-binding capacity, transferrin saturation, and ferritin concentrations), which help distinguish among microcytic anemia caused by iron deficiency, chronic inflammation, and thalassemia; (2) *plasma unconjugated bilirubin, haptoglobin, and lactate dehydrogenase levels,* which are abnormal in hemolytic anemia; (3) *serum and red cell folate and vitamin* B_{12} *concentrations,* which are low in megaloblastic anemia; (4) *hemoglobin electrophoresis,* which is used to detect abnormal hemoglobin; and (5) the *Coombs test,* which is used to detect antibodies or complement bound to red cells in suspected cases of antibody-mediated hemolytic anemia. In isolated anemia, tests performed on the peripheral blood usually suffice to establish the cause. By contrast, when anemia occurs along with thrombocytopenia and/or granulocytopenia, it is much more likely to be associated with marrow aplasia or infiltration; in such instances a marrow examination usually is warranted.

As discussed later, the clinical consequences of anemia are determined by its severity, rapidity of onset, and underlying

Table 12.2 Adult Reference Ranges for Red Blood Cells[a]

	Units	Men	Women
Hemoglobin (Hb)	g/dL	13.2–16.7	11.9–15.0
Hematocrit (Hct)	%	38–48	35–44
Red cell count	$\times 10^6/\mu L$	4.2–5.6	3.8–5.0
Reticulocyte count	%	0.5–1.5	0.5–1.5
Mean cell volume (MCV)	fL	81–97	81–97
Mean cell Hb (MCH)	pg	28–34	28–34
Mean cell Hb concentration (MCHC)	g/dL	33–35	33–35
Red cell distribution width (RDW)		11.5–14.8	

[a]Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used in interpreting a laboratory test.

pathogenic mechanism. If the onset is slow, the deficit in O_2-carrying capacity is compensated for by increases in cardiac output, respiratory rate, and red cell 2,3-diphosphoglycerate (DPG), a glycolytic pathway intermediate that enhances the release of O_2 from hemoglobin. These adaptive changes mitigate the effects of mild to moderate anemia in otherwise healthy persons but are less effective in those with compromised pulmonary or cardiac function. Pallor, fatigue, and lassitude are common to all forms of anemia. Anemia caused by the premature destruction of red cells *(hemolytic anemia)* is associated with hyperbilirubinemia, jaundice, and pigment gallstones (if hemolysis is chronic), all related to increases in the turnover of hemoglobin. Anemia that stems from *ineffective hematopoiesis* (the premature death of marrow erythroid progenitors) is associated with inappropriate increases in iron absorption from the gut, which can lead to iron overload *(secondary hemochromatosis)* with consequent damage to endocrine organs and the heart. If left untreated, a severe congenital anemia such as β-thalassemia major inevitably results in growth retardation, skeletal abnormalities, and cachexia.

SUMMARY

PATHOLOGY OF ANEMIA

Causes

- Blood loss (hemorrhage)
- Increased red cell destruction (hemolysis)
- Decreased red cell production

Morphology

- Microcytic (iron deficiency, thalassemia)
- Macrocytic (folate or vitamin B_{12} deficiency)
- Normocytic but with abnormal shapes (hereditary spherocytosis, sickle cell disease)

Clinical Manifestations

- **Acute:** shortness of breath, organ failure, shock
- **Chronic**
  - Pallor, fatigue, lassitude
  - With hemolysis: jaundice and gallstones
  - With ineffective erythropoiesis: iron overload, heart and endocrine failure
  - If severe and congenital: growth retardation, bone deformities due to reactive marrow hyperplasia

ANEMIA OF BLOOD LOSS: HEMORRHAGE

Anemia of blood loss can be divided into anemia caused by acute bleeding (hemorrhage) and anemia caused by chronic blood loss (described later). **The effects of acute bleeding are mainly due to the loss of intravascular volume, which if massive can lead to cardiovascular collapse, shock, and death.** If blood loss exceeds 20% of blood volume, the immediate threat is hypovolemic shock rather than anemia. If the patient survives, hemodilution begins at once and achieves its full effect within 2 to 3 days; only then is the full extent of the red cell loss revealed. The anemia is normocytic and normochromic. Recovery from blood loss anemia is enhanced by a compensatory rise in the erythropoietin level, which stimulates increased red cell production and reticulocytosis within a period of 5 to 7 days.

With chronic blood loss, iron stores are gradually depleted. Iron is essential for hemoglobin synthesis and erythropoiesis, and its deficiency leads to a chronic anemia of underproduction. Iron deficiency anemia can occur in other clinical settings as well; it is described later along with other forms of anemia caused by decreased red cell production.

HEMOLYTIC ANEMIA

Hemolytic anemias are a diverse group of disorders that have as a common feature accelerated red cell destruction (hemolysis). By definition, the red cell life span is shortened to less than its normal 120 days, often markedly so. Regardless of cause, low tissue O_2 levels trigger increased erythropoietin release from the kidney, which in turn stimulates the growth of erythroid elements and increased release of reticulocytes from the bone marrow. Thus, *erythroid hyperplasia* and *reticulocytosis* are hallmarks of all hemolytic anemias. In severe hemolytic anemias, the erythropoietic drive may be so pronounced that *extramedullary hematopoiesis* appears in the liver, spleen, and lymph nodes.

There are several ways to organize hemolytic anemias. One approach groups them according to whether the pathogenic red cell defect is *intrinsic (intracorpuscular)* or *extrinsic (extracorpuscular)* (see Table 12.1). A second more clinically useful approach groups hemolytic anemias according to whether hemolysis is primarily extravascular or intravascular. ***Extravascular hemolysis* is caused by defects that increase the destruction of red cells by phagocytes, particularly in the spleen.** The spleen contains large numbers of macrophages, the principal cell responsible for the removal of damaged or antibody-coated red cells from the circulation. Because extreme alterations of shape are necessary for red cells to navigate the splenic sinusoids, any reduction in red cell deformability makes this passage difficult, and red cells that become "stuck" are recognized and phagocytosed by resident splenic macrophages. As described later in the chapter, diminished deformability is a major cause of red cell destruction in several hemolytic anemias. Findings that are relatively specific for extravascular hemolysis

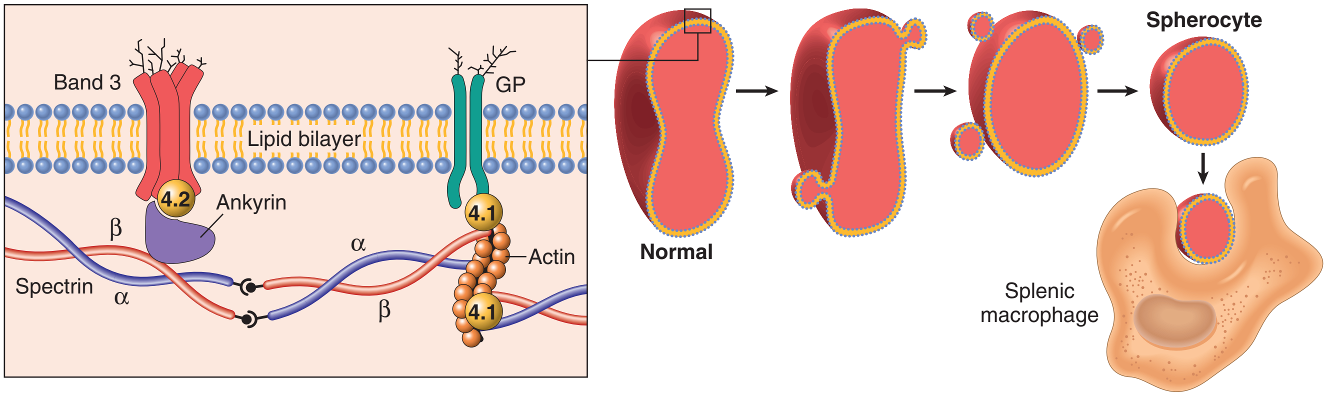

Fig. 12.1 Pathogenesis of hereditary spherocytosis. *(Left panel)* Normal organization of the major red cell membrane skeleton proteins. Mutations in α-spectrin, β-spectrin, ankyrin, band 4.2, and band 3 that weaken the association of the membrane skeleton with the overlying plasma membrane cause red cells to shed membrane vesicles and transform into spherocytes *(right panel)*. The nondeformable spherocytes are trapped in the splenic cords and phagocytosed by macrophages. *GP,* Glycophorin.

(as compared to intravascular hemolysis) include the following:

- *Hyperbilirubinemia* and *jaundice*, stemming from degradation of hemoglobin in macrophages
- Varying degrees of *splenomegaly* due to "work hyperplasia" of phagocytes in the spleen
- If long-standing, formation of *bilirubin-rich gallstones* (pigment stones) and an increased risk of *cholelithiasis*

***Intravascular hemolysis*, by contrast, is characterized by injuries so severe that red cells literally burst within the circulation**. Intravascular hemolysis may result from mechanical forces (e.g., turbulence created by a defective heart valve) or biochemical or physical agents that severely damage the red cell membrane (e.g., fixation of complement, or exposure to clostridial toxins or heat). Findings that distinguish intravascular hemolysis from extravascular hemolysis include the presence of the following:

- *Hemoglobinemia, hemoglobinuria,* and *hemosiderinuria.* Hemoglobin released into the circulation is small enough to pass into the urinary space. Here, it is partially resorbed by renal tubular cells and processed into hemosiderin, which is then lost in the urine when renal tubular cells are sloughed.
- *Loss of iron,* which may lead to iron deficiency if hemolysis is persistent. By contrast, iron recycling by phagocytes is very efficient, and so iron deficiency is not a feature of extravascular hemolytic anemias.

A final feature of both intravascular and extravascular hemolysis is decreased serum levels of *haptoglobin,* a plasma protein that binds free hemoglobin and is then removed from the circulation. Apparently macrophages "regurgitate" sufficient hemoglobin during consumption of red cells to cause haptoglobin levels to fall, even when hemolysis is entirely extravascular.

We now turn to some of the common hemolytic anemias.

Hereditary Spherocytosis

This disorder stems from inherited (intrinsic) defects in the red cell membrane that lead to the formation of spherocytes, nondeformable cells that are highly vulnerable to sequestration and destruction in the spleen. Hereditary spherocytosis is usually transmitted as an autosomal dominant trait; a more severe, autosomal recessive form of the disease affects a small minority of patients.

Pathogenesis

Hereditary spherocytosis is caused by inherited defects in the membrane skeleton, a network of proteins that stabilizes the lipid bilayer of the red cell (Fig. 12.1). The major membrane skeleton protein is spectrin, a long, flexible heterodimer that self-associates at one end and binds short actin filaments at its other end. These contacts create a two-dimensional meshwork that is connected to the transmembrane proteins band 3 and glycophorin via the linker proteins ankyrin, band 4.2, and band 4.1.

Mutations that cause hereditary spherocytosis most frequently involve ankyrin, band 3, or spectrin. **The common feature of the pathogenic mutations is that they weaken vertical interactions between the membrane skeleton and intrinsic red cell membrane proteins**. This defect destabilizes the lipid bilayer of red cells, which shed membrane vesicles into the circulation as they age. Little cytoplasm is lost in the process and as a result the surface area-to-volume ratio decreases progressively with time until the cells become spherical (Fig. 12.1).

The critical role of the spleen in hereditary spherocytosis is illustrated by the beneficial effect of splenectomy; although the red cell defect and spherocytes persist, the anemia is corrected. Red cells must undergo extreme degrees of deformation to pass through the splenic cords. The floppy discoid shape of normal red cells allows considerable latitude for shape changes. By contrast, spherocytes have limited deformability and are sequestered in the splenic cords, where they are destroyed by the plentiful resident macrophages.

MORPHOLOGY

On smears, **spherocytes** are dark red and lack central pallor (Fig. 12.2). The excessive red cell destruction and resultant anemia lead to a compensatory hyperplasia of red cell progenitors in the marrow and an increase in red cell production

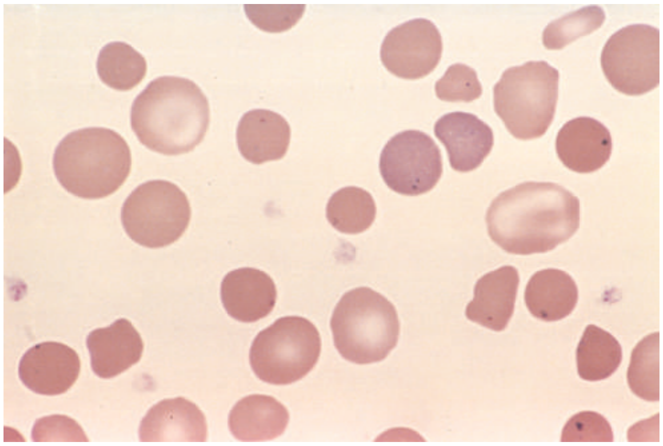

Fig. 12.2 Hereditary spherocytosis—peripheral blood smear. Note the anisocytosis and several hyperchromic spherocytes. Howell-Jolly bodies (small nuclear remnants) are also present in the red cells of this asplenic patient. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

marked by reticulocytosis. **Splenomegaly** is more common and prominent in hereditary spherocytosis than in any other form of hemolytic anemia. The splenic weight usually is between 500 and 1000 g. The enlargement results from marked congestion of the splenic cords and increases in the numbers of macrophages. Phagocytosed red cells are seen within macrophages lining the sinusoids and, in particular, within the cords. The other general features of hemolytic anemia also are present, including **cholelithiasis,** which occurs in 40% to 50% of patients with hereditary spherocytosis.

Clinical Features. The characteristic features are anemia, splenomegaly, and jaundice. The anemia is variable in severity, ranging from subclinical to profound; most commonly it is moderate in degree. Because of their spherical shape, red cells in hereditary spherocytosis show increased *osmotic fragility* when placed in hypotonic salt solutions, a characteristic that can help establish the diagnosis.

The course is generally stable but may be punctuated by *aplastic crises,* the most severe of which are triggered by *parvovirus B19 infection*. This virus has a marked tropism for erythroblasts, which undergo apoptosis during viral replication. Until the immune response controls the infection (usually in 10–14 days), the marrow may be virtually devoid of red cell progenitors. Because of the shortened life span of red cells in hereditary spherocytosis, a lack of red cell production, even for a few days, results in rapid worsening of the anemia. Blood transfusions may be needed to support patients until the infection is cleared.

There is no specific treatment. Splenectomy improves the anemia by removing the major site of red cell destruction. The benefits of splenectomy must be weighed against the increased risk of serious bacterial infections, particularly in children. Partial splenectomy is gaining favor in children because this approach produces hematologic improvement while maintaining protection against sepsis. The downside is that because the partially resected spleen eventually regains its size, many patients will need a second resection. The hope is that this can be delayed until adulthood, when the risk of serious infection is lower.

Sickle Cell Anemia

Hemoglobinopathies **are a group of hereditary disorders caused by inherited mutations that lead to structural abnormalities in hemoglobin**. Sickle cell anemia, the prototypic hemoglobinopathy, is caused by a mutation in β-globin that creates sickle hemoglobin (HbS). Numerous other hemoglobinopathies have been described, but these are infrequent and beyond the scope of this discussion.

Sickle cell anemia is the most common familial hemolytic anemia. In parts of Africa where malaria is endemic, the gene frequency approaches 30% as a result of a protective effect against *Plasmodium falciparum* malaria. In the United States, approximately 8% of blacks are heterozygous HbS carriers and about 1 in 600 have sickle cell anemia.

Pathogenesis

Sickle cell anemia is caused by a single amino acid substitution in β-globin that results in a tendency for deoxygenated HbS to self-associate into polymers. Normal hemoglobins are tetramers composed of two pairs of similar chains. On average, the normal adult red cell contains 96% HbA ($\alpha 2\beta 2$), 3% HbA2 ($\alpha 2\delta 2$), and 1% fetal Hb (HbF, $\alpha 2\gamma 2$). In patients with sickle cell anemia, HbA is completely replaced by HbS, whereas in heterozygous carriers, only about half is replaced. HbS differs from HbA by having a valine residue instead of a glutamate residue at the 6th amino acid position in β-globin. On deoxygenation HbS molecules undergo a conformational change that allows polymers to form via intermolecular contacts involving the abnormal valine residue. These polymers distort the red cell, which assumes an elongated crescentic, or sickle, shape (Fig. 12.3).

The sickling of red cells initially is reversible on reoxygenation. However, membrane distortion produced by each sickling episode leads to an influx of calcium, which causes the loss of potassium and water and also damages the membrane skeleton. With time, this cumulative damage creates *irreversibly sickled cells* that rapidly undergo hemolysis.

Three factors are particularly important in determining whether clinically significant polymerization of HbS occurs in patients:

- *The intracellular levels of hemoglobins other than HbS*. In heterozygotes approximately 40% of Hb is HbS and the remainder is HbA, which interacts only weakly with deoxygenated HbS. Because HbA greatly retards HbS polymerization, the red cells of HbS heterozygotes have little tendency to sickle in vivo. Such persons are said to have *sickle cell trait*. Similarly, because fetal hemoglobin (HbF) interacts weakly with HbS, newborns with sickle cell anemia do not manifest the disease until HbF falls to adult levels, generally around the age of 5 to 6 months. Hemoglobin C (HbC), another mutant β-globin, has a lysine residue instead of the normal glutamic acid residue at position 6. About 2.3% of American blacks are heterozygous carriers of HbC and about 1 in 1250 newborns are compound HbC/HbS heterozygotes. HbC has a greater tendency to aggregate with HbS than does

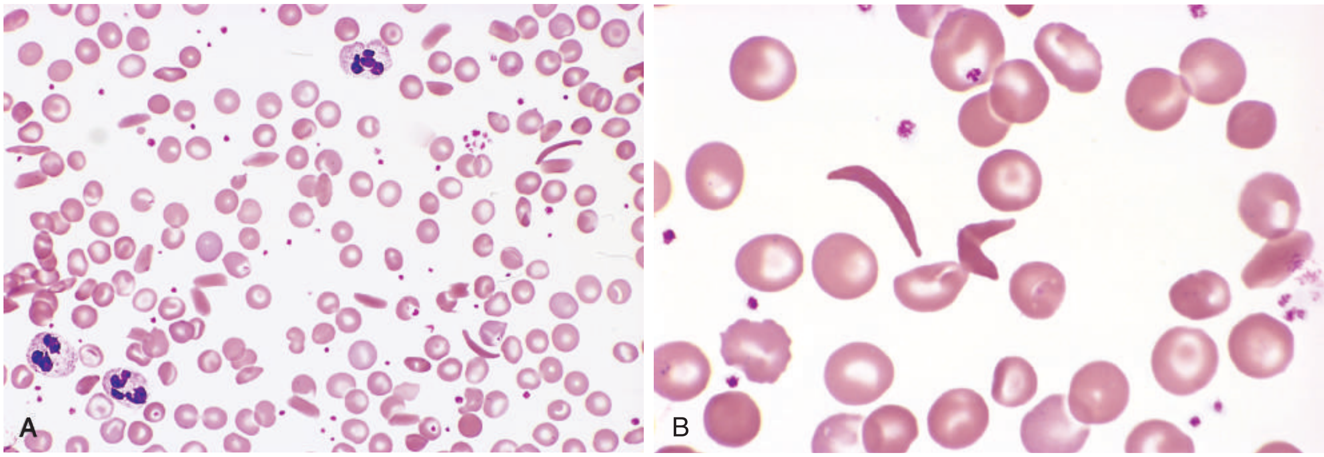

Fig. 12.3 Sickle cell anemia—peripheral blood smear. (A) Low magnification shows sickle cells, anisocytosis, poikilocytosis, and target cells. (B) Higher magnification shows an irreversibly sickled cell in the center. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

HbA, and as a result HbS/HbC compound heterozygotes have a symptomatic sickling disorder called *HbSC disease*.

- *The intracellular concentration of HbS*. The polymerization of deoxygenated HbS is strongly concentration-dependent. Thus, red cell dehydration, which increases the Hb concentration, facilitates sickling. Conversely, the coexistence of α-thalassemia (described later), which decreases the Hb concentration, reduces sickling.
- *The time required for red cells to pass through the microvasculature.* The normal transit times of red cells through capillary beds are too short for significant polymerization of deoxygenated HbS to occur. Hence, the tissues that are most susceptible to obstruction by sickling are those in which blood flow is normally sluggish, such as the spleen and the bone marrow. However, sickling may occur in other microvascular beds in the face of factors that retard the passage of red cells, particularly inflammation. Recall that inflammation slows blood flow by increasing the adhesion of leukocytes and red cells to endothelium and by inducing the exudation of fluid through leaky vessels (Chapter 4). In addition, sickle red cells have a greater tendency than normal red cells to adhere to endothelial cells, apparently because repeated bouts of sickling cause membrane damage that makes the red cells sticky. These factors conspire to prolong the transit times of sickle red cells, increasing the probability of clinically significant sickling.

The sickling of red cells has two major pathologic consequences: chronic moderately severe hemolytic anemia, produced by red cell membrane damage, and vascular obstructions, which result in ischemic tissue damage and pain crises (Fig. 12.4). The mean life span of red cells in sickle cell anemia averages only 20 days (one-sixth of normal), and the severity of the hemolysis correlates with the fraction of irreversibly sickled cells that are present in the blood. Vasoocclusion, by contrast, does not correlate with the number of irreversibly sickled cells and instead appears to result from superimposed factors such as infection, inflammation, dehydration, and acidosis, all of which enhance the tendency of red cells to sickle within the microvasculature.

MORPHOLOGY

The anatomic alterations in sickle cell anemia stem from (1) severe chronic hemolytic anemia, (2) increased breakdown of heme to bilirubin, and (3) microvascular obstructions, which provoke tissue ischemia and infarction. In peripheral smears, elongated, spindled, or boat-shaped **irreversibly sickled red cells** are evident (Fig. 12.3). Both the anemia and the vascular stasis lead to hypoxia-induced fatty changes in the heart, liver, and renal tubules. There is a compensatory **hyperplasia of erythroid progenitors** in the marrow. The cellular proliferation in the marrow often causes bone resorption and secondary new bone formation, resulting in prominent cheekbones and changes in the skull resembling a "crewcut" in radiographs. Extramedullary hematopoiesis may appear in the liver and spleen.

In children there is moderate **splenomegaly** (splenic weight up to 500 g) due to red pulp congestion caused by entrapment of sickled red cells. However, chronic splenic erythrostasis produces hypoxic damage and infarcts, which with time reduce the spleen to a useless nubbin of fibrous tissue. This process, referred to as **autosplenectomy,** is complete by adulthood.

Vascular congestion, thrombosis, and infarction can affect any organ, including the bones, liver, kidney, retina, brain, lung, and skin. The bone marrow is particularly prone to ischemia because of its sluggish blood flow and high rate of metabolism. Priapism, another frequent problem, can lead to penile fibrosis and erectile dysfunction. As with the other hemolytic anemias, **hemosiderosis** and **pigment gallstones** are common.

Clinical Features. From its onset, the disease runs an unremitting course punctuated by sudden crises. Homozygous sickle cell disease usually is asymptomatic until 6 months of age when the shift from HbF to HbS is complete. The anemia is moderate to severe; most patients have hematocrits of 18% to 30% (normal range, 38%–48%). The

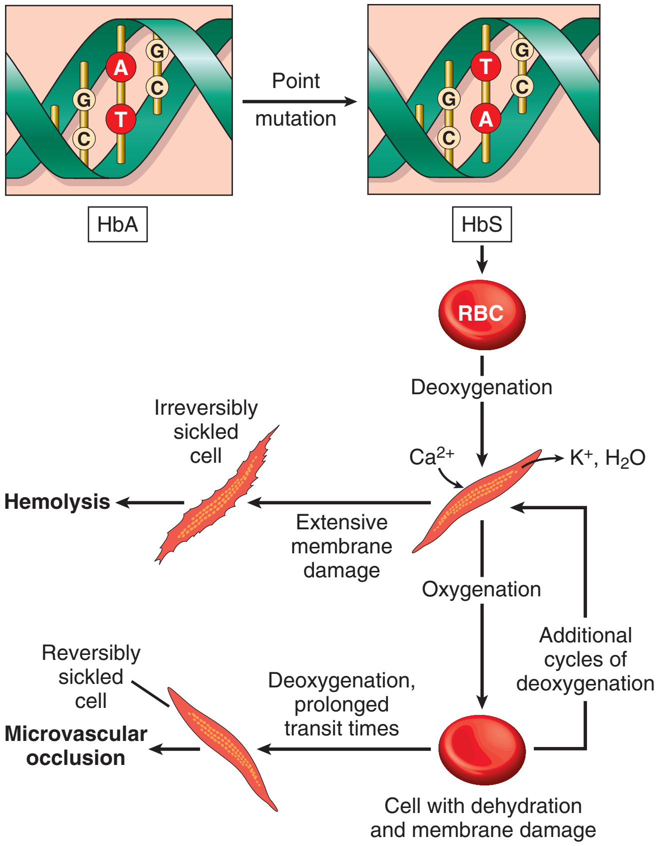

Fig. 12.4 Pathophysiology of sickle cell disease.

chronic hemolysis is associated with hyperbilirubinemia and compensatory reticulocytosis.

Much more serious are vasoocclusive crises, which are characteristically associated with pain and often lead to tissue damage and significant morbidity and mortality. Among the most common and serious of these vasoocclusive crises are the following:

- *Hand-foot syndrome*, resulting from infarction of bones in the hands and feet, is the most common presenting symptom in young children.
- *Acute chest syndrome,* in which sluggish blood flow in inflamed lung (e.g., an area of pneumonia) leads to sickling within hypoxemic pulmonary beds. This exacerbates pulmonary dysfunction, creating a vicious circle of worsening pulmonary and systemic hypoxemia, sickling, and vasoocclusion. Acute chest syndrome may also be triggered by fat emboli emanating from infarcted bone.
- *Stroke,* which sometimes occurs in the setting of the acute chest syndrome. Stroke and the acute chest syndrome are the two leading causes of ischemia-related death.
- *Proliferative retinopathy*, a consequence of vasoocclusions in the eye that can lead to loss of visual acuity and blindness.

Another acute event, *aplastic crisis,* is caused by a sudden decrease in red cell production. As in hereditary spherocytosis, this usually is triggered by the infection of erythroblasts by parvovirus B19 and, although severe, is self-limited.

In addition to these crises, patients with sickle cell disease are prone to infections. Both children and adults with sickle cell disease are functionally asplenic, making them susceptible to infections caused by encapsulated bacteria, such as pneumococci. In adults the basis for "hyposplenism" is autoinfarction. In the earlier childhood phase of splenic enlargement, congestion caused by trapped sickled red cells apparently interferes with bacterial sequestration and killing; hence, even children with enlarged spleens are at risk for the development of fatal septicemia. Patients with sickle cell disease also are predisposed to *Salmonella* osteomyelitis, possibly in part because of poorly understood acquired defects in complement function.

In homozygous sickle cell disease, irreversibly sickled red cells are seen in routine peripheral blood smears. In sickle cell trait, sickling can be induced in vitro by exposing cells to marked hypoxia. The diagnosis is confirmed by electrophoretic demonstration of HbS. Prenatal diagnosis of sickle cell anemia can be performed by analyzing fetal DNA obtained by amniocentesis or biopsy of chorionic villi.

The clinical course of sickle cell disease is highly variable. As a result of improvements in supportive care, an increasing number of patients are surviving into adulthood. Approximately 50% of patients now survive beyond the fifth decade. Of particular importance is prophylactic treatment with penicillin to prevent pneumococcal infections, especially in children younger than age 5.

A mainstay of therapy is hydroxyurea, a "gentle" inhibitor of DNA synthesis. Hydroxyurea reduces pain crises and lessens the anemia through several effects, including (1) an increase in levels of HbF; (2) an anti-inflammatory effect because of the inhibition of white cell production; (3) an increase in red cell size, which lowers the intracellular hemoglobin concentration; and (4) its metabolism to NO, a potent vasodilator and inhibitor of platelet aggregation. Encouraging results also have been obtained with allogeneic bone marrow transplantation, which is potentially curative.

Thalassemia

Thalassemias are inherited disorders caused by mutations in globin genes that decrease the synthesis of α- or β-globin. Decreased synthesis of one globin results not only in a deficiency of Hb, but also in red cell damage that is caused by precipitates formed from excess unpaired "normal" globin chains. The mutations that cause thalassemia are particularly common in Mediterranean, African, and Asian regions in which malaria is endemic. As with HbS, it is hypothesized that globin mutations associated with thalassemia protect against falciparum malaria.

Pathogenesis

A diverse collection of α-globin and β-globin mutations underlies the thalassemias, which are autosomal codominant conditions. As described previously, adult hemoglobin, or HbA, is a tetramer composed of two α chains and two β chains. The α chains are encoded by two α-globin

Table 12.3 Clinical and Genetic Classification of Thalassemias

Clinical Syndrome	Genotype	Clinical Features	Molecular Genetics
β-Thalassemias			Mainly point mutations that lead to defects in the transcription, splicing, or translation of β-globin mRNA
β-Thalassemia major	Homozygous β-thalassemia (β^0/β^0, β^+/β^+, β^0/β^+)	Severe anemia; regular blood transfusions required	
β-Thalassemia intermedia	Variable (β^0/β^+, β^+/β^+, β^0/β, β^+/β)	Moderately severe anemia; regular blood transfusions not required	
β-Thalassemia minor	Heterozygous β-thalassemia (β^0/β, β^+/β)	Asymptomatic with mild or absent anemia; red cell abnormalities seen	
α-Thalassemias			Mainly gene deletions
Silent carrier	–/α, α/α	Asymptomatic; no red cell abnormality	
α-Thalassemia trait	–/–, α/α (Asian) –/α, –/α (black African, Asian)	Asymptomatic, like β-thalassemia minor	
HbH disease	–/–, –/α	Severe; resembles β-thalassemia intermedia	
Hydrops fetalis	–/–, –/–	Lethal in utero without transfusions	

HgH, Hemoglobin H; *mRNA*, messenger ribonucleic acid.

genes lying in tandem on chromosome 16, whereas the β chains are encoded by a single β-globin gene located on chromosome 11. The clinical features vary widely depending on the specific combination of mutated alleles that are inherited by the patient (Table 12.3), as described next.

β-Thalassemia

Mutations associated with β-thalassemia fall into two categories: (1) β^0, in which no β-globin chains are produced; and (2) β^+, in which there is reduced (but detectable) β-globin synthesis. Sequencing of β-thalassemia genes has shown more than 100 different causative mutations, a majority consisting of single-base changes. Persons inheriting one abnormal allele have *β-thalassemia minor* (also known as *β-thalassemia trait*), which is asymptomatic or mildly symptomatic. Most people inheriting any two β^0 and β^+ alleles have *β-thalassemia major*; occasionally, persons inheriting at least one β^+ allele have a milder disease termed *β-thalassemia intermedia*. In contrast with α-thalassemia (described later), gene deletions rarely underlie β-thalassemia (Table 12.3).

The mutations responsible for β-thalassemia are diverse and disrupt β-globin synthesis in several different ways. The most common mutations lead to abnormal RNA splicing, whereas others fall in the β-globin gene promoter or coding regions. The specific nature of the mutation determines whether the outcome is a β^+ or β^0 allele.

Defective synthesis of β-globin in β-thalassemia contributes to anemia through two mechanisms: (1) inadequate HbA formation, resulting in small (microcytic), poorly hemoglobinized (hypochromic) red cells; and (2) by allowing the accumulation of unpaired α-globin chains, which form toxic precipitates that severely damage the membranes of red cells and erythroid precursors. A high fraction of erythroid precursors are so badly damaged that they die by apoptosis (Fig. 12.5), a phenomenon termed *ineffective erythropoiesis*, and the few red cells that are produced have a shortened life span. Ineffective hematopoiesis has another untoward effect; it is associated with an inappropriate increase in the absorption of dietary iron, which without medical intervention inevitably leads to *iron overload*. The increased iron absorption is caused by inappropriately low hepcidin, which is a negative regulator of iron absorption (see later).

α-Thalassemia

Unlike β-thalassemia, **α-thalassemia is caused mainly by deletions involving one or more of the α-globin genes.** The severity of the disease is proportional to the number of α-globin genes that are deleted (Table 12.3). For example, loss of a single α-globin gene produces a silent-carrier state, whereas deletion of all four α-globin genes is lethal in utero because the red cells have virtually no oxygen-delivering capacity. With loss of three α-globin genes there is a relative excess of β-globin or (early in life) γ-globin chains. Excess β-globin and γ-globin chains form relatively stable β4 and γ4 tetramers known as *HbH* and *Hb Bart*, respectively, which cause less membrane damage than the free α-globin chains that are found in β-thalassemia; as a result, ineffective erythropoiesis is less pronounced in α-thalassemia. Unfortunately, both HbH and Hb Bart have an abnormally high affinity for oxygen, which renders them ineffective at delivering oxygen to the tissues.

MORPHOLOGY

A range of morphologies is seen, depending on the specific underlying molecular lesion. On one end of the spectrum is β-thalassemia minor and α-thalassemia trait, in which abnormalities are confined to the peripheral blood. In smears the red cells are small (microcytic) and pale (hypochromic), but regular in shape. Often seen are **target cells,** cells with an increased surface area-to-volume ratio that allows the cytoplasm to collect in a central, dark-red "puddle." On the other end of the spectrum, in β-thalassemia major peripheral blood smears show marked **microcytosis, hypochromia, poikilocytosis** (variation in cell shape), and **anisocytosis** (variation in cell size). Nucleated red cells (normoblasts) are also seen that reflect the underlying erythropoietic drive. β-Thalassemia intermedia and

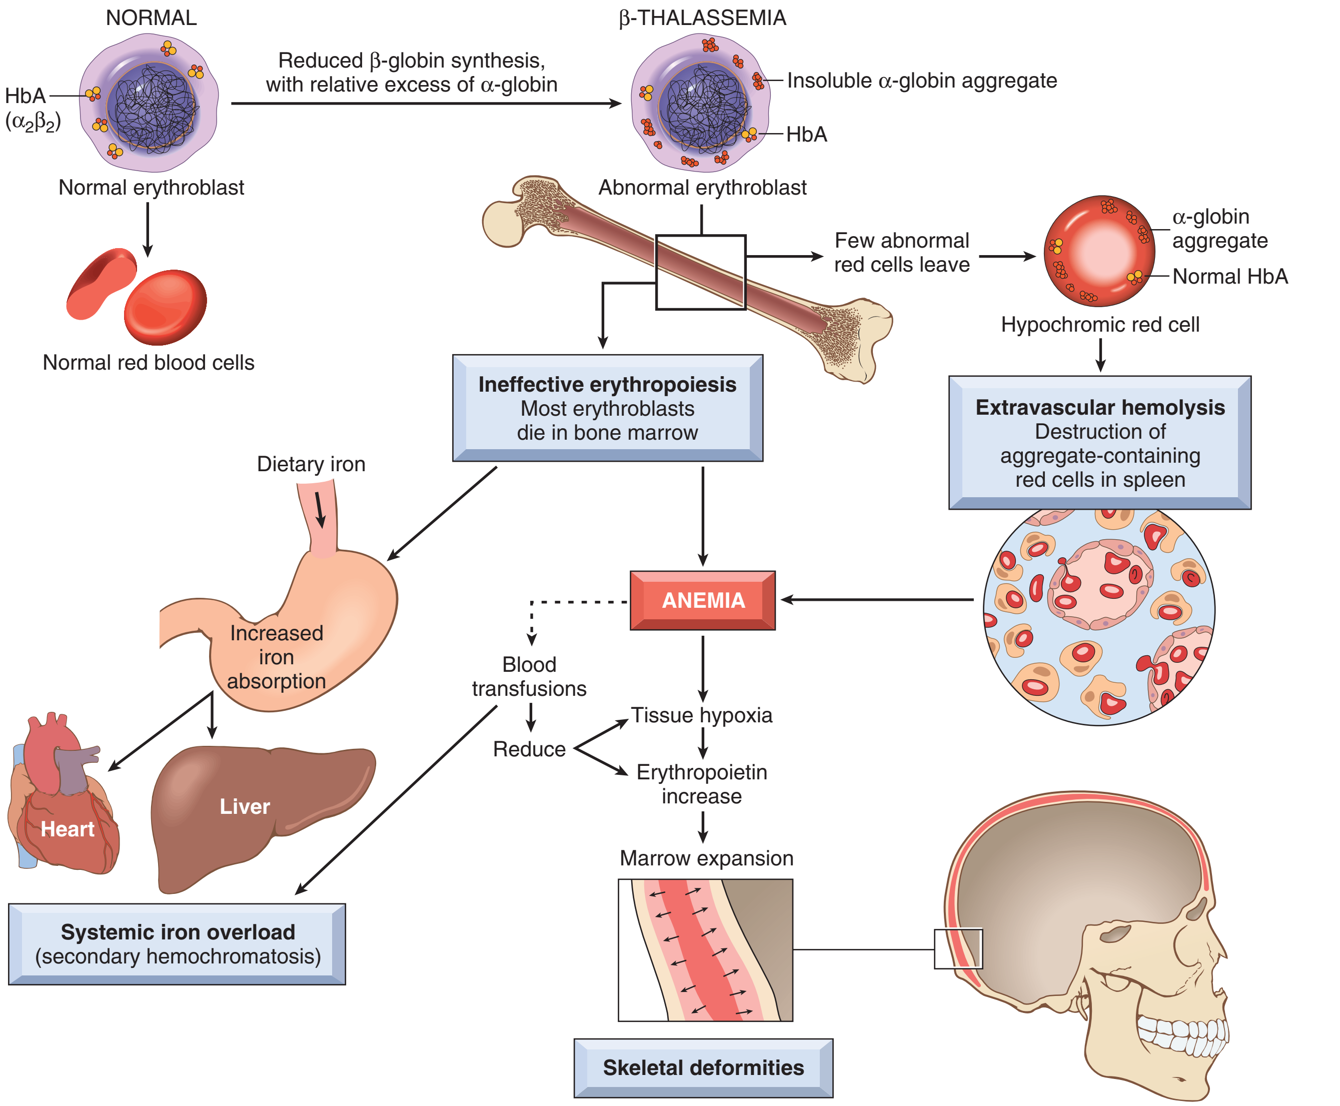

Fig. 12.5 Pathogenesis of β-thalassemia major. Note that aggregates of excess α-globin are not visible on routine blood smears. Blood transfusions constitute a double-edged sword, diminishing the anemia and its attendant complications but also adding to the systemic iron overload.

HbH disease are associated with peripheral smear findings that lie between these two extremes.

The anatomic changes in β-thalassemia major are similar in kind to those seen in other hemolytic anemias but are profound in degree. Ineffective erythropoiesis and hemolysis result in a striking hyperplasia of erythroid progenitors, with a shift toward early forms. The expanded erythropoietic marrow may completely fill the intramedullary space of the skeleton, invade the bony cortex, impair bone growth, and produce **skeletal deformities.** Extramedullary hematopoiesis and hyperplasia of mononuclear phagocytes result in prominent **splenomegaly,** hepatomegaly, and lymphadenopathy. The ineffective erythropoietic precursors consume nutrients and produce growth retardation and a degree of **cachexia** reminiscent of that seen in cancer patients. Unless steps are taken to prevent iron overload, during the span of years severe **hemosiderosis** develops (Fig. 12.5). HbH disease and β-thalassemia intermedia are also associated with splenomegaly, erythroid hyperplasia, and growth retardation related to anemia, but these are less severe than in β-thalassemia major.

Clinical Features. *β-Thalassemia trait* and *α-thalassemia trait* are typically asymptomatic. There is usually only a mild microcytic hypochromic anemia; generally, these patients have a normal life expectancy. Iron deficiency anemia is associated with a similar red cell appearance and must be excluded by appropriate laboratory tests (described later).

β-Thalassemia major manifests postnatally as HbF synthesis diminishes. Affected children suffer from growth retardation that commences in infancy. They are sustained by blood transfusions, which improve the anemia and reduce the skeletal deformities associated with excessive erythropoiesis. With transfusions alone, survival into the second or third decade is possible, but systemic iron overload gradually develops owing to inappropriate uptake of iron from the gut and the iron load in transfused red cells. Unless patients are treated aggressively with iron chelators, cardiac dysfunction from *secondary hemochromatosis* inevitably develops and often is fatal in the second or third decade of life. When feasible, hematopoietic stem cell

transplantation at an early age is the treatment of choice. *HbH disease* and *β-thalassemia intermedia* are not as severe as β-thalassemia major, because the imbalance in α- and β-globin chain synthesis is not as great and hematopoiesis is more effective. Anemia is of moderate severity and patients usually do not require transfusions. Thus, the iron overload that is so common in β-thalassemia major is rarely seen.

The diagnosis of β-thalassemia major can be strongly suspected on clinical grounds. Hb electrophoresis shows a profound reduction or absence of HbA and increased levels of HbF. The HbA2 level may be normal or increased. Similar but less severe changes are noted in patients affected by β-thalassemia intermedia. Prenatal diagnosis of β-thalassemia is challenging, but can be made in specialized centers by DNA analysis. In fact, thalassemia was the first disease diagnosed by DNA-based tests, opening the way for the field of molecular diagnostics. The diagnosis of β-thalassemia minor is made by Hb electrophoresis, which typically shows a reduced level of HbA (α2β2) and an increased level of HbA2 (α2δ2). HbH disease can be diagnosed by detection of β4 tetramers by electrophoresis.

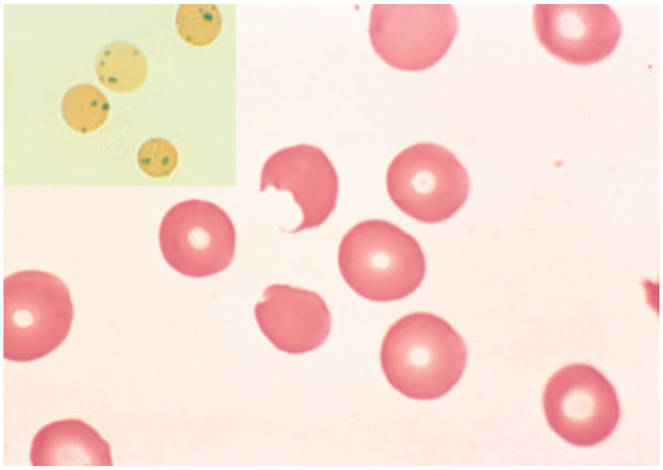

Fig. 12.6 Glucose-6-phosphate dehydrogenase deficiency after oxidant drug exposure—peripheral blood smear. (Inset) Red cells with precipitates of denatured globin (Heinz bodies) shown by supravital staining. As the splenic macrophages pluck out these inclusions, "bite cells" similar to the one in this smear are produced. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Glucose-6-Phosphate Dehydrogenase Deficiency

Red cells are constantly exposed to both endogenous and exogenous oxidants, which are normally inactivated by reduced glutathione (GSH). Abnormalities affecting enzymes responsible for the synthesis of GSH leave red cells vulnerable to oxidative injury and hemolysis. By far the most common of these conditions is glucose-6-phosphate dehydrogenase (G6PD) deficiency. The G6PD gene is on the X chromosome. More than 400 G6PD variants have been identified, but only a few are associated with disease. One is G6PD A$^-$, which is carried by approximately 10% of black males in the United States. G6PD A$^-$ has a normal enzymatic activity but a decreased half-life. Because red cells do not synthesize proteins, older G6PD A$^-$ red cells become progressively deficient in enzyme activity and GSH. This in turn renders older red cells more sensitive to oxidant damage.

Pathogenesis

G6PD deficiency is associated with transient episodes of intravascular hemolysis caused by exposure to an environmental factor (usually infectious agents or drugs) that produces oxidant stress. Incriminated drugs include antimalarials (e.g., primaquine), sulfonamides, nitrofurantoin, phenacetin, aspirin (in large doses), and vitamin K derivatives. More commonly episodes of hemolysis are triggered by infection, which induce phagocytes to generate oxidants as part of the host response. These oxidants, such as hydrogen peroxide, are normally sopped up by GSH, which is converted to oxidized GSH in the process. Because regeneration of GSH is impaired in G6PD-deficient cells, oxidants are free to "attack" other red cell components including globin chains. Oxidized hemoglobin denatures and precipitates, forming intracellular inclusions called *Heinz bodies*, which can damage the red cell membrane so severely that intravascular hemolysis results. Other cells with lesser damage lose their deformability and suffer further injury when splenic phagocytes attempt to "pluck out" the Heinz bodies, creating *bite cells* (Fig. 12.6). Such cells become trapped on recirculation to the spleen and are destroyed by phagocytes (extravascular hemolysis).

Clinical Features. Hemolysis typically develops 2 or 3 days after drug exposure and is of variable severity. Because G6PD is X-linked, the red cells of affected males are uniformly deficient and vulnerable to oxidant injury. By contrast, random inactivation of one X chromosome in heterozygous females (Chapter 7) creates two populations of red cells, one normal and the other G6PD-deficient. Most carrier females are unaffected except for those with a large proportion of deficient red cells (a chance situation known as *unfavorable lyonization*). In the case of the G6PD A$^-$ variant, it is mainly older red cells that are susceptible to lysis. Because the marrow compensates for the anemia by increasing its production of new red cells with adequate levels of G6PD, the hemolysis abates even if the drug exposure continues. In other variants such as G6PD Mediterranean, found mainly in the Middle East, the enzyme deficiency and the hemolysis that occur on exposure to oxidants are more severe.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a hemolytic anemia that stems from acquired mutations in *PIGA*, a gene required for the synthesis of phosphatidylinositol glycan (PIG), which serves as a membrane anchor for many proteins. Because *PIGA* is X-linked, normal cells have only one active *PIGA* gene, a mutation of which is sufficient to cause PIGA deficiency. The pathogenic mutations in PNH occur in an early hematopoietic progenitor that is capable of giving rise to red cells, leukocytes, and platelets. Progeny of the *PIGA*-mutated clone lack the ability to make "PIG-tailed" proteins, including several that limit the activity of complement; as a result, red cells derived from *PIGA*-deficient precursors are inordinately sensitive

to lysis by the complement C5b-C9 membrane attack complex. Leukocytes share the same deficiency but are less sensitive to complement than are red cells, and so red cells take the brunt of the attack. The nocturnal hemolysis that gives PNH its name occurs because complement fixation is enhanced by the decrease in blood pH that accompanies sleep (owing to CO_2 retention). However, most patients present less dramatically with anemia and iron deficiency resulting from chronic intravascular hemolysis.

The most feared complication of PNH is thrombosis, which often occurs within abdominal vessels such as the portal vein and the hepatic vein. The prothrombotic state also is somehow related to excessive complement activity, as Eculizimab, an antibody that binds C5 and inhibits the assembly of the C5b–C9 membrane attack complex, greatly lessens the incidence of thrombosis as well as the degree of intravascular hemolysis. Eculizimab has no effect on early stages of complement fixation, and treated patients continue to have varying degrees of extravascular hemolysis because of the deposition of C3b on red cell surfaces. Loss of C5b-C9 activity in patients receiving Eculizimab poses a risk for *Neisseria* infections, particularly meningococcal sepsis; thus, all treated patients must be vaccinated against *N. meningococcus*.

Immunohemolytic Anemia

Immunohemolytic anemia is caused by antibodies that bind to determinants on red cell membranes. These antibodies may arise spontaneously or be induced by exogenous agents such as drugs or chemicals. Immunohemolytic anemia is uncommon and is classified based on (1) the nature of the antibody and (2) the presence of predisposing conditions (summarized in Table 12.4).

The diagnosis depends on the detection of antibodies and/or complement on red cells. This is done with the *direct Coombs test,* in which the patient's red cells are incubated with antibodies against human immunoglobulin or complement. In a positive test result, these antibodies cause the patient's red cells to clump (agglutinate). The *indirect Coombs test,* which assesses the ability of the patient's serum to agglutinate test red cells bearing defined surface determinants, can then be used to characterize the target of the antibody.

Warm Antibody Immunohemolytic Anemia

In this entity, hemolysis results from the binding of high-affinity autoantibodies to red cells, which are then removed from the circulation by phagocytes in the spleen and elsewhere. In addition to frank erythrophagocytosis, incomplete consumption ("nibbling") of antibody-coated red cells by macrophages removes membrane and transforms red cells into *spherocytes,* which are rapidly destroyed in the spleen, just as in hereditary spherocytosis (described earlier). Warm antibody immunohemolytic anemia is caused by immunoglobulin G (IgG) or (rarely) IgA antibodies that are active at 37°C. More than 60% of cases are idiopathic (primary), whereas another 25% are secondary to an underlying immunologic disorder (e.g., systemic lupus erythematosus) or are induced by drugs. The clinical severity is variable, but most patients have chronic mild anemia and moderate splenomegaly and require no treatment.

The mechanisms of hemolysis induced by drugs are varied and in some instances poorly understood. Drugs such as α-methyldopa induce autoantibodies against intrinsic red cell constituents, in particular Rh blood group antigens. Presumably, the drug somehow alters the immunogenicity of native epitopes and thereby circumvents T cell tolerance (Chapter 5). Other drugs such as penicillin act as haptens, which induce an antibody response by binding covalently to red cell membrane proteins. Sometimes antibodies recognize a drug in the circulation and form immune complexes that are deposited on red cells. Here they may fix complement or act as opsonins, either of which can lead to hemolysis.

Table 12.4 Classification of Immunohemolytic Anemias

Warm Antibody Type
Primary (idiopathic) *Secondary*: B cell neoplasms (e.g., chronic lymphocytic leukemia), autoimmune disorders (e.g., systemic lupus erythematosus), drugs (e.g., α-methyldopa, penicillin, quinidine)
Cold Antibody Type
Acute: Mycoplasma infection, infectious mononucleosis *Chronic*: idiopathic, B cell lymphoid neoplasms (e.g., lymphoplasmacytic lymphoma)

Cold Antibody Immunohemolytic Anemia

Cold antibody immunohemolytic anemia usually is caused by low-affinity IgM antibodies that bind to red cell membranes only at temperatures below 30°C, such as occur in distal parts of the body (e.g., ears, hands, and toes) in cold weather. Although bound IgM fixes complement, the latter steps of the complement cascade occur inefficiently at temperatures lower than 37°C. As a result, most cells with bound IgM pick up some C3b but are not lysed intravascularly. When these cells travel to warmer areas, the weakly bound IgM antibody is released, but the coating of C3b remains. Because C3b is an opsonin (Chapter 2), the cells are phagocytosed by macrophages, mainly in the spleen and liver; hence, in most cases the hemolysis is mainly extravascular. Binding of pentavalent IgM also crosslinks red cells and causes them to clump (*agglutinate*). Sludging of blood in capillaries because of agglutination often produces *Raynaud phenomenon* in the extremities of affected individuals. Cold agglutinins sometimes also appear transiently during recovery from pneumonia caused by *Mycoplasma* spp. and infectious mononucleosis, producing a mild anemia of little clinical importance. More important, chronic forms of cold agglutinin hemolytic anemia occur in association with certain B cell neoplasms or as an idiopathic condition.

Hemolytic Anemia Resulting From Mechanical Trauma to Red Cells

Hemolysis of red cells due to their exposure to abnormal mechanical forces occurs in two major settings. Clinically significant *traumatic hemolysis* is sometimes produced by defective cardiac valve prostheses, which may create sufficiently turbulent blood flow to shear red cells (the blender

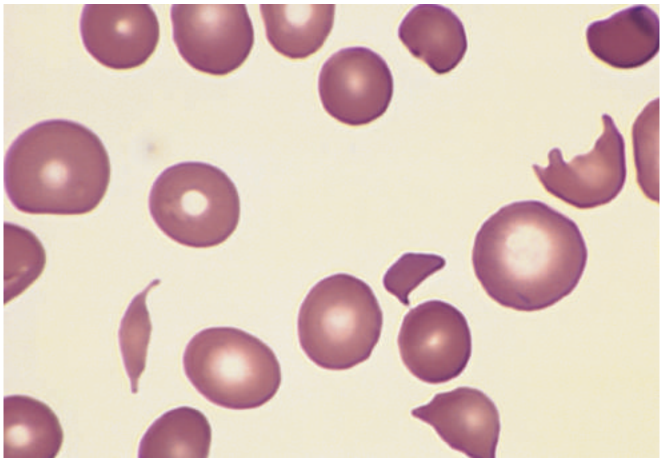

Fig. 12.7 Microangiopathic hemolytic anemia—peripheral blood smear. This specimen from a patient with hemolytic uremic syndrome contains several fragmented red cells. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

effect). More commonly, it occurs incidentally during an activity involving repeated physical pounding of one or more body parts (e.g., marathon racing, karate chopping, bongo drumming). *Microangiopathic hemolytic anemia* is observed in pathologic states in which small vessels become partially obstructed or narrowed by lesions that predispose passing red cells to mechanical damage. The most frequent of these conditions is disseminated intravascular coagulation (DIC) (see later), in which vessels are narrowed by the intravascular deposition of fibrin. Other causes of microangiopathic hemolytic anemia include malignant hypertension, systemic lupus erythematosus, thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and disseminated cancer. Mechanical fragmentation of red cells (*schistocytosis*) leads to the appearance of characteristic "burr cells," "helmet cells," and "triangle cells" in peripheral blood smears (Fig. 12.7). Although microangiopathic hemolysis is not usually a major clinical problem in and of itself, it often points to a serious underlying condition.

Malaria

It is estimated that malaria affects 500 million and kills more than 1 million people per year, making it one of the most serious afflictions of humans. Malaria is endemic in Asia and Africa, but with widespread jet travel cases are now seen all over the world. It is caused by one of five types of protozoa. Of these, the most important is *Plasmodium falciparum*, which causes tertian malaria (falciparum malaria), a disorder with a high fatality rate. The other four species of *Plasmodium* that infect humans—*Plasmodium malariae, Plasmodium vivax, Plasmodium knowlesi*, and *Plasmodium ovale*—cause relatively benign disease. All forms are transmitted by the bite of female *Anopheles* mosquitoes, and humans are the only natural reservoir.

Pathogenesis

The life cycle of plasmodia is complex (Fig. 12.8). As mosquitoes feed on human blood, *sporozoites* are introduced from the saliva and within a few minutes infect liver cells. Here the parasites multiply rapidly to form a schizont containing thousands of *merozoites*. After a period of days to several weeks that varies with the *Plasmodium* species, the infected hepatocytes release the merozoites, which quickly infect red cells. Intraerythrocytic parasites either continue asexual reproduction to produce more merozoites or give rise to *gametocytes* capable of infecting the next hungry mosquito. During their asexual reproduction in red cells, each of the four forms of malaria develops into *trophozoites*. The asexual phase is completed when the trophozoites give rise to new merozoites, which escape by lysing the red cells.

Fatal falciparum malaria often involves the small vessels of the brain, a complication known as cerebral malaria. Normally, red cells bear negatively charged surfaces that interact poorly with endothelial cells. Infection of red cells with *P. falciparum* induces the appearance of positively charged surface knobs containing parasite-encoded proteins, which bind to adhesion molecules expressed on activated endothelium. Several endothelial cell adhesion molecules, including intercellular adhesion molecule-1 (ICAM-1), appear to mediate this interaction, which leads to the trapping of red cells in postcapillary venules. In an unfortunate minority of patients, mainly children, this process involves cerebral vessels, which become engorged and occluded.

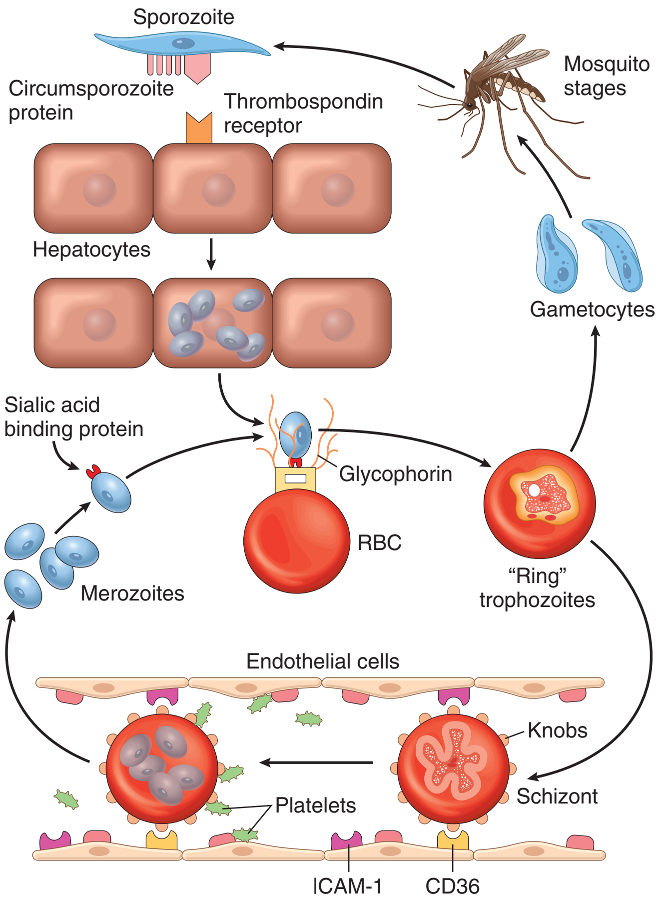

Fig. 12.8 Life cycle of *Plasmodium falciparum. ICAM-1*, Intercellular adhesion molecule-1; *RBC*, red blood cell. *(Drawn by Dr. Jeffrey Joseph, Department of Pathology, Beth Israel Deaconess Hospital, Boston, Massachusetts.)*

MORPHOLOGY

Red cell trophozoites from each *Plasmodium* species have a somewhat distinctive appearance, allowing expert observers to determine which species is responsible for an infection from examination of appropriately stained thick smears of peripheral blood. The destruction of red cells leads to **hemolytic anemia**, with its attendant features and laboratory findings. A characteristic brown malarial pigment derived from hemoglobin called **hematin** is released from the ruptured red cells and produces discoloration of the spleen, liver, lymph nodes, and bone marrow. Activation of defense mechanisms in the host leads to a marked hyperplasia of mononuclear phagocytes, producing **massive splenomegaly** and occasional hepatomegaly.

Clinical Features

Showers of new merozoites are released from the red cells at intervals of approximately 24 hours for *P. knowlesi*, 48 hours for *P. vivax, P. ovale,* and *P. falciparum*, and 72 hours for *P. malariae.* Episodic shaking, chills, and fever coincide with this release. Hemolytic anemia of varying severity is a constant feature. *Cerebral malaria* associated with *P. falciparum* is rapidly progressive; convulsions, coma, and death usually occur within days to weeks. Fortunately, falciparum malaria more often pursues a chronic course that may be punctuated at any time by *blackwater fever.* The trigger is obscure for this uncommon complication, which is associated with massive intravascular hemolysis, hemoglobinemia, hemoglobinuria, and jaundice.

With appropriate chemotherapy, the prognosis for patients with most forms of malaria is good; however, falciparum malaria is becoming more difficult to treat due to the emergence of drug-resistant strains. Because of the potentially serious consequences of the disease, early diagnosis and treatment are important. The ultimate solution is an effective vaccine, which is long sought but still elusive.

SUMMARY

HEMOLYTIC ANEMIA

Hereditary Spherocytosis

- Autosomal dominant disorder caused by mutations that affect the red cell membrane skeleton, leading to loss of membrane and eventual conversion of red cells to spherocytes, which are phagocytosed and removed in the spleen
- Manifested by anemia, splenomegaly

Sickle Cell Anemia

- Autosomal recessive disorder resulting from a mutation in β-globin that causes deoxygenated hemoglobin to self-associate into long polymers that distort the red cell
- Blockage of vessels by sickled cells causes pain crises and tissue infarction, particularly of the marrow and spleen
- Red cell membrane damage caused by repeated bouts of sickling results in a moderate to severe hemolytic anemia
- Patients are at high risk for bacterial infections and stroke

Thalassemia

- Autosomal codominant disorders caused by mutations in α- or β-globin that reduce hemoglobin synthesis, resulting in a microcytic, hypochromic anemia. In β-thalassemia, unpaired α-globin chains form aggregates that damage red cell precursors and further impair erythropoiesis.

Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

- X-linked disorder caused by mutations that destabilize G6PD, making red cells susceptible to oxidant damage

Immunohemolytic Anemia

- Caused by antibodies against either normal red cell constituents or antigens modified by haptens (such as drugs)
- Antibody binding results in either red cell opsonization and extravascular hemolysis or (uncommonly) complement fixation and intravascular hemolysis

Malaria

- Intracellular red cell parasite that causes chronic hemolysis of variable severity
- Falciparum malaria may be fatal because of the propensity of infected red cells to adhere to small vessels in the brain (cerebral malaria)

ANEMIA OF DIMINISHED ERYTHROPOIESIS

Anemias of diminished erythropoiesis include those caused by an inadequate dietary supply of nutrients, particularly iron, folic acid, and vitamin B_{12}. Other anemias of this type are associated with bone marrow failure (aplastic anemia), systemic inflammation (anemia of chronic inflammation), or bone marrow infiltration by tumor or inflammatory cells (myelophthisic anemia). In this section, some common examples of anemias of these types are discussed individually.

Iron Deficiency Anemia

Deficiency of iron is the most common nutritional deficiency in the world and results in clinical signs and symptoms that are mostly related to anemia. About 10% of people living in developed countries and 25% to 50% of those in developing countries are anemic, and in both settings the most frequent cause is iron deficiency. The factors responsible for iron deficiency differ in various populations and are best understood in the context of normal iron metabolism.

The normal total body iron mass is about 2.5 g for women and 3.5 g for men. Approximately 80% of functional body iron is present in hemoglobin, with the remainder located in myoglobin and iron-containing enzymes (e.g., catalase, cytochromes). The iron storage pool, consisting of hemosiderin and ferritin-bound iron in the liver, spleen, bone marrow, and skeletal muscle, contains on average 15% to 20% of total body iron. Because *serum ferritin* is largely

derived from this storage pool, the serum ferritin level is a good measure of iron stores. *Assessment of bone marrow iron* is another reliable but more invasive method for estimating iron stores. Iron is transported in the plasma bound to the protein *transferrin*. In normal persons, transferrin is about 33% saturated with iron, yielding serum iron levels that average 120 μg/dL in men and 100 μg/dL in women. Thus, the normal total iron-binding capacity of serum is 300 to 350 μg/dL.

In keeping with the high prevalence of iron deficiency, evolutionary pressures have yielded metabolic pathways that are strongly biased toward iron retention. Iron is lost at a rate of 1 to 2 mg/day through the shedding of mucosal and skin epithelial cells, and this loss must be balanced by the absorption of dietary iron, which is tightly regulated (described later). The normal daily Western diet contains 10 to 20 mg of iron. Most is found in heme within meat and poultry, with the remainder present as inorganic iron in vegetables. About 20% of heme and 1% to 2% of nonheme iron are absorbable; hence, the average Western diet contains sufficient iron to balance fixed daily losses.

Regulation of iron absorption occurs within the duodenum (Fig. 12.9). After reduction by ferric reductase, ferrous

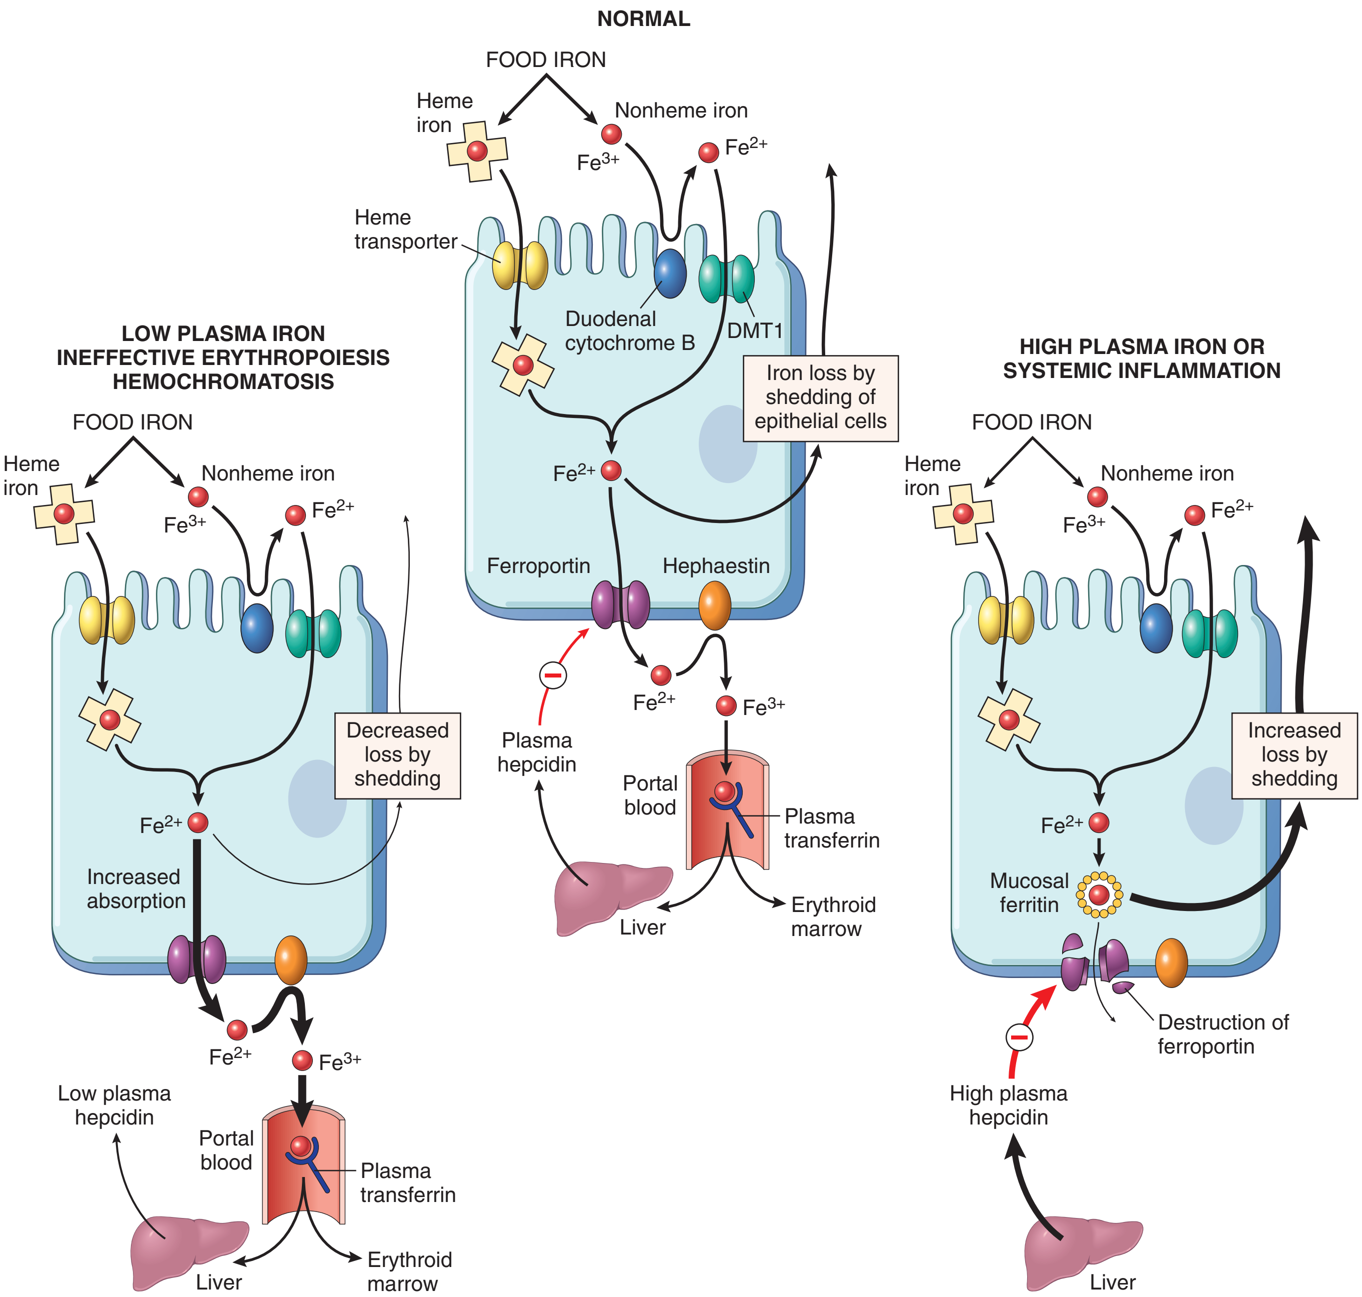

Fig. 12.9 Regulation of iron absorption. Duodenal epithelial cell uptake of heme and nonheme iron discussed in the text is depicted. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin balances iron uptake and loss to maintain iron hemeostasis by down-regulating ferroportin and limiting iron uptake (middle panel). Hepcidin rises in the setting of systemic inflammation or when iron levels are high, decreasing iron uptake and increasing iron loss by the shedding of duodenocytes (right panel), and it falls in the setting of low plasma iron or primary hemochromatosis, resulting in increased iron uptake (left panel) with reduced shedding. *DMT1*, Divalent metal transporter-1.

iron (Fe^{2+}) is transported across the apical membrane by divalent metal transporter-1 (DMT1). A second transporter, ferroportin, then moves iron from the cytoplasm to the plasma across the basolateral membrane. The newly absorbed iron is next oxidized by hephaestin and ceruloplasmin to ferric iron (Fe^{3+}), the form of iron that binds to transferrin. Both DMT1 and ferroportin are widely distributed in the body and are involved in iron transport in other tissues as well. As depicted in Fig. 12.9 (middle panel), part of the iron that enters enterocytes is delivered to transferrin by ferroportin, whereas the remainder is incorporated into cytoplasmic ferritin and is lost through the exfoliation of mucosal cells.

The fraction of iron that is absorbed is regulated by hepcidin, a small peptide that is synthesized and secreted from the liver in an iron-dependent fashion. In general, high iron levels in the plasma enhance hepcidin production, whereas low iron levels suppress it. However, hepcidin production also is sensitive to inflammation and to factors released from erythroblasts in the bone marrow. Specifically, hepcidin levels rise in the face of systemic inflammation because of the direct effects of inflammatory mediators such as IL-6 on hepatocytes, and in the setting of ineffective hematopoiesis, which is marked by increased numbers of erythroblasts in the bone marrow. Hepcidin circulates to the duodenum, where it binds ferroportin and induces its internalization and degradation. Thus, when hepcidin concentrations are elevated (Fig. 12.9, right panel), such as when serum iron levels are high or there is systemic inflammation, ferroportin levels fall and more iron is incorporated into cytoplasmic ferritin and is lost by excretion. Conversely, when hepcidin levels are low (Fig. 12.9, left panel), such as when there is iron deficiency, ineffective hematopoiesis, or the genetic defects that lead to primary hemochromatosis (Chapter 16), the basolateral transport of iron is increased. In iron deficiency, the suppression of hepcidin is beneficial as it serves to help to correct the deficiency, but inappropriately low levels of hepcidin, as in primary hemochromatosis, eventually lead to systemic iron overload.

Pathogenesis

Iron deficiency arises in a variety of settings:

- **Chronic blood loss is the most important cause of iron deficiency anemia in the Western world.** The most common sources of bleeding are the gastrointestinal tract (e.g., peptic ulcers, colon cancer, hemorrhoids) and the female genital tract (e.g., menorrhagia, metrorrhagia, endometrial cancer).
- **In the developing world, low intake and poor bioavailability because of predominantly vegetarian diets are the most common causes of iron deficiency.** In the United States, low dietary intake is an infrequent culprit but is sometimes culpable in infants fed exclusively milk, in the impoverished, in the elderly, and in teenagers subsisting predominantly on junk food.
- Increased demands not met by normal dietary intake occur worldwide during pregnancy and infancy.
- Malabsorption can occur with celiac disease or after gastrectomy (Chapter 15).

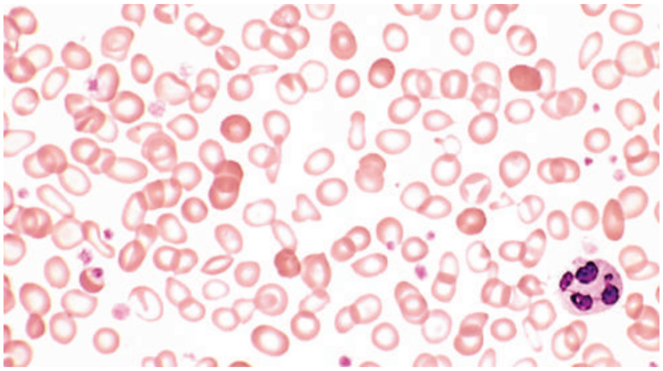

Fig. 12.10 Iron deficiency anemia—peripheral blood smear. Note the increased central pallor of most of the red cells. Scattered, fully hemoglobinized cells, from a recent blood transfusion, stand out in contrast. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Regardless of the cause, iron deficiency develops insidiously. Iron stores are depleted first, marked by a decline in serum ferritin and the absence of stainable iron in the bone marrow. These changes are followed by a decrease in serum iron and a rise in the serum transferrin. Ultimately, the capacity to synthesize hemoglobin, myoglobin, and other iron-containing proteins is diminished, leading to microcytic anemia, impaired work and cognitive performance, and even reduced immunocompetence.

Clinical Features. In most instances iron deficiency anemia is mild and asymptomatic. Nonspecific manifestations, such as weakness, listlessness, and pallor, may be present in severe cases. With long-standing anemia, abnormalities of the fingernails, including thinning, flattening, and "spooning," may appear. A curious but characteristic neurobehavioral complication is *pica,* the compunction to consume nonfoodstuffs such as dirt or clay.

In peripheral smears, red cells are *microcytic* and *hypochromic* (Fig. 12.10). Diagnostic criteria include anemia, hypochromic and microcytic red cell indices, low serum ferritin and iron levels, low transferrin saturation, increased total iron-binding capacity, and, ultimately, response to iron therapy. For unclear reasons, the platelet count often is elevated. Erythropoietin levels are elevated, but the marrow response is blunted by the iron deficiency; thus, marrow cellularity usually is only slightly increased.

Persons often die with iron deficiency anemia, but virtually never of it. An important point is that in well-nourished persons, microcytic hypochromic anemia is not a disease but rather a symptom of some underlying disorder.

Anemia of Chronic Inflammation

Often referred to as the anemia of chronic disease, anemia associated with chronic inflammation is the most common form of anemia in hospitalized patients. It superficially resembles the anemia of iron deficiency but arises instead from the suppression of erythropoiesis by systemic inflammation. It occurs in a variety of disorders associated with sustained inflammation:

- Chronic microbial infections, such as osteomyelitis, bacterial endocarditis, and lung abscess

- Chronic immune disorders, such as rheumatoid arthritis and regional enteritis
- Neoplasms, such as Hodgkin lymphoma and carcinomas of the lung and breast

Pathogenesis

The anemia of chronic inflammation stems from high levels of plasma hepcidin, which blocks the transfer of iron to erythroid precursors by downregulating ferroportin in macrophages. The elevated hepcidin levels are caused by proinflammatory cytokines such as IL-6, which increase hepatic hepcidin synthesis. In addition, chronic inflammation blunts erythropoietin synthesis by the kidney, lowering red cell production by the marrow. The functional advantages of these adaptations in the face of systemic inflammation are unclear; they may serve to inhibit the growth of iron-dependent microorganisms or to augment certain aspects of host immunity.

Clinical Features. As in anemia of iron deficiency, the serum iron levels usually are low in the anemia of chronic disease, and the red cells may be slightly hypochromic and microcytic. Unlike iron deficiency anemia, however, storage iron in the bone marrow and serum ferritin are increased and the total iron-binding capacity is reduced. Administration of erythropoietin and iron can improve the anemia, but only effective treatment of the underlying condition is curative.

Megaloblastic Anemias

The two principal causes of megaloblastic anemia are folate deficiency and vitamin B_{12} deficiency. Both vitamins are required for DNA synthesis and the effects of their deficiency on hematopoiesis are essentially identical. However, the causes and consequences of folate and vitamin B_{12} deficiency differ in important ways. We will first review some of the common features and then touch on those that are specific to folate and vitamin B_{12} deficiency.

Pathogenesis

Megaloblastic anemia stems from metabolic defects that lead to inadequate biosynthesis of thymidine, one of the building blocks of DNA. As we will discuss, folate and vitamin B_{12} are both essential factors for the synthesis of thymidylate, which is required for DNA replication. Thymidine deficiency causes abnormalities in rapidly dividing cells throughout the body, but the hematopoietic marrow is most severely affected. Because the synthesis of RNA and cytoplasmic elements proceeds at a normal rate and thus outpaces that of the nucleus, the hematopoietic precursors show *nuclear-cytoplasmic asynchrony* (described later). This maturational derangement contributes to the anemia in several ways. Many red cell progenitors are so defective in DNA synthesis that they undergo apoptosis in the marrow *(ineffective hematopoiesis)*. Others mature into red cells but do so after fewer cell divisions, further diminishing the output of red cells. Granulocyte and platelet precursors also are affected (although not as severely) and most patients present with pancytopenia (anemia, thrombocytopenia, and granulocytopenia).

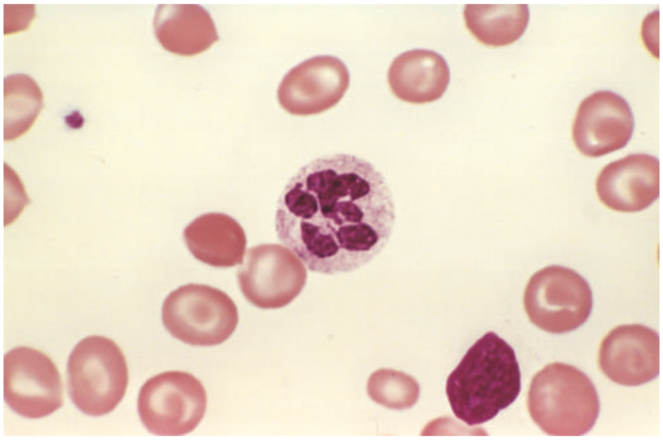

Fig. 12.11 Megaloblastic anemia. A peripheral blood smear shows a hypersegmented neutrophil with a six-lobed nucleus. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

MORPHOLOGY

Certain morphologic features are common to all forms of megaloblastic anemia. The bone marrow is markedly hypercellular and contains numerous megaloblastic erythroid progenitors. **Megaloblasts** are larger than normal erythroid progenitors (normoblasts) and have delicate, finely reticulated nuclear chromatin (indicative of nuclear immaturity). As megaloblasts differentiate and acquire hemoglobin, the nucleus retains its finely distributed chromatin and fails to undergo the chromatin clumping typical of normoblasts, a classic example of nuclear-cytoplasmic asynchrony. The granulocytic precursors also demonstrate nuclear-cytoplasmic asynchrony, yielding **giant metamyelocytes.** Megakaryocytes may also be abnormally large and have bizarre multilobed nuclei.

In the peripheral blood the earliest change is the appearance of **hypersegmented neutrophils** (Fig. 12.11), which appear before the onset of anemia. Normal neutrophils have three or four nuclear lobes, but in megaloblastic anemias they often have five or more. The red cells typically include large, **egg-shaped macroovalocytes;** the MCV often is greater than 110 fL (normal, 82–96 fL). Although macrocytes appear hyperchromic, in reality their hemoglobin content is normal. Large, misshapen platelets also may be seen. Morphologic changes in other systems, especially the gastrointestinal tract, also occur, giving rise to some of the clinical manifestations.

Folate (Folic Acid) Deficiency Anemia

Folate deficiency is usually the result of inadequate dietary intake, sometimes complicated by increased metabolic demands. Although folate is present in nearly all foods, it is destroyed by 10 to 15 minutes of cooking, and as a result folate stores are marginal in a surprising number of healthy persons. The risk of overt folate deficiency is highest in those with a poor diet (the economically deprived, the indigent, and the elderly) or those with increased metabolic needs (pregnant women and patients with chronic hemolytic anemias, such as sickle cell disease).

Deficiency may also stem from problems with absorption or metabolism. Food folates are predominantly in polyglutamate form and must be split into monoglutamates for absorption, a conversion that is inhibited by acidic foods and substances found in beans and other legumes. Some drugs, such as phenytoin (dilantin), also interfere with folate absorption, whereas others, such as methotrexate, inhibit folate metabolism. Malabsorptive disorders, such as *celiac disease* and *tropical sprue*, that affect the upper third of the small intestine where folate is absorbed, may also impair folate uptake.

Pathogenesis

The metabolism and functions of folate are complex. Here it is sufficient to note that its conversion within cells from dihydrofolate to tetrahydrofolate by *dihydrofolate reductase* is particularly important. Tetrahydrofolate acts as an acceptor and donor of one-carbon units in several reactions that are required for the synthesis of deoxythymidine monophosphate (dTMP). If intracellular stores of folate fall, insufficient dTMP is synthesized and DNA replication is blocked, leading to megaloblastic anemia.

Clinical Features. The onset of the anemia of folate deficiency is insidious, being associated with nonspecific symptoms such as weakness and easy fatigability. The clinical picture may be complicated by the coexistent deficiency of other vitamins, especially in alcoholics. Because the cells lining the gastrointestinal tract, like the hematopoietic system, turn over rapidly, symptoms referable to the alimentary tract, such as sore tongue, are common. Unlike in vitamin B_{12} deficiency (described later), neurologic abnormalities do not occur.

The diagnosis of a megaloblastic anemia is readily made from the examination of smears of peripheral blood and bone marrow. The anemia of folate deficiency is best distinguished from that of vitamin B_{12} deficiency by measuring serum and red cell folate and vitamin B_{12} levels.

Vitamin B_{12} (Cobalamin) Deficiency Anemia

Vitamin B_{12} is widely present in foods, is resistant to cooking and boiling, and is even synthesized by gut flora. Thus, unlike folate, vitamin B_{12} deficiency is virtually never caused by inadequate intake except in vegetarians who scrupulously avoid milk and eggs. Instead, deficiencies typically arise from some abnormality that interferes with vitamin B_{12} absorption, a complex process involving the following steps:

1. Peptic digestion releases dietary vitamin B_{12}, allowing it to bind a salivary protein called *haptocorrin.*
2. On entering the duodenum, haptocorrin–B_{12} complexes are processed by pancreatic proteases; this releases B_{12}, which attaches to *intrinsic factor* secreted from the parietal cells of the gastric fundic mucosa.
3. The intrinsic factor–B_{12} complexes pass to the distal ileum and attach to cubilin, a receptor for intrinsic factor, and are taken up into enterocytes.
4. The absorbed vitamin B_{12} is transferred across the basolateral membranes of enterocytes to plasma *transcobalamin,* which delivers vitamin B_{12} to the liver and other cells of the body.

After absorption, the body handles vitamin B_{12} very efficiently. It is stored in the liver, which normally contains reserves sufficient to support bodily needs for 5 to 20 years. Because of these large liver stores, clinical presentations of vitamin B_{12} deficiency typically follow years of unrecognized malabsorption.

Pathogenesis

The most frequent cause vitamin B_{12} deficiency is *pernicious anemia*, which is believed to result from an autoimmune attack on the gastric mucosa that suppresses the production of intrinsic factor. Histologically, there is a *chronic atrophic gastritis* marked by a loss of parietal cells, a prominent infiltrate of lymphocytes and plasma cells, and megaloblastic changes in mucosal cells similar to those found in erythroid precursors. The serum of most affected patients contains several types of *autoantibodies* that block the binding of vitamin B_{12} to intrinsic factor or prevent binding of the intrinsic factor–vitamin B_{12} complex to cubilin. Autoantibodies are of diagnostic use, but they are not thought to be the primary cause of the gastric pathology; rather, it seems that an *autoreactive T cell response* initiates gastric mucosal injury and triggers the formation of autoantibodies. When the mass of intrinsic factor-secreting cells falls below a threshold (and reserves of stored vitamin B_{12} are depleted), anemia develops.

Other causes of vitamin B_{12} malabsorption include *gastrectomy* (leading to loss of intrinsic factor–producing cells), *ileal resection* (resulting in loss of intrinsic factor–B_{12} complex–absorbing cells), and disorders that disrupt the function of the distal ileum (such as *Crohn disease*, *tropical sprue*, and *Whipple disease*). Particularly in older persons, *gastric atrophy* and *achlorhydria* may interfere with the production of acid and pepsin, which are needed to release the vitamin B_{12} from its bound form in food.

The metabolic defects responsible for the anemia of vitamin B_{12} deficiency are intertwined with folate metabolism. Vitamin B_{12} is required for recycling tetrahydrofolate, which, as described previously, is the form of folate that is needed for DNA synthesis. In keeping with this relationship, the anemia of vitamin B_{12} deficiency is reversed with the administration of folate.

By contrast, folate administration does not prevent and may in fact worsen certain neurologic symptoms that are specific to vitamin B_{12} deficiency. The main neurologic lesions associated with vitamin B_{12} deficiency are demyelination of the posterior and lateral columns of the spinal cord, sometimes beginning in the peripheral nerves. In time, axonal degeneration may supervene. The severity of the neurologic manifestations is not related to the degree of anemia. Indeed, neurologic disease may occur in the absence of overt megaloblastic anemia.

Clinical Features. The manifestations of vitamin B_{12} deficiency are nonspecific. As with all anemias, findings include pallor, easy fatigability, and, in severe cases, dyspnea and even congestive heart failure. The increased destruction of erythroid progenitors because of ineffective erythropoiesis may give rise to *mild jaundice*, and megaloblastic changes in the oropharyngeal epithelium may produce a *beefy red tongue*. The *spinal cord disease* begins with symmetric numbness, tingling, and burning in the feet or hands, followed by

unsteadiness of gait and loss of position sense, particularly in the toes. Although the anemia responds dramatically to parenteral vitamin B_{12}, the neurologic manifestations often fail to resolve. As discussed in Chapter 15, patients with pernicious anemia have an increased risk for the development of gastric carcinoma.

Findings supporting the diagnosis of vitamin B_{12} deficiency are (1) low serum vitamin B_{12} levels, (2) normal or elevated serum folate levels, (3) moderate to severe macrocytic anemia, (4) leukopenia with hypersegmented granulocytes, and (5) a dramatic reticulocytic response (within 2 to 3 days) to parenteral administration of vitamin B_{12}. Pernicious anemia is associated with all of these findings plus the presence of serum antibodies to intrinsic factor.

Aplastic Anemia

Aplastic anemia is a disorder in which multipotent myeloid stem cells are suppressed, leading to bone marrow failure and pancytopenia. The marrow often is virtually devoid of recognizable hematopoietic elements. It must be distinguished from pure red cell aplasia, in which only erythroid progenitors are affected and anemia is the only manifestation.

Pathogenesis

The pathogenesis of aplastic anemia is not fully understood, but two major etiologies have been invoked: an extrinsic, immune-mediated suppression of marrow progenitors, and an intrinsic abnormality of stem cells. Experimental studies have focused on a model in which activated T cells suppress hematopoietic stem cells. It is hypothesized that stem cells are first antigenically altered by exposure to drugs, infectious agents, or other unidentified environmental insults. This provokes a cellular immune response, during which activated T_H1 cells produce cytokines such as interferon-γ (IFN-γ) and TNF that suppress and kill hematopoietic progenitors. This scenario is supported by experience with immunosuppressive therapy directed against T cells, which restores hematopoiesis in 60% to 70% of patients.

Alternatively, **the notion that aplastic anemia results from an intrinsic stem cell abnormality is supported by observations showing that from 5% to 10% of patients have inherited defects in telomerase**, which, as mentioned earlier, is needed for the maintenance and stability of chromosomes. It is hypothesized that the defect in telomerase leads to premature senescence of hematopoietic stem cells. Of further interest, the bone marrow cells in an additional 50% of cases have unusually short telomeres, possibly stemming from as-yet undiscovered defects in telomerase or excessive replication of hematopoietic stem cells. These two mechanisms are not mutually exclusive, because genetically altered stem cells (e.g., those with abnormal telomeres) also might express "neoantigens" that serve as targets for a T cell attack.

Clinical Features. Aplastic anemia affects persons of all ages and both sexes. The slowly progressive anemia causes the insidious development of weakness, pallor, and dyspnea. Thrombocytopenia often manifests with petechiae and ecchymoses. Neutropenia may set the stage for serious infections.

It is important to separate aplastic anemia from anemia caused by marrow infiltration (myelophthisic anemia), "aleukemic leukemia," and granulomatous diseases, which may have similar clinical presentations but are easily distinguished by examination of the bone marrow. Aplastic anemia does not cause splenomegaly; if present, another diagnosis should be sought.

The prognosis is unpredictable. Withdrawal of an inciting drug sometimes leads to remission, but this is the exception. Hematopoietic stem cell transplantation often is curative, particularly in nontransfused patients younger than 40 years of age. Transfusion sensitizes patients to alloantigens, producing a high rate of engraftment failure; thus, it must be minimized in persons eligible for transplantation. Successful transplantation requires "conditioning" with immunosuppressive radiation or chemotherapy, reinforcing the notion that autoimmunity has an important role in the disease. As mentioned earlier, patients who are poor transplantation candidates often benefit from immunosuppressive therapy.

Myelophthisic Anemia

Myelophthisic anemia is caused by extensive infiltration of the marrow by tumors or other lesions. It most commonly is associated with metastatic breast, lung, or prostate cancer. Other tumors, advanced tuberculosis, lipid storage disorders, and osteosclerosis may produce a similar clinical picture. The principal manifestations include anemia and thrombocytopenia; in general, the white cell series is less affected. Characteristically misshapen red cells, some resembling teardrops, are seen in the peripheral blood. Immature granulocytic and erythrocytic precursors also may be present *(leukoerythroblastosis)* along with mild leukocytosis. Treatment is directed at the underlying condition.

SUMMARY

ANEMIA OF DIMINISHED ERYTHROPOIESIS

Iron Deficiency Anemia

- Caused by chronic bleeding or inadequate iron intake; results in insufficient hemoglobin synthesis and hypochromic, microcytic red cells

Anemia of Chronic Inflammation

- Caused by inflammatory cytokines, which increase hepcidin levels and thereby sequester iron in macrophages, and also suppress erythropoietin production

Megaloblastic Anemia

- Caused by deficiencies of folate or vitamin B_{12} that lead to inadequate synthesis of thymidine and defective DNA replication
- Results in enlarged abnormal hematopoietic precursors (megaloblasts), ineffective hematopoiesis, macrocytic anemia, and (in most cases) pancytopenia

Aplastic Anemia

- Caused by bone marrow failure (hypocellularity) resulting from diverse causes, including exposures to toxins and radiation, idiosyncratic reactions to drugs and viruses, and inherited defects in telomerase and DNA repair

Myelophthisic Anemia

- Caused by replacement of the bone marrow by infiltrative processes such as metastatic carcinoma and granulomatous disease
- Leads to the appearance of early erythroid and granulocytic precursors (leukoerythroblastosis) and teardrop-shaped red cells in the peripheral blood

POLYCYTHEMIA

Polycythemia, or *erythrocytosis,* denotes an increase in red cells per unit volume of peripheral blood. It may be *absolute* (defined as an increase in total red cell mass) or *relative.* Relative polycythemia results from dehydration, such as occurs with water deprivation, prolonged vomiting, diarrhea, or the excessive use of diuretics. Absolute polycythemia is described as *primary* when the increased red cell mass results from an autonomous proliferation of erythroid progenitors, and *secondary* when the excessive proliferation stems from elevated levels of erythropoietin. Primary polycythemia (polycythemia vera) is a clonal myeloid neoplasm considered later in this chapter. The increases in erythropoietin that cause secondary forms of absolute polycythemia include a variety of causes (Table 12.5).

Table 12.5 Pathophysiologic Classification of Polycythemia

Relative
Reduced plasma volume (hemoconcentration)
Absolute
Primary
Abnormal proliferation of myeloid stem cells, normal or low erythropoietin levels (polycythemia vera); inherited activating mutations in the erythropoietin receptor (rare)
Secondary
Increased erythropoietin levels *Adaptive:* Lung disease, high-altitude living, cyanotic heart disease *Paraneoplastic:* Erythropoietin-secreting tumors (e.g., renal cell carcinoma, hepatomacellular carcinoma, cerebellar hemangioblastoma) *Surreptitious:* Endurance athletes

White Cell Disorders

Disorders of white cells include deficiencies (leukopenias) and proliferations, which may be reactive or neoplastic. Reactive proliferation in response to a primary, often microbial, disease is common. Neoplastic disorders, although less common, are more ominous: They cause approximately 9% of all cancer deaths in adults and a staggering 40% in children younger than 15 years of age.

Presented next are brief descriptions of some nonneoplastic conditions, followed by more detailed considerations of the malignant proliferations of white cells.

NONNEOPLASTIC DISORDERS OF WHITE CELLS

Leukopenia

Leukopenia results most commonly from a decrease in granulocytes, the most numerous circulating white cells. Lymphopenia is much less common; it is associated with rare congenital immunodeficiency diseases, advanced human immunodeficiency virus (HIV) infection, and treatment with high doses of corticosteroids. Only the more common leukopenias of granulocytes are discussed here.

Neutropenia/Agranulocytosis

A reduction in the number of granulocytes in blood is known as *neutropenia* or, when severe, agranulocytosis. Neutropenic persons are susceptible to severe, potentially fatal bacterial and fungal infections. The risk of infection rises sharply as the neutrophil count falls below 500 cells/μL.

Pathogenesis

The mechanisms underlying neutropenia can be divided into two broad categories:

- *Decreased granulocyte production.* Clinically important reductions in granulopoiesis are most often caused by marrow hypoplasia (as occurs transiently with cancer chemotherapy and chronically with aplastic anemia) or extensive replacement of the marrow by tumor (such as with leukemia). Alternatively, neutrophil production may be suppressed while other blood lineages are unaffected. This is most often caused by certain drugs or by neoplastic proliferations of cytotoxic T cells and natural killer (NK) cells (so-called "large granular lymphocytic leukemia").
- *Increased granulocyte destruction.* This can be encountered with immune-mediated injury (triggered in some cases by drugs) or in overwhelming bacterial, fungal, or rickettsial infections resulting from increased peripheral use. Splenomegaly also can lead to the sequestration and accelerated removal of neutrophils.

MORPHOLOGY

The alterations in the bone marrow depend on the underlying cause. Compensatory marrow hypercellularity is seen when there is excessive neutrophil destruction or ineffective

granulopoiesis, such as occurs in megaloblastic anemia. Drugs that selectively suppress granulocytopoiesis are associated with decreased numbers of granulocytic precursors and preservation of erythroid elements and megakaryocytes, while myelotoxic chemotherapy drugs reduce the number of elements from all lineages.

Clinical Features. Infections constitute the major problem. They commonly take the form of ulcerating, necrotizing lesions of the gingiva, floor of the mouth, buccal mucosa, pharynx, or other sites within the oral cavity *(agranulocytic angina)*. Owing to the lack of leukocytes, such lesions often contain large masses or sheets of microorganisms. In addition to local inflammation, systemic symptoms usually are present consisting of malaise, chills, and fever. Because of the danger of sepsis, patients are started on broad-spectrum antibiotics covering both bacterial and fungal infections at the first sign of infection. Depending on the clinical context, patients also may be treated with granulocyte colony-stimulating factor (G-CSF), a growth factor that speeds recovery of neutrophil counts.

Reactive Leukocytosis

An increase in the number of white cells in the blood is common in a variety of inflammatory states caused by microbial and nonmicrobial stimuli. Leukocytoses are relatively nonspecific and are classified according to the particular white cell series that is affected (Table 12.6). As discussed later, in some cases reactive leukocytosis may mimic leukemia. Such *"leukemoid reactions"* must be distinguished from true white cell malignancies. Infectious mononucleosis merits separate consideration because it gives rise to a distinctive syndrome associated with lymphocytosis.

Table 12.6 Causes of Leukocytosis

Neutrophilic Leukocytosis
Acute bacterial infections (especially those caused by pyogenic organisms); sterile inflammation caused by, e.g., tissue necrosis (myocardial infarction, burns)
Eosinophilic Leukocytosis (Eosinophilia)
Allergic disorders such as asthma, hay fever, allergic skin diseases (e.g., pemphigus, dermatitis herpetiformis); parasitic infestations; drug reactions; certain malignancies (e.g., Hodgkin lymphoma and some non-Hodgkin lymphomas); collagen-vascular disorders and some vasculitides; atheroembolic disease (transient)
Basophilic Leukocytosis (Basophilia)
Rare, often indicative of a myeloproliferative neoplasm (e.g., chronic myeloid leukemia)
Monocytosis
Chronic infections (e.g., tuberculosis), bacterial endocarditis, rickettsiosis, and malaria; collagen vascular diseases (e.g., systemic lupus erythematosus); and inflammatory bowel diseases (e.g., ulcerative colitis)
Lymphocytosis
Accompanies monocytosis in many disorders associated with chronic immunologic stimulation (e.g., tuberculosis, brucellosis); viral infections (e.g., hepatitis A, cytomegalovirus, Epstein-Barr virus); *Bordetella pertussis* infection

Infectious Mononucleosis

Infectious mononucleosis is an acute, self-limited disease of adolescents and young adults that is caused by Epstein-Barr virus (EBV), a member of the herpesvirus family. The infection is characterized by (1) fever, sore throat, and generalized lymphadenitis and (2) a lymphocytosis of activated, CD8+ T cells. Of note, cytomegalovirus infection induces a similar syndrome that can be differentiated only by serologic methods.

EBV is ubiquitous in all human populations. In the developing world, EBV infection in early childhood is nearly universal. Even though infected children mount an immune response (described later), most remain asymptomatic and more than half continue to shed virus, usually for life. By contrast, in developed countries with better standards of hygiene, infection typically is delayed until adolescence or young adulthood and symptomatic infection is much more common. For unclear reasons, only about 20% of healthy seropositive persons in developed countries shed the virus, and only about 50% of those exposed to the virus acquire the infection.

Pathogenesis

Transmission to a seronegative "kissing cousin" usually involves direct oral contact. It is hypothesized that the virus initially infects oropharyngeal epithelial cells and then spreads to underlying lymphoid tissue (tonsils and adenoids), where mature B cells are infected. The infection of B cells takes one of two forms. In a minority of cells, the infection is lytic, leading to viral replication and release of virions. More commonly, the infection is nonproductive and the virus persists in latent form as an extrachromosomal episome.

B cells that are latently infected with EBV become "activated" and proliferate as a result of the action of several viral proteins (Chapter 6). These cells disseminate in the circulation and secrete antibodies with unusual specificities, including the antibodies that recognize sheep red cells that are detected in diagnostic tests for mononucleosis. During acute infections, EBV is shed in the saliva; it is not known whether the source of these virions is oropharyngeal epithelial cells or B cells.

The host T cell response controls the proliferation of EBV-infected B cells and the spread of the virus. Early in the course of the infection, IgM antibodies are formed against viral capsid antigens. Later the serologic response shifts to IgG antibodies, which persist for life. More important in the control of the EBV-positive B cell proliferation are cytotoxic CD8+ T cells. Virus-specific CD8+ T cells appear in the circulation as atypical lymphocytes, a finding that is characteristic of mononucleosis. In otherwise healthy persons, the fully developed humoral and cellular responses to EBV act as brakes on viral shedding. In most cases, however, a small number of latently infected EBV-positive B cells escape the immune response and persist for the life of the patient. As described later, **impaired T cell immunity places patients at high risk for EBV-driven B cell proliferations**.

MORPHOLOGY

The major alterations involve the blood, lymph nodes, spleen, liver, and occasionally other organs. There is peripheral blood **leukocytosis**; the white cell count is usually between 12,000 and 18,000 cells/μL. Typically more than half of these cells are large **atypical lymphocytes,** 12 to 16 μm in diameter, with an oval, indented, or folded nucleus and abundant cytoplasm with a few azurophilic granules (Fig. 12.12). These atypical lymphocytes, which are sufficiently distinctive to suggest the diagnosis, are mainly CD8+ T cells.

Lymphadenopathy is common and is most prominent in the posterior cervical, axillary, and groin regions. On histologic examination, the enlarged nodes are flooded by atypical lymphocytes, which occupy the paracortical (T cell) areas. A few cells resembling Reed-Sternberg (RS) cells, the hallmark of Hodgkin lymphoma, often are seen. Because of these atypical features, special tests are sometimes needed to distinguish the reactive changes of mononucleosis from lymphoma.

The **spleen** is enlarged in most cases, weighing between 300 and 500 g, and exhibits a heavy infiltration of atypical lymphocytes. As a result of the rapid increase in splenic size and the infiltration of the trabeculae and capsule by the lymphocytes, such spleens are fragile and are prone to rupture after even minor trauma.

Atypical lymphocytes usually also infiltrate the portal areas and sinusoids of the liver. Scattered apoptotic cells or foci of parenchymal necrosis associated with a lymphocytic infiltrate also may be present—a picture that can be difficult to distinguish from that in other forms of viral hepatitis.

Clinical Features. Infectious mononucleosis classically manifests with fever, sore throat, and lymphadenitis, but atypical presentations are not unusual. Sometimes there is little or no fever and only fatigue and lymphadenopathy exist, raising the specter of lymphoma; fever of unknown origin, unassociated with lymphadenopathy or other localized findings; hepatitis that is difficult to differentiate from one of the hepatotropic viral syndromes (Chapter 16); or a febrile rash resembling rubella. Ultimately, the diagnosis depends on the following, in increasing order of specificity: (1) the presence of atypical lymphocytes in the peripheral blood; (2) a positive heterophil reaction (Monospot test); and (3) a rising titer of antibodies specific for EBV antigens. In most patients, mononucleosis resolves within 4 to 6 weeks, but sometimes the fatigue lasts longer. Occasionally, one or more complications supervene. Perhaps the most common of these is hepatic dysfunction, associated with jaundice, elevated liver enzyme levels, disturbed appetite, and, rarely, even liver failure. Other complications involve the nervous system, kidneys, bone marrow, lungs, eyes, heart, and spleen (including fatal splenic rupture).

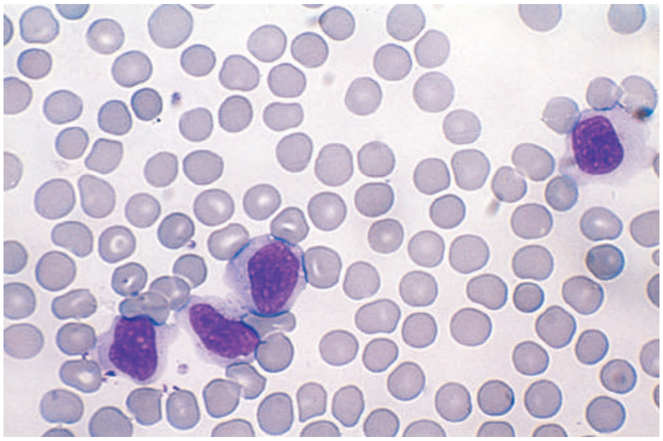

Fig. 12.12 Atypical lymphocytes in infectious mononucleosis.

EBV is a potent transforming virus that plays a role in the pathogenesis of a number of human malignancies, including several types of B cell lymphoma (Chapter 6). A serious complication in those lacking T cell immunity is unimpeded EBV-driven B cell proliferation. This process can be initiated by an acute infection or by the reactivation of a latent B cell infection and generally begins as a polyclonal proliferation that transforms to overt monoclonal B cell lymphoma over time. Reconstitution of immunity (e.g., by cessation of immunosuppressive drugs) is sometimes sufficient to cause complete regression of the B cell proliferation, which is uniformly fatal if left untreated.

The importance of the cellular immune response in controlling EBV infection also is driven home by *X-linked lymphoproliferative syndrome (XLP),* a rare inherited immunodeficiency characterized by an ineffective response to EBV. Most affected boys have mutations in the *SH2D1A* gene, which encodes a signaling protein that participates in the activation of T and NK cells. In more than 50% of cases, EBV causes an acute overwhelming infection, often complicated by hemophagocytic lymphohistiocytosis (HLH, described later), whereas other patients succumb to EBV-driven lymphoma or secondary infections related to hypogammaglobulinemia, the basis of which is not understood.

Reactive Lymphadenitis

Infections and nonmicrobial inflammatory stimuli often activate immune cells residing in lymph nodes, which act as defensive barriers. Any immune response against foreign antigens can lead to lymph node enlargement (lymphadenopathy). Infections causing lymphadenitis are varied and numerous, and may be acute or chronic. In most instances the histologic appearance of the lymph node reaction is nonspecific. A somewhat distinctive form of lymphadenitis that occurs with cat-scratch disease is described separately later.

Acute Nonspecific Lymphadenitis

This form of lymphadenitis may be isolated to a group of nodes draining a local infection, or be generalized, as in systemic infectious and inflammatory conditions.

MORPHOLOGY

Inflamed nodes in acute nonspecific lymphadenitis are swollen, gray-red, and engorged. Histologically, there are **large germinal centers** containing numerous mitotic figures. When the cause is a pyogenic organism, a neutrophilic infiltrate is seen around the follicles and within the lymphoid sinuses. With severe infections,

the centers of follicles can undergo necrosis, leading to the formation of an abscess.

Affected nodes are tender and may become fluctuant if abscess formation is extensive. The overlying skin is frequently red and may develop draining sinuses. With control of the infection the lymph nodes may revert to a normal "resting" appearance or, if damaged, undergo scarring.

Chronic Nonspecific Lymphadenitis

Depending on the causative agent, chronic nonspecific lymphadenitis can assume one of three patterns: follicular hyperplasia, paracortical hyperplasia, or sinus histiocytosis.

MORPHOLOGY

Follicular Hyperplasia. This pattern occurs with infections or inflammatory processes that activate B cells, which migrate into B cell follicles and create the **follicular (or germinal center) reaction.** Reactive follicles contain numerous activated B cells, scattered T cells, phagocytic macrophages containing nuclear debris (tingible body macrophages), and a meshwork of antigen-presenting follicular dendritic cells. Causes of follicular hyperplasia include **rheumatoid arthritis, toxoplasmosis,** and early **HIV infection.** This form of lymphadenitis must be distinguished from follicular lymphoma (discussed later). Findings that favor follicular hyperplasia are (1) the preservation of the lymph node architecture; (2) variation in the shape and size of the germinal centers; (3) the presence of a mixture of germinal center lymphocytes of varying shapes and sizes; and (4) prominent phagocytic and mitotic activity in germinal centers.

Paracortical Hyperplasia. This pattern is caused by immune reactions involving the **T cell regions** of the lymph node. When activated, parafollicular T cells transform into large proliferating immunoblasts that can efface the B cell follicles. Paracortical hyperplasia is encountered in **viral infections** (such as EBV), after certain **vaccinations** (e.g., smallpox), and in immune reactions induced by **drugs** (especially phenytoin).

Sinus Histiocytosis. This reactive pattern is characterized by distention and prominence of the lymphatic sinusoids, owing to a marked **hypertrophy of lining endothelial cells** and an **infiltrate of macrophages (histiocytes).** It often is encountered in lymph nodes draining cancers and may represent an immune response to the tumor or its products

Cat-Scratch Disease

Cat-scratch disease is a self-limited lymphadenitis caused by the bacterium *Bartonella henselae.* It is primarily a disease of childhood; 90% of the patients are younger than 18 years of age. It manifests with regional lymphadenopathy, most frequently in the axilla and the neck. The nodal enlargement appears approximately 2 weeks after a feline scratch or, less commonly, after a splinter or thorn injury. An inflammatory nodule, vesicle, or eschar is sometimes visible at the site of the skin injury. In most patients the lymph node enlargement regresses during a period of 2 to 4 months. Rarely, encephalitis, osteomyelitis, or thrombocytopenia may develop in patients.

MORPHOLOGY

The nodal changes in cat-scratch disease are quite characteristic. Initially sarcoidlike granulomas form, but these then undergo central necrosis associated with an infiltrate of neutrophils. These **irregular stellate necrotizing granulomas** are similar in appearance to those seen in a limited number of other infections, such as lymphogranuloma venereum. The microbe is extracellular and can be visualized with silver stains. The diagnosis is based on a history of exposure to cats, the characteristic clinical findings, a positive result on serologic testing for antibodies to *Bartonella*, and the distinctive morphologic changes in the lymph nodes.

Hemophagocytic Lymphohistiocytosis (HLH)

HLH is an uncommon disorder in which a viral infection or other proinflammatory exposures trigger activation of macrophages throughout the body, leading to phagocytosis of blood cells and their precursors, cytopenias, and symptoms related to systemic inflammation and organ dysfunction. Inherited defects in several genes that regulate the function of immune cells are associated with a greatly elevated risk of HLH. The involved genes and proteins are diverse, but they share a common feature in that they are required for the cytolytic function of CD8+ T cells and NK cells. Owing to this defect in "killer lymphocytes," cytotoxic lymphocytes are unable to kill their targets (e.g. virus infected cells) and remain engaged with targeted cells for longer than normal periods of time, leading to excessive release of cytokines, such as interferon gamma, that activate macrophages. The unbridled macrophage activation results in the release of toxic levels of additional proinflammatory cytokines, such as TNF and IL-6, producing signs and symptoms that closely resemble those associated with sepsis and other conditions that lead to the systemic inflammatory response syndrome (SIRS) (Chapter 4).

HLH occurs in several distinct settings. It is most common in infants and young children with homozygous defects in genes that are required for cytotoxic lymphocyte function, such the gene *PRF1*, which encodes perforin, an essential component of cytotoxic granules. In this setting the trigger may be some normally trivial childhood viral infection. Other times, HLH arises in older male children and adolescents with X-linked lymphoproliferative disorder, in which the trigger is EBV infection. In those affected, inherited defects in a signaling molecule called SLAM-associated protein (SAP) leads to inefficient killing of EBV-infected B cells. HLH also may complicate other systemic inflammatory disorders, such as rheumatologic conditions. At least a subset of these individuals have heterozygous defects in genes required for cytotoxic lymphocyte function, creating a genetic background that increases the likelihood of HLH. Finally, HLH may be seen as a secondary phenomenon in patients with peripheral T cell lymphomas. The precise mechanism in this context is uncertain; aberrant cytokine production by malignant T cells leading to dysregulation of non-neoplastic cytotoxic lymphocytes is suspected.

Regardless of cause, patients with HLH typically present with fever, splenomegaly, and pancytopenia. In severe cases, DIC and organ failure may supervene. An

examination of the bone marrow shows macrophages phagocytosing red cells, platelets, and nucleated marrow cells. Laboratory abnormalities typically include a very high ferritin level (>10,000 μg/L), hypertriglyceridemia, high serum levels of soluble IL2 receptor, and low levels of circulating NK cells and cytotoxic T lymphocytes. In concert, these findings are quite sensitive and specific for HLH. Treatment varies depending on the underlying cause, but it is generally poor. In those with HLH stemming from inherited defects, hematopoietic stem cell transplantation offers a chance for cure.

NEOPLASTIC PROLIFERATIONS OF WHITE CELLS

The most important disorders of white cells are neoplasms. Virtually all of these tumors are considered to be malignant, but they demonstrate a wide range of behaviors, ranging from some of the most aggressive cancers of man to tumors that are so indolent that they were only recognized recently as true neoplasms. Hematologic malignancies occur at all ages and include disorders that preferentially affect infants, children, and young adults, as well as the very old. As a group they are quite common; in aggregate, there are about 150,000 new hematologic malignancies diagnosed each year in the United States.

Current systems of classifying white cell neoplasms rely on a mixture of morphologic and molecular criteria, including lineage-specific protein markers and genetic findings. We will organize our discussion by dividing the white cell neoplasms into four broad categories based on the origin and differentiation state of the tumor cells, as follows:

- *Lymphoid neoplasms*, which include certain leukemias and the non-Hodgkin and Hodgkin lymphomas. In many instances these tumors are composed of cells resembling some normal stage of lymphocyte differentiation, a feature that serves as one of the bases for their classification. A special group of lymphoid neoplasms are the plasma cell neoplasms and related entities, in which many of the clinical manifestations stem from abnormal immunoglobulins that are synthesized and secreted from the neoplastic cells.
- *Myeloid neoplasms*, which include certain leukemias, myelodysplastic syndromes (MDSs), and myeloproliferative neoplasms. These tumors have in common an origin from a hematopoietic stem cell or some other very early hematopoietic progenitor, and they typically involve the bone marrow.
- *Histiocytic neoplasms*, which include proliferative lesions of macrophages and dendritic cells. Of special interest is a spectrum of proliferations of Langerhans cells *(Langerhans cell histiocytoses)*.

Lymphoid Neoplasms

The numerous lymphoid neoplasms vary widely in their clinical presentation and behavior, and thus present challenges to students and clinicians alike. Some characteristically manifest as *leukemias,* with involvement of the bone marrow and the peripheral blood. Others tend to present as *lymphomas,* tumors that produce masses in lymph nodes or other tissues. *Plasma cell tumors* usually arise within the bones and manifest as discrete masses, causing systemic symptoms related to the production of a complete or partial monoclonal immunoglobulin. Although these tendencies are reflected in the names given to particular entities, in reality all lymphoid neoplasms have the potential to spread to lymph nodes and other tissues, especially the liver, spleen, bone marrow, and peripheral blood. Because of their overlapping clinical behavior, the diagnosis of lymphoid neoplasms is based on the morphologic and molecular characteristics of the tumor cells. Stated another way, for purposes of diagnosis and prognostication, it is most important to focus on what kind of cell the tumor is made up of, not where the tumor resides in the patient.

Two groups of lymphomas are recognized: *Hodgkin lymphomas* and *non-Hodgkin lymphomas.* Although both arise most commonly in lymphoid tissues, Hodgkin lymphoma is set apart by the presence of distinctive neoplastic RS giant cells (see later), which usually are greatly outnumbered by nonneoplastic inflammatory cells. The biologic behavior and clinical treatment of Hodgkin lymphoma also are different from those of NHLs, making the distinction of practical importance.

An international group of pathologists, molecular biologists, and clinicians working on behalf of the World Health Organization (WHO) has formulated a widely accepted classification scheme for lymphoid neoplasms and myeloid neoplasms (discussed later) that relies on a combination of morphologic, phenotypic, genotypic, and clinical features. As background for the subsequent discussion of this classification, certain important principles warrant consideration:

- **B and T cell tumors often are composed of cells that are arrested at or derived from a specific stage of normal lymphocyte differentiation** (Fig. 12.13). The diagnosis and classification of these tumors rely heavily on tests (either immunohistochemistry or flow cytometry) that detect lineage-specific antigens (e.g., B cell, T cell, and NK cell markers) and markers of maturity. By convention, many such markers are identified by their cluster of differentiation (CD) number.
- **Class switching and somatic hypermutation are mistake-prone forms of regulated genomic instability that place germinal center B cells at relatively high risk for potentially transforming mutations.** The most common lymphomas are derived from B cells that have migrated into germinal centers following antigen stimulation. This conclusion is drawn from analyses showing that most B cell lymphomas have undergone somatic hypermutation, an event confined to germinal center B cells. Normal germinal center B cells also undergo immunoglobulin class switching, which allows B cells to express immunoglobulins other than IgM. Many of the recurrent chromosomal translocations found in mature B cell malignancies involve the immunoglobulin loci and appear to stem from "accidents" during attempted diversification of the immunoglobulin genes. By contrast, mature T cells, which are genomically stable, give rise to lymphoma infrequently and only very rarely have chromosomal translocations involving the T cell receptor loci.

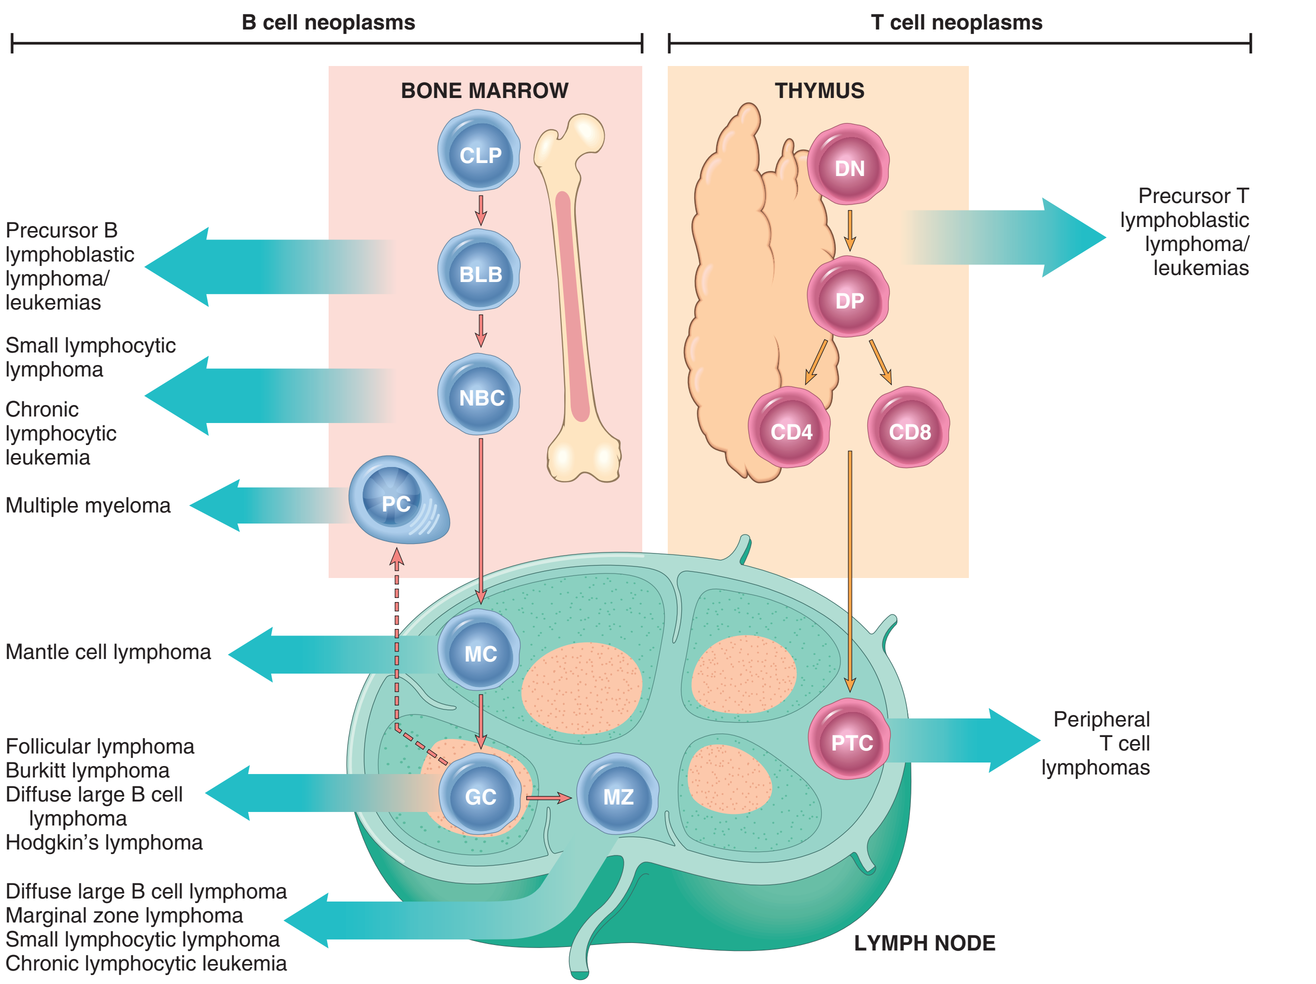

Fig. 12.13 Origin of lymphoid neoplasms. Stages of B and T cell differentiation from which specific lymphoid and tumors emerge are shown. *BLB*, Pre-B lymphoblast; *CLP*, common lymphoid progenitor; *DN*, CD4–/CD8– (double-negative) pro-T cell; *DP*, CD4+/CD8+ (double-positive) pre-T cell; *GC*, germinal center B cell; *MC*, mantle zone B cell; *MZ*, marginal zone B cell; *NBC*, naive B cell; *PC*, plasma cell; *PTC*, peripheral T cell.

- **Like other cancers, lymphoid neoplasms are derived from a single transformed cell and are therefore clonal.** As described in Chapter 5, precursor B and T cells rearrange their antigen receptor genes through a mechanism that ensures that each lymphocyte makes a single, unique antigen receptor. Because antigen receptor gene rearrangement virtually always precedes transformation, the daughter cells derived from a given malignant progenitor share the same antigen receptor gene configuration and synthesize identical antigen receptor proteins (either immunoglobulins or T cell receptors). Thus, analyses of antigen receptor genes and their protein products can be used to differentiate lymphoid neoplasms (which are clonal) from immune reactions (which are polyclonal).
- **Lymphoid neoplasms often disrupt normal immune function.** Both immunodeficiency (made evident by increased susceptibility to infection) and autoimmunity may be seen, sometimes in the same patient. Ironically, patients with inherited or acquired immunodeficiencies are at high risk for the development of certain lymphoid neoplasms, particularly those associated with EBV infection.
- **Although NHLs often manifest at a particular tissue site, sensitive molecular assays usually show that the tumor is widely disseminated at diagnosis.** As a result, with few exceptions, only systemic therapies are curative for those with NHL. By contrast, Hodgkin lymphoma often arises at a single site and spreads in a predictable fashion to contiguous lymph node groups.

The WHO classification of lymphoid neoplasms (Table 12.7) considers the morphology, cell of origin (determined by immunophenotyping), clinical features, and genotype (e.g., karyotype, presence of viral genomes) of each entity. As is evident, the diagnostic entities are numerous. We will focus our discussion on a subset that are particularly clinically important or pathogenically illustrative:

- Precursor B and T cell lymphoblastic lymphoma/leukemia—commonly called acute lymphoblastic leukemia (ALL)
- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- Follicular lymphoma
- Mantle cell lymphoma

Table 12.7 WHO Classification of Lymphoid Neoplasms[a]

Precursor B Cell Neoplasms
Precursor B cell leukemia/lymphoma (B-ALL)
Peripheral B Cell Neoplasms
B cell chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma (SLL)
B cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Mantle cell lymphoma
Follicular lymphoma
Extranodal marginal zone lymphoma
Splenic and nodal marginal zone lymphoma
Hairy cell leukemia
Plasmacytoma/plasma cell myeloma
Diffuse large B cell lymphoma (multiple subtypes)
Burkitt lymphoma
Precursor T Cell Neoplasms
Precursor T cell leukemia/lymphoma (T-ALL)
Peripheral T/NK Cell Neoplasms
T cell prolymphocytic leukemia
T cell granular lymphocytic leukemia
Mycosis fungoides/Sézary syndrome
Peripheral T cell lymphoma, unspecified
Angioimmunoblastic T cell lymphoma
Anaplastic large cell lymphoma
Enteropathy-type T cell lymphoma
Panniculitis-like T cell lymphoma
Hepatosplenic γδ T cell lymphoma
Adult T cell lymphoma/leukemia
Extranodal NK/T cell lymphoma
Aggressive NK cell leukemia
Hodgkin Lymphoma
Nodular sclerosis
Mixed cellularity
Lymphocyte-rich
Lymphocyte-depleted
Lymphocyte predominant

NK, Natural killer; *WHO*, World Health Organization.
[a]Entries in *italics* are among the most common lymphoid tumors.

- Extranodal marginal zone lymphoma
- Diffuse large B cell lymphomas
- Burkitt lymphoma
- Multiple myeloma and related entities
- Hodgkin lymphoma

Together these neoplasms constitute more than 90% of the lymphoid tumors seen in the United States.

The salient features of the more common lymphoid leukemias, non-Hodgkin lymphomas, and plasma cell tumors are summarized in Table 12.8 and are discussed in the following sections. We will then cover Hodgkin lymphoma and finish by briefly mentioning a few uncommon entities with distinctive clinicopathologic features.

Precursor B and T Cell Neoplasms

Acute Lymphoblastic Leukemia/Lymphoma

Acute lymphoblastic leukemia/lymphomas (ALLs) are neoplasms composed of immature B (pre-B) or T (pre-T) cells, which are referred to as *lymphoblasts*. About 85% are B-ALLs, which typically manifest as childhood acute "leukemias." The less common T-ALLs tend to present in adolescent males as thymic "lymphomas." There is, however, considerable overlap in the clinical behavior of B- and T-ALL; for example, many T-ALLs present with or evolve to a leukemic picture. Because of their morphologic and clinical similarities, the various forms of ALL will be considered here together.

ALL is the most common cancer of children. Approximately 2500 new cases are diagnosed each year in the United States, most occurring in individuals younger than 15 years of age. ALL is almost three times as common in whites as in blacks and is slightly more frequent in boys than in girls. Hispanics have the highest incidence of any ethnic group. B-ALL peaks in incidence at about the age of 3, perhaps because the number of normal bone marrow pre-B cells (the cell of origin) is greatest very early in life. Similarly the peak incidence of T-ALL is in adolescence, the age when the thymus reaches its maximum size.

Pathogenesis

Many chromosomal aberrations seen in ALL dysregulate the expression and function of transcription factors that are required for the normal differentiation of B and T cell progenitors. Up to 70% of T-ALLs have gain-of-function mutations in *NOTCH1*, a gene that is essential for T cell differentiation, whereas a high fraction of B-ALLs has loss-of-function mutations in genes that are required for B cell differentiation, such as *PAX5*. These varied mutations appear to promote maturation arrest and increased self-renewal, a feature of immortalized cells, which, as mentioned, is one of the hallmarks of cancers.

In keeping with the multistep origins of cancer, mutations in transcription factor genes are not sufficient to produce ALL, and aberrations that drive cell growth, such as mutations that increase tyrosine kinase activity and RAS signaling, also are common. Ongoing deep sequencing of ALL genomes is rapidly filling in the remaining gaps. Early returns suggest that fewer than 10 mutations are sufficient to produce full-blown ALL; hence, compared to solid tumors, ALL is a genetically simple tumor.

MORPHOLOGY

In leukemic presentations, **the marrow is hypercellular and packed with lymphoblasts,** which replace normal marrow elements. **Mediastinal masses** occur in 50% to 70% of T-ALLs, which are also more likely to be associated with lymphadenopathy and splenomegaly. In both B- and T-ALL, the tumor cells have scant basophilic cytoplasm and nuclei with delicate, finely stippled chromatin and small nucleoli (Fig. 12.14A). In keeping with the aggressive clinical behavior, the mitotic rate is high. The appearance of the blasts is identical in pre-B and pre-T ALLs and is not sufficiently characteristic to exclude the other major subtype of acute leukemia, acute myeloid leukemia (AML, discussed later). For this reason, definitive diagnosis relies on stains performed with antibodies specific for B and T cell antigens (Fig. 12.14B–C). Histochemical stains are also helpful, in that (in contrast to myeloblasts) lymphoblasts are myeloperoxidase-negative and often contain periodic acid-Schiff–positive glycogen granules.

Table 12.8 Characteristics of the More Common Lymphoid Leukemias, Non-Hodgkin Lymphomas, and Plasma Cell Tumors

Clinical Entity	Frequency	Salient Morphology	Cell of Origin	Comments
Precursor B cell lymphoblastic leukemia/lymphoma	85% of childhood acute leukemias	Lymphoblasts with irregular nuclear contours, condensed chromatin, small nucleoli, and scant, agranular cytoplasm	TdT+ precursor B cell	Usually manifests as acute leukemia; less common in adults; prognosis is predicted by karyotype
Precursor T cell leukemia/lymphoma	15% of childhood acute leukemias; 40% of childhood lymphomas	Identical to precursor B cell lymphoblastic leukemia/lymphoma	TdT+ precursor T cell	Most common in adolescent males; often manifests as a mediastinal mass associated with *NOTCH1* mutations
Small lymphocytic lymphoma/chronic lymphocytic leukemia	3%–4% of adult lymphomas; 30% of all leukemias	Small resting lymphocytes mixed with variable numbers of large activated cells; lymph nodes diffusely effaced	CD5+ B cell	Occurs in older adults; usually involves nodes, marrow, spleen; and peripheral blood; indolent
Follicular lymphoma	40% of adult lymphomas	Frequent small "cleaved" cells mixed with large cells; nodular (follicular) growth pattern	Germinal center B cell	Associated with t(14;18); indolent
Mantle cell lymphoma	6% of adult lymphomas	Small to intermediate-sized irregular lymphocytes; diffuse growth pattern	CD5+ B cell overexpressing cyclin D1	Associated with t(11;14); moderately aggressive
Extranodal marginal zone lymphoma	~5% of adult lymphomas	Tumor cells often home to epithelium, creating "lymphoepithelial lesions"	CD5–, CD10–B cell	Associated with chronic inflammation; indolent
Diffuse large B cell lymphoma	40%–50% of adult lymphomas	Variable; most resemble large germinal center B cells; diffuse growth pattern	Germinal center or postgerminal center B cell	Heterogeneous, may arise at extranodal sites; aggressive
Burkitt lymphoma	<1% of lymphomas in the United States	Intermediate-sized cells with several nucleoli; diffuse growth pattern; frequent apoptotic cells ("starry sky" appearance)	Germinal center B cell	Associated with t(8;14) and EBV (subset); highly aggressive
Plasmacytoma/plasma cell myeloma	Most common lymphoid neoplasm in older adults	Plasma cells in sheets, sometimes with prominent nucleoli or inclusions containing immunoglobulin	Postgerminal center B cell	CRAB (hyper**c**alcemia, **r**enal failure, **a**nemia, **b**one fractures)

EBV, Epstein-Barr virus; *TdT*, terminal deoxynucleotidyl transferase.

The peripheral blood findings are highly variable. The white cell count may be greater than 100,000 cells/µL but in about half of the patients is less than 10,000 cells/µL. A few patients have no circulating blasts (aleukemic leukemia). Anemia almost always is present, and the platelet count usually is below 100,000/µL. Neutropenia is another common finding.

Genetics. Approximately 90% of ALLs have nonrandom karyotypic abnormalities. Most common in childhood pre–B cell tumors are hyperdiploidy (more than 50 chromosomes/cell) and a (12;21) translocation involving the *ETV6* and *RUNX1* genes, creating a fusion gene encoding an aberrant transcription factor, whereas about 25% of adult pre–B cell tumors have a (9;22) translocation involving the *ABL* and *BCR* genes. Pre–T cell tumors are associated with diverse chromosomal aberrations, including frequent translocations involving the T cell receptor loci and certain transcription factor genes, as well as mutations that inactivate tumors suppressor genes such as *PTEN* (leading to increased pro-growth signaling) and *CDKN2A*, which encodes a negative regulator of the cell cycle and a positive regulator of p53.

Immunophenotype. As mentioned, immunophenotyping is very useful in subtyping ALLs and distinguishing them from AML. Terminal deoxynucleotidyl transferase (TdT), an enzyme specifically expressed in pre–B and pre–T cells, is present in more than 95% of cases. Further subtyping of ALL into pre–B and pre–T cell types relies on stains for lineage-specific markers, such as the B cell marker CD19 and the T cell marker CD3.

Clinical Features. ALL is an aggressive disease, and most patients present within a few weeks of the onset of symptoms. Among the most important signs and symptoms are the following:

- *Symptoms related to depression of marrow function*, including fatigue resulting from anemia; fever, reflecting infections secondary to neutropenia; and bleeding due to thrombocytopenia
- *Mass effects caused by neoplastic infiltration*, including bone pain resulting from marrow expansion and infiltration of the subperiosteum; generalized lymphadenopathy, splenomegaly, and hepatomegaly; and in T-ALL, complications related to compression of large vessels and airways in the mediastinum
- *Central nervous system manifestations* resulting from meningeal spread, such as headache, vomiting, and nerve palsies

Despite its highly malignant natural history, pediatric ALL is one of the great success stories of oncology. With aggressive chemotherapy, about 95% of children with ALL obtain a remission, and 75% to 85% are cured. It is sobering

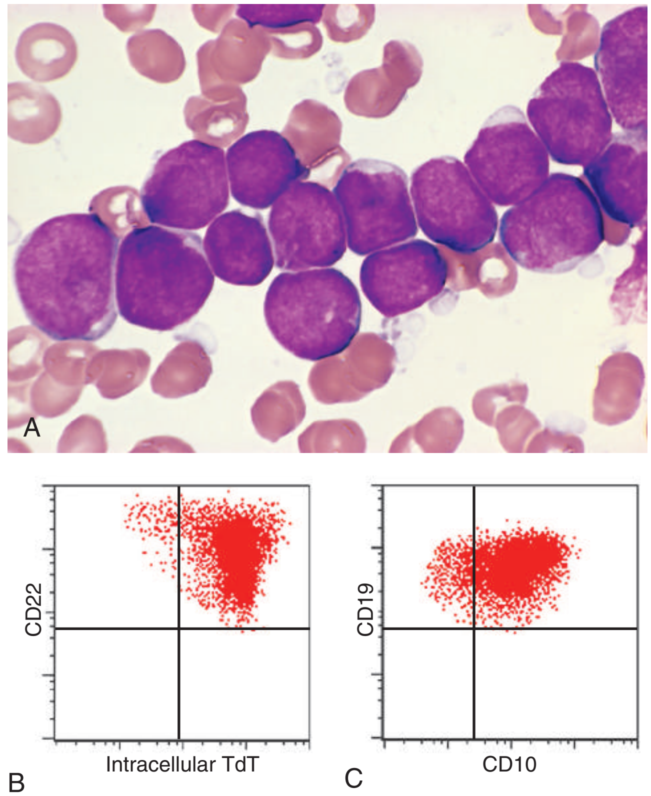

Fig. 12.14 Acute lymphoblastic leukemia (ALL). (A) Lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. (B) and (C) show flow cytometry results for the ALL shown in (A). The tumor cells are positive for the B cell markers CD19 and CD22; CD10 (a marker expressed on a subset of ALLs), and TdT (a specialized DNA polymerase that is expressed in pre-B and pre-T cells). *(A, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.* B and C, *Courtesy of Dr. Louis Picker, Oregon Health Science Center, Portland, Oregon.)*

to consider, however, that ALL remains the leading cause of cancer deaths in children, and that only 35% to 40% of affected adults are cured. Several factors are associated with a worse prognosis: (1) age younger than 2 years, largely because these tumors are genetically distinct, often being associated with translocations involving the *MLL* gene; (2) presentation in adolescence or adulthood; and (3) peripheral blood blast counts greater than 100,000. Favorable prognostic markers include (1) age between 2 and 10 years, (2) a low white cell count, and (3) hyperdiploidy. The molecular detection of residual disease after therapy also is predictive of a worse outcome in both B- and T-ALL and is being used to guide therapy.

Although most chromosomal aberrations in ALL alter the function of transcription factors, the t(9;22) instead creates a fusion gene encoding a constitutively active BCR-ABL tyrosine kinase (described later under chronic myeloid leukemia). Treatment of t(9;22)-positive ALLs with BCR-ABL kinase inhibitors in combination with conventional chemotherapy is highly effective and has improved the outcome for this subtype of B-ALL in both children and adults. Tests to identify other "targetable" mutated tyrosine kinases in ALLs lacking BCR-ABL are under development. The outlook for adults with ALL remains guarded, in part because of differences in the molecular pathogenesis of adult and childhood ALL, and also because older adults cannot tolerate the intensive chemotherapy regimens that are curative in children.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL) are essentially identical, differing only in the extent of peripheral blood involvement. Somewhat arbitrarily, if the peripheral blood lymphocyte count exceeds 5000 cells/μL, the patient is diagnosed with CLL. Most cases fit the diagnostic criteria for CLL, which is the most common leukemia of adults in the Western world. By contrast, SLL constitutes only 4% of NHLs. For unclear reasons, CLL/SLL is much less common in Asia.

Pathogenesis

CLL/SLL is an indolent, slowly growing tumor in which increased tumor cell survival appears to be more important than tumor cell proliferation per se. In line with this idea, CLL/SLL cells contain high levels of BCL2, a protein that inhibits apoptosis (Chapters 1 and 6). One mechanism of *BCL2* overexpression appears to be chromosomal deletions that lead to the loss of genes encoding micro-RNAs that are negative regulators of *BCL2*. *Also of critical importance are signals generated by surface immunoglobulin (the so-called B cell receptor, or BCR).* BCR signals flow through an intermediary called *Bruton tyrosine kinase (BTK)* that ultimately contributes to the expression of genes that promote the survival of CLL/SLL cells.

CLL/SLL also causes immune dysregulation, particularly of normal B cells. Through unclear mechanisms, the accumulation of CLL/SLL cells suppresses normal B cell function, often resulting in *hypogammaglobulinemia*. Paradoxically, approximately 15% of patients develop autoantibodies against their own red cells or platelets. When present, the autoantibodies are made by nonmalignant bystander B cells, indicating that CLL/SLL cells somehow impair immune tolerance.

MORPHOLOGY

Involved lymph nodes are effaced by sheets of small lymphocytes and by scattered ill-defined foci of larger, actively dividing cells (Fig. 12.15A). The predominant cells are small, resting lymphocytes with dark, round nuclei, and scanty cytoplasm (Fig. 12.15B). The foci of mitotically active cells are called **proliferation centers,** which are pathognomonic for CLL/SLL. In addition to the lymph nodes, the bone marrow, spleen, and liver are involved in almost all cases. In most patients there is an absolute **lymphocytosis** featuring small, mature-looking lymphocytes. These circulating cells are fragile and during the preparation of smears many are disrupted, producing characteristic **smudge cells.** Variable numbers of larger activated lymphocytes also are usually present in blood smears.

Immunophenotype and Genetics. CLL/SLL is a neoplasm of mature B cells expressing the CD20 and surface immunoglobulins. The tumor cells also express CD5. This

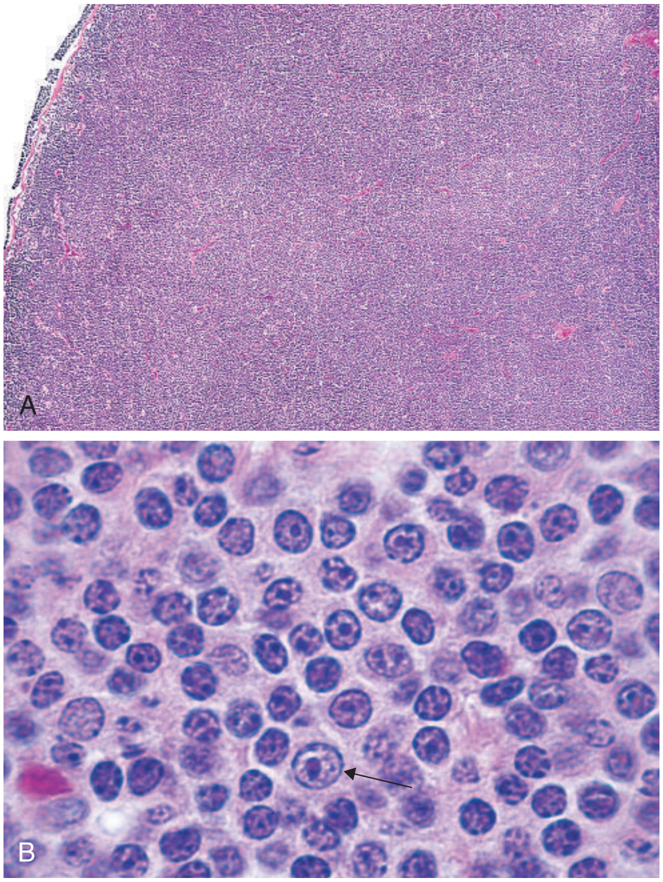

Fig. 12.15 Small lymphocytic lymphoma/chronic lymphocytic leukemia—lymph node. (A) Low-power view shows diffuse effacement of nodal architecture. (B) At high power, a majority of the tumor cells have the appearance of small, round lymphocytes. A "prolymphocyte," a larger cell with a centrally placed nucleolus, also is present in this field *(arrow)*. (A, *Courtesy of Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

is a helpful diagnostic clue, since among B cell lymphomas only CLL/SLL and mantle cell lymphoma (discussed later) commonly express CD5. Approximately 50% of tumors have karyotypic abnormalities, the most common of which are trisomy 12 and deletions involving portions of chromosomes 11, 13, and 17. *Unlike in other B cell neoplasms, chromosomal translocations are rare.*

Clinical Features. When first detected, CLL/SLL often is asymptomatic. The most common signs and symptoms are nonspecific and include easy fatigability, weight loss, and anorexia. Generalized lymphadenopathy and hepatosplenomegaly are present in 50% to 60% of patients. The leukocyte count may be increased only slightly (in SLL) or may exceed 200,000 cells/μL. Hypogammaglobulinemia develops in more than 50% of the patients, usually late in the course, and leads to an increased susceptibility to bacterial infections. Less commonly, autoimmune hemolytic anemia and thrombocytopenia are seen.

The course and prognosis of CLL/SLL are highly variable and depend on the disease stage and genetic findings. For example, the presence of abnormalities in the *TP53* tumor suppressor gene is associated with an overall survival of less than 30% at 10 years, whereas isolated abnormalities of chromosome 13q are associated with an overall survival that is not significantly different from that of the matched general population. Insights into the molecular pathogenesis of CLL/SLL has led to development of effective new drugs that variously inhibit BCR signaling (e.g., by targeting BTK) or BCL2 function. However, cure may only be achieved with hematopoietic stem cell transplantation, which is reserved for relatively young patients who fail conventional therapies. A small fraction of tumors transform to aggressive tumors resembling diffuse large B cell lymphoma *(Richter transformation)*; after transformation occurs, the median survival is less than 1 year.

Follicular Lymphoma

This relatively common tumor constitutes 40% of the adult NHLs in the United States. Like CLL/SLL, it occurs much less frequently in Asian populations.

Pathogenesis

Greater than 85% of follicular lymphomas have a characteristic (14;18) translocation that fuses the *BCL2* gene on chromosome 18 to the *IgH* locus on chromosome 14. This chromosomal rearrangement results in the inappropriate "overexpression" of BCL2 protein, which you will recall is an inhibitor of apoptosis that contributes to cell survival (Chapters 1 and 6). Whole genome sequencing of follicular lymphomas has identified additional mutations in genes encoding histone-modifying proteins in about one-third of cases, suggesting that epigenetic changes also contribute to the genesis of these tumors.

MORPHOLOGY

Lymph nodes usually are effaced by a distinctly **nodular proliferation** (Fig. 12.16A). Most commonly, the predominant neoplastic cells are so-called "**centrocytes**", cells slightly larger than resting lymphocytes that have angular "cleaved" nuclei with prominent indentations and linear infoldings (Fig. 12.16B). The nuclear chromatin is coarse and condensed, and nucleoli are indistinct. These centrocytes are mixed with variable numbers of **centroblasts**, larger cells with vesicular chromatin, several nucleoli, and modest amounts of cytoplasm. In most tumors, centroblasts are a minor component of the overall cellularity, mitoses are infrequent, and single necrotic cells (cells undergoing apoptosis) are not seen. These features help to distinguish follicular lymphoma from follicular hyperplasia, in which mitoses and apoptosis are prominent. Uncommonly, large cells predominate, a histologic pattern that correlates with a more aggressive clinical behavior.

Immunophenotype. These tumors express B cell markers such as CD20 and the germinal center B cell markers CD10 and BCL6; of note, BCL6 is a transcription factor that is required for the generation of germinal center B cells.

Clinical Features. Follicular lymphoma mainly occurs in adults older than 50 years of age and affects males and females equally. It usually manifests as painless, generalized lymphadenopathy. The bone marrow is involved at diagnosis in approximately 80% of cases. Although the

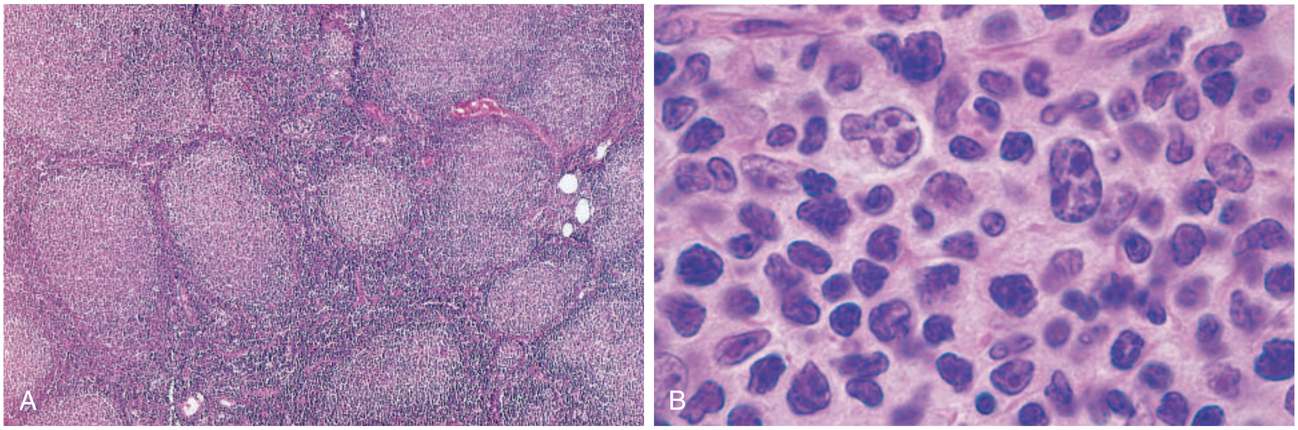

Fig. 12.16 Follicular lymphoma—lymph node. (A) Nodular aggregates of lymphoma cells are present throughout. (B) At high magnification, small lymphoid cells with condensed chromatin and irregular or cleaved nuclear outlines (centrocytes) are mixed with a population of larger cells with nucleoli (centroblasts). *(A, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

natural history is prolonged (overall median survival, approximately 10 years), follicular lymphoma is not curable, an unfortunate feature shared with most other relatively indolent lymphoid malignancies. As a result, therapy with cytotoxic drugs and rituximab (anti-CD20 antibody) is reserved for those with bulky, symptomatic disease. BTK and BCL2 inhibitors are also active in this disease and are being evaluated in clinical trials. In about 30% to 40% of patients, follicular lymphoma progresses to diffuse large B cell lymphoma. This transformation is an ominous event, as tumors arising from such conversions are much less curable than de novo diffuse large B cell lymphomas, described later.

Mantle Cell Lymphoma

Mantle cell lymphoma is composed of cells resembling the naive B cells found in the mantle zones of normal lymphoid follicles. It constitutes approximately 6% of all NHLs and occurs mainly in men older than 50 years of age.

Pathogenesis

Almost all tumors have an (11;14) translocation that fuses the cyclin D1 gene to the IgH locus. This translocation leads to overexpression of cyclin D1, which you will recall stimulates growth by promoting the progression of cells from the G_1 phase to the S phase of the cell cycle (Chapter 6).

MORPHOLOGY

Mantle cell lymphoma may involve lymph nodes in a diffuse or vaguely nodular pattern. Proliferation centers are absent, a feature that helps to distinguish mantle cell lymphoma from CLL/SLL. The tumor cells usually are slightly larger than normal lymphocytes and have an irregular nucleus, inconspicuous nucleoli, and scant cytoplasm. Less commonly, the cells are larger and morphologically resemble lymphoblasts. The bone marrow is involved in most cases and the peripheral blood in about 20% of cases. The tumor sometimes arises in the gastrointestinal tract, often manifesting as multifocal submucosal nodules that grossly resemble polyps (lymphomatoid polyposis).

Immunophenotype. The tumor cells express surface IgM and IgD, the B cell antigen CD20, and CD5, and they contain high levels of cyclin D1 protein.

Clinical Features. Most patients present with fatigue and lymphadenopathy and are found to have generalized disease involving the bone marrow, spleen, liver, and (often) the gastrointestinal tract. These tumors are moderately aggressive and incurable. The median survival is 4 to 6 years. Like CLL/SLL cells, mantle cell lymphoma cells depend on signals generated through BTK for survival, and it is hoped that newly available BTK inhibitors will improve clinical outcomes.

Extranodal Marginal Zone Lymphoma

This indolent B cell tumor arises most commonly in epithelial tissues such as the stomach, salivary glands, small and large bowel, lungs, orbit, and breast.

Pathogenesis

Extranodal marginal zone lymphoma is an example of a cancer that arises within and is sustained by chronic inflammation. It tends to develop within tissues that are involved by chronic inflammation triggered by autoimmune disorders (such as the salivary gland in Sjögren syndrome and the thyroid gland in Hashimoto thyroiditis) or that are the sites of chronic infection (such as *H. pylori* gastritis). In the case of *H. pylori*–associated gastric marginal zone lymphoma, eradication of *H. pylori* with antibiotic therapy often leads to regression of the tumor cells, which depend on inflammatory cytokines secreted by *H. pylori*–specific T cells for their growth and survival. Based on these observations, it is supposed that the disease is initiated within the context of a polyclonal immune reaction. With the acquisition of still-unknown initiating mutations, a B cell clone emerges that depends on antigen-stimulated T-helper cells for signals that drive growth and survival. At this stage, withdrawal of the responsible antigen causes tumor involution. As further clonal evolution leads to greater tumor cell autonomy, spread to distant sites may occur. This theme of polyclonal to monoclonal transition during lymphomagenesis is also applicable to

the pathogenesis of EBV-induced lymphoma (discussed in Chapter 6).

MORPHOLOGY

The clonal B cells characteristically infiltrate the epithelium of involved tissues, often collecting in small aggregates that are called **lymphoepithelial lesions.** In some tumors the tumor cells accumulate abundant pale cytoplasm or exhibit plasma cell differentiation, features that are characteristic but not pathognomonic.

Immunophenotype. This is a tumor of mature B cells expressing CD20 and surface immunoglobulin, usually IgM.

Clinical Features. These tumors often present as swelling of the salivary gland, thyroid or orbit or are discovered incidentally in the setting of *H. pylori*–induced gastritis or an imaging procedure. When localized, they are often cured by simple excision followed by radiotherapy.

Diffuse Large B Cell Lymphoma

Diffuse large B cell lymphoma is the most common type of lymphoma in adults, accounting for approximately 35% of adult NHLs. It includes several subtypes that share an aggressive natural history.

Pathogenesis

About one-third of diffuse large B cell lymphomas have rearrangements of the *BCL6* gene, located on 3q27, and an even higher fraction of tumors have activating point mutations in the *BCL6* promoter. Both aberrations result in increased levels of BCL6 protein, an important transcriptional regulator of gene expression in germinal center B cells. Another 30% of tumors have a (14;18) translocation involving the *BCL2* gene that results in overexpression of BCL2 protein. Some of these tumors may represent "transformed" follicular lymphomas. The remaining tumors have other diverse driver mutations, such as translocations involving the *MYC* gene.

MORPHOLOGY

The neoplastic B cells are large (at least three to four times the size of resting lymphocytes) and vary in appearance from tumor to tumor. In many tumors, cells with round or oval nuclear contours, dispersed chromatin, several distinct nucleoli, and modest amounts of pale cytoplasm predominate (Fig. 12.17). In other tumors the cells have a round or multilobate vesicular nucleus, one or two prominent centrally placed nucleoli, and abundant pale or basophilic cytoplasm. Occasionally, the tumor cells are highly anaplastic and include tumor giant cells resembling RS cells, the malignant cells of Hodgkin lymphoma.

Immunophenotype. These tumors express the B cell antigen CD20. Many also express surface IgM and/or IgG. Other antigens (e.g., CD10, BCL2) are variably expressed.

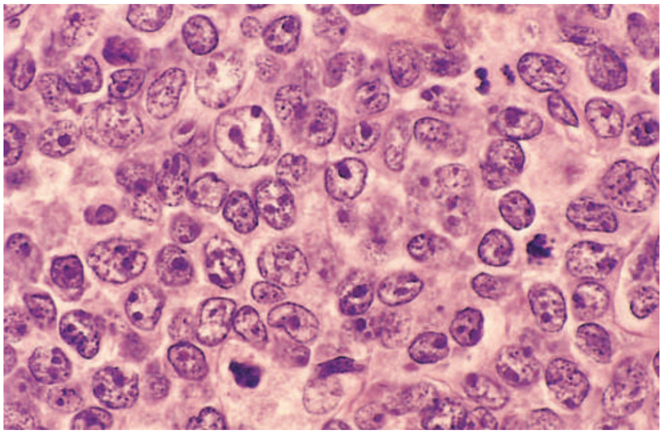

Fig. 12.17 Diffuse large B cell lymphoma—lymph node. The tumor cells have large nuclei with open chromatin and prominent nucleoli. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Special Subtypes. Several distinctive clinicopathologic subtypes are included in the category of diffuse large B cell lymphoma.

- *EBV-associated diffuse large B cell lymphomas* arise in the setting of AIDS, iatrogenic immunosuppression (e.g., in transplant recipients), and the elderly. In the posttransplantation setting, these tumors often begin as EBV-driven polyclonal B cell proliferations that may regress if immune function is restored.
- *Kaposi sarcoma herpesvirus* (KSHV), also called *human herpesvirus type 8* (HHV-8), is associated with rare *primary effusion lymphomas,* which may arise within the pleural cavity, pericardium, or peritoneum. These tumors are latently infected with KSHV, which encodes proteins homologous to several known oncoproteins, including cyclin D1. As with EBV-related lymphomas, most affected patients are immunosuppressed.
- *Mediastinal large B cell lymphoma* occurs most often in young women and shows a predilection for spread to abdominal viscera and the central nervous system.

Clinical Features. Although the median age at presentation is about 60 years, diffuse large B cell lymphoma can occur at any age; it constitutes about 15% of childhood lymphomas. Patients typically present with a rapidly enlarging, often symptomatic mass at one or several sites. Extranodal presentations are common. The gastrointestinal tract is the most common extranodal site, but tumors can appear in virtually any organ or tissue. Unlike the more indolent lymphomas (e.g., follicular lymphoma), involvement of the liver, spleen, and bone marrow is not common at diagnosis.

Without treatment, diffuse large cell B cell lymphomas are aggressive and rapidly fatal. With intensive combination chemotherapy and anti-CD20 immunotherapy, complete remissions are achieved in 60% to 80% of the patients; of these, approximately 50% remain free of disease and appear to be cured. For those not so fortunate, other aggressive treatments (e.g., high-dose chemotherapy and hematopoietic stem cell transplantation) offer some hope.

Burkitt Lymphoma

Burkitt lymphoma is endemic in parts of Africa and occurs sporadically in other geographic areas, including the United States. Histologically, the African and nonendemic diseases are identical, although there are clinical and virologic differences.

Pathogenesis

Burkitt lymphoma is highly associated with translocations involving the *MYC* gene on chromosome 8 that result in overexpression of the MYC transcription factor. As mentioned in Chapter 6, MYC is a master regulator of Warburg metabolism (aerobic glycolysis), a cancer hallmark that is associated with rapid cell growth. In keeping with this association, Burkitt lymphoma is said to be the fastest growing human tumor. Most translocations fuse *MYC* with the IgH gene on chromosome 14, but variant translocations involving the κ or λ light chain loci also are observed. The net result of each is the same—the dysregulation and overexpression of *MYC*. In most endemic cases and about 20% of sporadic cases, the tumor cells are latently infected with EBV, a relationship also discussed in Chapter 6.

MORPHOLOGY

The tumor cells are intermediate in size and typically have round or oval nuclei and two to five distinct nucleoli (Fig. 12.18). There is a moderate amount of basophilic or amphophilic cytoplasm that often contains small, lipid-filled vacuoles (a feature appreciated on smears). Very high rates of proliferation and apoptosis are characteristic, the latter accounting for the presence of numerous tissue macrophages containing ingested nuclear debris. These benign macrophages often are surrounded by a clear space, creating a **"starry sky" pattern.**

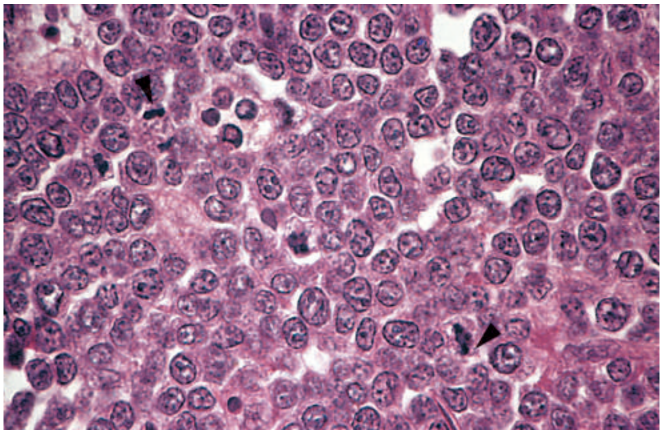

Fig. 12.18 Burkitt lymphoma—lymph node. The tumor cells and their nuclei are fairly uniform, giving a monotonous appearance. Note the high level of mitotic activity *(arrowheads)* and prominent nucleoli. The "starry sky" pattern produced by interspersed, lightly staining, normal macrophages is better appreciated at a lower magnification. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Immunophenotype. These tumors express surface IgM, the B cell marker CD20, and the germinal center B cell markers CD10 and BCL6.

Clinical Features. Both the endemic and nonendemic sporadic forms affect mainly children and young adults. Burkitt lymphoma accounts for approximately 30% of childhood NHLs in the United States. The disease usually arises at extranodal sites. Endemic tumors often manifest as maxillary or mandibular masses, whereas abdominal tumors involving the bowel, retroperitoneum, and ovaries are more common in North America. Leukemic presentations sometimes occur and must be distinguished from ALL, which is treated with different drug regimens. Burkitt lymphoma is highly aggressive; however, with very intensive chemotherapy regimens, a majority of patients can be cured.

Plasma Cell Neoplasms and Related Entities

These B cell proliferations contain neoplastic plasma cells that virtually always secrete a monoclonal immunoglobulin or immunoglobulin fragment, which serve as tumor markers and often have pathologic consequences. Collectively, plasma cell neoplasms and related disorders account for about 15% of the deaths caused by lymphoid neoplasms. The most common and deadly of these neoplasms is multiple myeloma, of which there are about 15,000 new cases per year in the United States.

A monoclonal immunoglobulin identified in the blood is referred to as an *M protein*, in reference to myeloma. Because complete M proteins have molecular weights of 160,000 or higher, they are restricted to the plasma and extracellular fluid and excluded from the urine in the absence of glomerular damage. However, *neoplastic plasma cells often synthesize excess immunoglobulin light chains along with complete immunoglobulins.* In unusual cases, tumors may produce only light chains, which are detected and quantified in the blood and the urine by highly sensitive tests.

Terms used to describe the abnormal immunoglobulins associated with plasma cell neoplasms include *monoclonal gammopathy, dysproteinemia,* and *paraproteinemia*. These abnormal proteins are associated with several clinicopathologic entities:

- *Multiple myeloma (plasma cell myeloma)*, the most important plasma cell neoplasm, usually presents as tumorous masses scattered throughout the skeletal system. *Solitary plasmacytoma* is an infrequent variant that presents as a single mass in bone or soft tissue. *Smoldering myeloma* is another uncommon variant defined by a lack of symptoms and a high plasma M component.
- *Monoclonal gammopathy of undetermined significance (MGUS)* is applied to patients without signs or symptoms who have small to moderately large M components in their blood. MGUS is very common in older adults and has a low but constant rate of transformation to a symptomatic monoclonal gammopathy, most often multiple myeloma.
- *Primary or immunocyte-associated amyloidosis* results from a monoclonal proliferation of plasma cells secreting light chains that are deposited as amyloid. Some

patients have overt multiple myeloma, but others have only a minor clonal population of plasma cells in the marrow.
- *Waldenström macroglobulinemia* is a syndrome in which high levels of IgM lead to symptoms related to hyperviscosity of the blood. It occurs in older adults, most commonly in association with lymphoplasmacytic lymphoma (described later).

With this background, we now turn to some of the specific clinicopathologic entities. Primary amyloidosis was discussed along with other disorders of the immune system in Chapter 5.

Multiple Myeloma

Multiple myeloma is one of the most common lymphoid malignancies; approximately 20,000 new cases are diagnosed in the United States each year. The median age at diagnosis is 70 years, and it is more common in males and in people of African origin. It principally involves the bone marrow and usually is associated with lytic lesions throughout the skeletal system.

The most frequent M protein produced by myeloma cells is IgG (60%), followed by IgA (20%–25%); only rarely are IgM, IgD, or IgE M proteins observed. In the remaining cases, the plasma cells produce only κ or λ light chains. Because free light chains are small in size, they are also excreted in the urine, where they are referred to as *Bence Jones proteins*. In many cases, the malignant plasma cells secrete both complete immunoglobulins and free light chains and thus produce both M proteins and Bence Jones proteins. As described later, the excess light chains have important pathogenic effects.

Pathogenesis

As with most other B cell malignancies, **myeloma often has chromosomal translocations that fuse the IgH locus on chromosome 14 to oncogenes such as the cyclin D1 and cyclin D3 genes.** As might be surmised from this, dysregulation of D cyclins is common in multiple myeloma and is believed to contribute to increases in cell proliferation. Proliferation of myeloma cells also is supported by the cytokine interleukin 6 (IL-6), which is produced by fibroblasts and macrophages in the bone marrow stroma. Late in the course, translocations involving *MYC* are sometimes observed, particularly in patients with aggressive disease.

Multiple myeloma has a number of untoward effects on the skeleton, the immune system, and the kidney, all of which contribute to morbidity and mortality:
- **Factors produced by neoplastic plasma cells mediate bone destruction, the major pathologic feature of multiple myeloma**. Of particular importance, myeloma-derived factors upregulate the expression of the receptor activator of NF-κB ligand (RANKL) by bone marrow stromal cells, which in turn activate osteoclasts. Other factors released from tumor cells are potent inhibitors of osteoblast function. The net effect is increased bone resorption, leading to hypercalcemia and pathologic fractures.
- **Myeloma causes defects in humoral immunity.** Through still-uncertain mechanisms, myeloma cells compromise the function of normal B cells. Ironically, although the plasma has elevated levels of immunoglobulin owing to the presence of an M protein, the production of functional antibodies often is profoundly depressed. As a result, patients are at high risk for bacterial infections.
- **Renal dysfunction** stems from several pathologic effects of myeloma that may occur alone or in combination. Most important are *obstructive proteinaceous casts*, which often form in the distal convoluted tubules and the collecting ducts. The casts consist mostly of Bence Jones proteins along with variable amounts of complete immunoglobulin, Tamm-Horsfall protein, and albumin. *Light chain deposition* in the glomeruli or the interstitium, either as amyloid or linear deposits, also may contribute to renal damage. Completing the assault is *hypercalcemia*, which may lead to dehydration and renal stones, and frequent bouts of *bacterial pyelonephritis*, which stem in part from the hypogammaglobulinemia.

MORPHOLOGY

Multiple myeloma usually manifests with **multifocal destructive skeletal lesions** that most commonly involve the vertebral column, ribs, skull, pelvis, femur, clavicle, and scapula. The lesions arise in the medullary cavity, erode cancellous bone, and progressively destroy the bone cortex. Bone destruction often leads to **pathologic fractures,** most frequently in the vertebral column or femur. The bone lesions usually appear as **punched-out defects** 1 to 4 cm in diameter (Fig. 12.19A). Microscopic examination of the marrow shows increased numbers of plasma cells, which usually constitute greater than 30% of the cellularity. Myeloma cells may resemble normal plasma cells but more often show abnormal features such as prominent nucleoli or abnormal cytoplasmic inclusions containing immunoglobulin (Fig. 12.19B). With disease progression, myeloma cells may spread to the viscera and other soft tissue sites, and in terminal stages a leukemic picture may emerge.

Renal involvement **(myeloma nephrosis)** is associated with proteinaceous casts consisting mostly of Bence Jones proteins that obstruct the distal convoluted tubules and the collecting ducts. Multinucleate giant cells derived from macrophages usually surround the casts. Very often the **epithelial cells adjacent to the casts become necrotic or atrophic** owing to the toxic effects of Bence Jones proteins. Other common pathologic processes involving the kidney include **metastatic calcification**, stemming from bone resorption and hypercalcemia; **light chain (AL) amyloidosis**, involving the renal glomeruli and vessel walls; and **bacterial pyelonephritis,** secondary to the increased susceptibility to bacterial infections. Rarely, infiltrates of neoplastic plasma cells are seen in the renal interstitium.

Clinical Features. Clinical findings stem mainly from (1) the effects of plasma cells on the skeleton; (2) the production of excessive immunoglobulins, which often have abnormal physicochemical properties; and (3) the suppression of humoral immunity.

Bone resorption often leads to *pathologic fractures* and *chronic pain*. The attendant *hypercalcemia* can give rise to neurologic manifestations, such as confusion, weakness, and lethargy, and contributes to renal dysfunction. Decreased

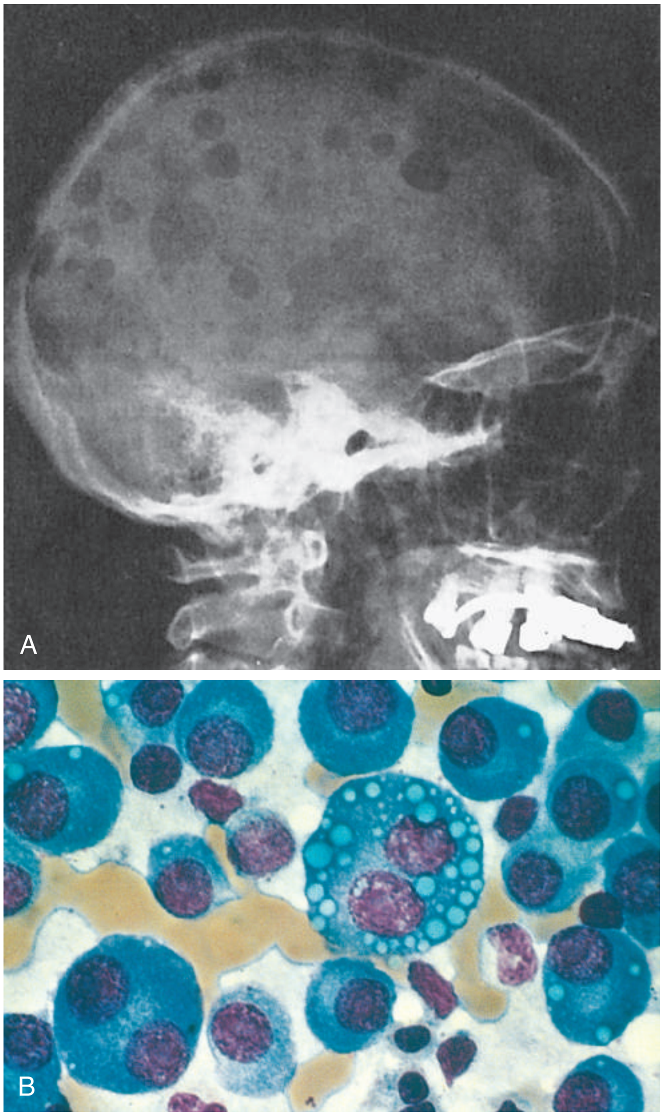

Fig. 12.19 Multiple myeloma. (A) Radiograph of the skull, lateral view. The sharply punched-out bone defects are most obvious in the calvaria. (B) Bone marrow aspirate. Normal marrow cells are largely replaced by plasma cells, including atypical forms with multiple nuclei, prominent nucleoli, and cytoplasmic droplets containing immunoglobulin.

production of normal immunoglobulins sets the stage for *recurrent bacterial infections*. Of great significance is *renal insufficiency*, which trails only infections as a cause of death. Renal failure occurs in up to 50% of patients and is associated strongly with the presence and level of *Bence Jones proteinuria*, highlighting the importance of free light chains in renal disease. Certain light chains also are prone to cause *amyloidosis* of the AL type (Chapter 5), which can exacerbate renal dysfunction and deposit in other tissues as well.

Laboratory analyses typically show increased levels of immunoglobulins in the blood and/or Bence Jones proteins in the urine. Free light chains and an M protein component are observed together in 60% to 70% of cases, whereas in about 20% of patients only free light chains are present. Around 1% of myelomas are nonsecretory; hence, the absence of detectable M component does not completely exclude the diagnosis.

The diagnosis rests on radiologic and laboratory findings. It can be strongly suspected when imaging studies show typical bone lesions, but definitive diagnosis requires a bone marrow examination. Marrow involvement often gives rise to a normocytic normochromic anemia, sometimes accompanied by moderate leukopenia and thrombocytopenia.

The prognosis is variable. Patients with multiple bony lesions, if untreated, rarely survive for more than 6 to 12 months, whereas patients with "smoldering myeloma" may be asymptomatic for many years. The median survival is 4 to 7 years. Although cures have yet to be achieved, new therapies offer hope. Myeloma cells are sensitive to inhibitors of the proteasome, a cellular organelle that degrades unwanted and misfolded proteins. As discussed in Chapter 2, misfolded proteins activate apoptotic pathways, and myeloma cells are prone to the accumulation of misfolded, unpaired immunoglobulin chains. Proteasome inhibitors likely induce myeloma cell death by exacerbating this inherent tendency. The thalidomide-like compound lenalidomide also is effective in treating myeloma, but through a different mechanism that involves its ability to stimulate the degradation of specific proteins with oncogenic activities. Biphosphonates, drugs that inhibit bone resorption, reduce pathologic fractures and limit the hypercalcemia. Hematopoietic stem cell transplantation prolongs life but has not yet proven to be curative.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma is a B cell neoplasm of older adults that usually presents in the sixth or seventh decade of life. Although bearing a superficial resemblance to CLL/SLL, it differs in that a substantial fraction of the tumor cells undergo terminal differentiation to plasma cells. Most commonly, the plasma cell component secretes monoclonal IgM, often in amounts sufficient to cause a hyperviscosity syndrome known as *Waldenström macroglobulinemia*. Unlike multiple myeloma, complications stemming from the secretion of free light chains (e.g., renal failure and amyloidosis) are relatively rare and bone destruction does not occur.

Pathogenesis

Virtually all cases of lymphoplasmacytic lymphoma are associated with acquired mutations in *MYD88*. The *MYD88* gene encodes an adaptor protein that participates in signaling events that activate NF-κB and also augment signals downstream of the BCR (Ig) complex, both of which may promote the growth and survival of the tumor cells.

MORPHOLOGY

Typically, the marrow contains an infiltrate of lymphocytes, plasma cells, and plasmacytoid lymphocytes in varying proportions, often accompanied by mast cell hyperplasia. Some tumors also contain a population of larger lymphoid cells with more vesicular nuclear chromatin and prominent nucleoli. Periodic acid-Schiff-positive inclusions containing immunoglobulin are frequently seen in the

cytoplasm **(Russell bodies)** or the nucleus **(Dutcher bodies)** of some of the plasma cells. At diagnosis the tumor has usually disseminated to the lymph nodes, spleen, and liver. Infiltration of the nerve roots, meninges, and more rarely the brain can also occur with disease progression.

Immunophenotype. The lymphoid component expresses B cell markers such as CD20 and surface immunoglobulin, whereas the plasma cell component secretes the same immunoglobulin that is expressed on the surface of the lymphoid cells. In almost all tumors, the secreted immunoglobulin is an IgM.

Clinical Features. The dominant presenting complaints are nonspecific and include weakness, fatigue, and weight loss. Approximately half the patients have lymphadenopathy, hepatomegaly, and splenomegaly. Anemia caused by marrow infiltration is common. About 10% of patients have *autoimmune hemolysis* caused by *cold agglutinins*, IgM antibodies that bind to red cells at temperatures of less than 37°C.

Patients with IgM-secreting tumors have additional signs and symptoms stemming from the physicochemical properties of IgM. Because of its large size, at high concentrations IgM greatly increases the viscosity of the blood, giving rise to a *hyperviscosity syndrome* characterized by the following:

- *Visual impairment* associated with venous congestion, which is reflected by striking tortuosity and distention of retinal veins; retinal hemorrhages and exudates may also contribute to problems with vision
- *Neurologic problems* such as headaches, dizziness, deafness, and stupor, all stemming from sluggish venous blood flow
- *Bleeding* related to the formation of complexes between macroglobulins and clotting factors as well as interference with platelet function
- *Cryoglobulinemia* resulting from the precipitation of macroglobulins at low temperatures, which produces symptoms such as Raynaud phenomenon and cold urticaria

Lymphoplasmacytic lymphoma is an incurable progressive disease. Because most IgM is intravascular, symptoms caused by the high IgM levels (e.g., hyperviscosity and hemolysis) can be alleviated temporarily by plasmapheresis. Tumor growth can be controlled with low doses of chemotherapeutic drugs and immunotherapy with anti-CD20 antibody, and recent work has shown that BTK inhibitors are also effective. Transformation to large-cell lymphoma occurs but is uncommon. Median survival is about 4 years.

Hodgkin Lymphoma

Hodgkin lymphoma encompasses a distinctive group of neoplasms that are characterized by the presence of *a tumor giant cell, the RS cell.* Unlike most NHLs, Hodgkin lymphomas arise in a single lymph node or chain of lymph nodes and typically spread in a stepwise fashion to anatomically contiguous nodes. Although the Hodgkin lymphomas are now understood to be unusual tumors of B cell origin, they are distinguished from the NHLs by their unusual pathologic and clinical features.

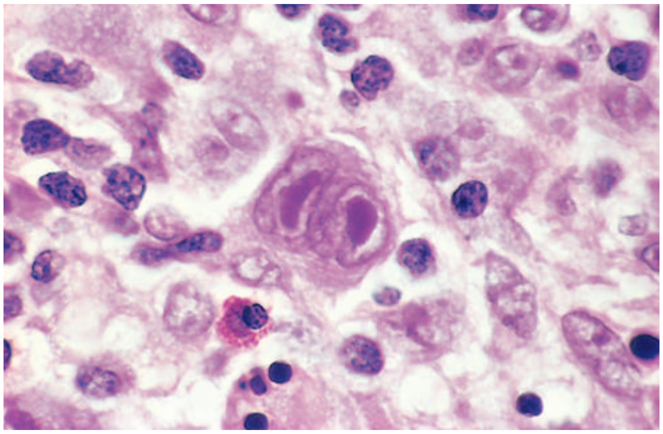

Fig. 12.20 Hodgkin lymphoma—lymph node. A binucleate Reed-Sternberg cell with large, inclusion-like nucleoli and abundant cytoplasm is surrounded by lymphocytes, macrophages, and an eosinophil. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Classification. Five subtypes of Hodgkin lymphoma are recognized: (1) nodular sclerosis, (2) mixed cellularity, (3) lymphocyte rich, (4) lymphocyte depletion, and (5) lymphocyte predominant. In the first four subtypes the RS cells share certain morphologic and immunophenotypic features (described later), leading some researchers to lump together these entities under the rubric *classical Hodgkin lymphoma*. The lymphocyte predominant type is set apart by the expression of germinal center B cell markers by the RS cells. This subtype and the two most common forms of classical Hodgkin lymphoma, the nodular sclerosis and mixed-cellularity types, are discussed next.

MORPHOLOGY

The sine qua non of Hodgkin lymphoma is the **Reed-Sternberg (RS) cell** (Fig. 12.20), a very large cell (15 to 45 μm in diameter) with an enormous multilobate nucleus, exceptionally prominent nucleoli, and abundant, usually slightly eosinophilic, cytoplasm. Particularly characteristic are cells with **two mirror-image nuclei or nuclear lobes, each containing a large (inclusion-like) acidophilic nucleolus surrounded by a clear zone**, features that impart an owl-eye appearance. Typical RS cells and variants have a characteristic immunophenotype, as they express CD15 and CD30 and fail to express CD45 (leukocyte common antigen), B cell antigens, and T cell antigens. As we shall see, "classic" RS cells are common in the mixed-cellularity subtype, uncommon in the nodular sclerosis subtype, and rare in the lymphocyte-predominance subtype; in these latter two subtypes, other characteristic RS cell variants predominate.

Nodular sclerosis Hodgkin lymphoma is the most common form. It is equally frequent in men and in women and has a striking propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes. Most patients are

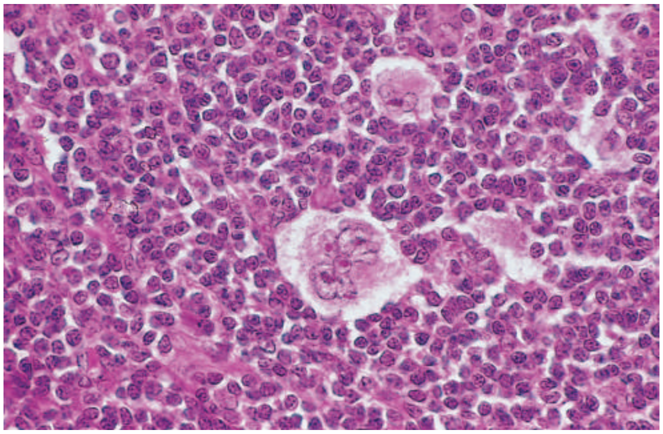

Fig. 12.21 Hodgkin lymphoma, nodular sclerosis type—lymph node. A distinctive "lacunar cell" with a multilobed nucleus containing many small nucleoli is seen lying within a clear space created by retraction of its cytoplasm. It is surrounded by lymphocytes. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

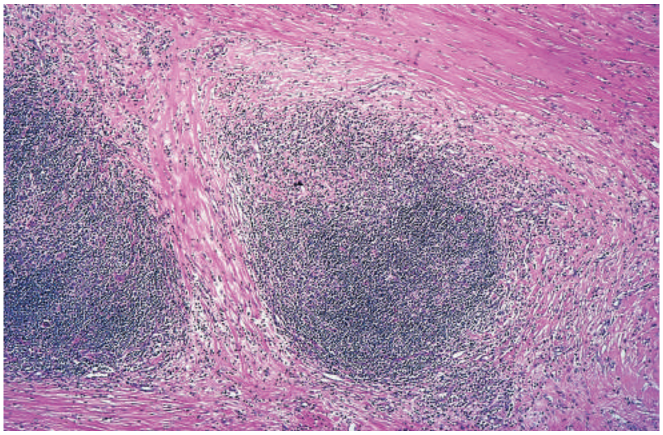

Fig. 12.22 Hodgkin lymphoma, nodular sclerosis type—lymph node. A low-power view shows well-defined bands of pink, acellular collagen that have subdivided the tumor cells into nodules. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

adolescents or young adults, and the overall prognosis is excellent. It is characterized morphologically by the following:

- **Lacunar cells** (Fig. 12.21), a particular RS cell variant that has a single multilobate nucleus, multiple small nucleoli, and abundant, pale-staining cytoplasm. In sections of formalin-fixed tissue, the cytoplasm often is torn away, leaving the nucleus lying in an empty space (a lacune). The immunophenotype of lacunar variants is identical to that of other RS cells found in classical subtypes.
- **Collagen bands**, which divide the involved lymphoid tissue into circumscribed nodules (Fig. 12.22). The fibrosis may be scant or abundant and the cellular infiltrate contains varying proportions of lymphocytes, eosinophils, histiocytes, and lacunar cells.

Mixed-cellularity Hodgkin lymphoma is the most common form of Hodgkin lymphoma in patients older than 50 years of age and comprises about 25% of cases overall. There is a male predominance. **Classic RS cells are plentiful** within a heterogeneous inflammatory infiltrate containing small lymphocytes, eosinophils, plasma cells, and macrophages (Fig. 12.23). This subtype is more likely to be disseminated and to be associated with systemic manifestations than the nodular sclerosis subtype.

Lymphocyte-predominant Hodgkin lymphoma, accounting for about 5% of cases, is characterized by the presence of **lymphohistiocytic (L&H) variant RS cells** that have a delicate multilobed, puffy nucleus resembling popped corn ("popcorn cell"). L&H variants usually are found within large nodules containing mainly small B cells admixed with variable numbers of macrophages (Fig. 12.24). Other reactive cells, such as eosinophils, are scanty or absent, and typical RS cells are rare. Unlike the RS variants in "classical" Hodgkin lymphoma, L&H variants express B cell markers (e.g., CD20) and usually fail to express CD15 and CD30. Most patients present with isolated cervical or axillary lymphadenopathy, and the prognosis typically is excellent.

It is apparent that Hodgkin lymphoma spans a wide range of histologic patterns that often simulate a reactive inflammatory

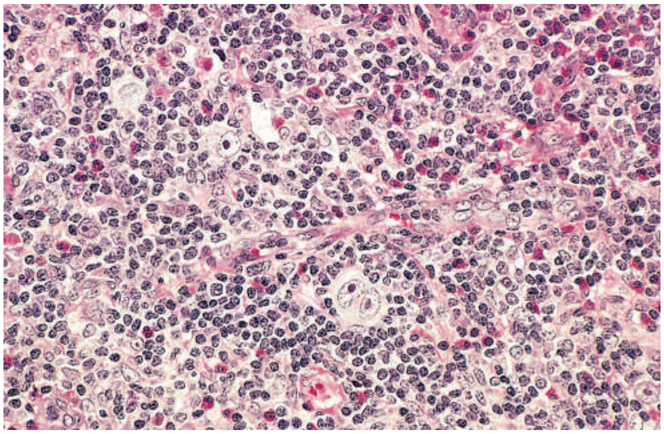

Fig. 12.23 Hodgkin lymphoma, mixed-cellularity type—lymph node. A diagnostic, binucleate Reed-Sternberg cell is surrounded by eosinophils, lymphocytes, and histiocytes. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

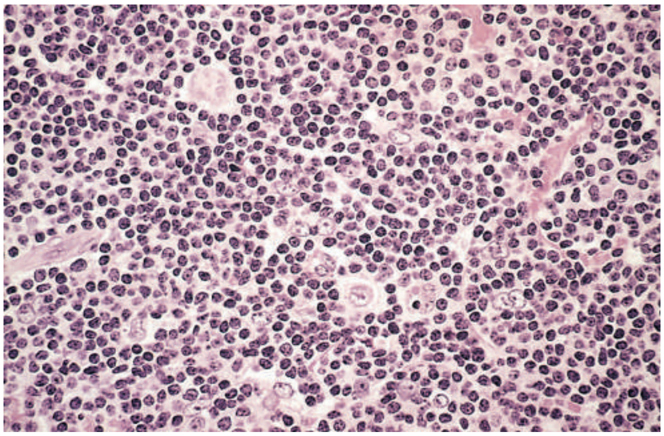

Fig. 12.24 Hodgkin lymphoma, nodular lymphocyte-predominant type—lymph node. Numerous mature-looking lymphocytes surround scattered, large, pale-staining lymphocytic and histiocytic variants ("popcorn" cells). *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

process. Regardless of subtype, **the diagnosis rests on the definitive identification of RS cells or variants in the appropriate background of reactive cells.** Immunophenotyping plays an important role in distinguishing Hodgkin lymphoma from reactive conditions and other forms of lymphoma. In all subtypes, involvement of the spleen, liver, bone marrow, and other organs may appear in due course and takes the form of irregular nodules composed of a mixture of RS cells and reactive cells, similar to what is observed in lymph nodes.

Pathogenesis

The origin of RS cells remained mysterious through most of the 20th century, but was finally solved by elegant studies performed on single microdissected RS cells. These showed that every RS cell from any given case possesses the same immunoglobulin gene rearrangements and that these rearranged immunoglobulin genes have undergone somatic hypermutation. As a result, it is now agreed that **Hodgkin lymphoma is a neoplasm that arises from germinal center B cells**.

Another clue into the etiology of Hodgkin lymphoma stems from the frequent involvement of EBV. EBV is present in the RS cells in as many as 70% of cases of the mixed-cellularity subtype and a smaller fraction of other "classical" forms of Hodgkin lymphoma. The structure of the EBV genome is identical in all RS cells in a given case, indicating that infection precedes (and therefore may be related to) transformation and clonal expansion. Thus, EBV infection probably is one of several steps contributing to tumor development, particularly of the mixed-cellularity subtype.

The characteristic nonneoplastic, inflammatory cell infiltrate is generated by a number of cytokines. Some of these are secreted by RS cells, including IL-5, a chemoattractant for eosinophils; transforming growth factor-β, a fibrogenic factor; and IL-13, which may stimulate RS cell growth through an autocrine mechanism. Conversely, the responding inflammatory cells, rather than being innocent bystanders, produce additional factors that aid the growth and survival of RS cells and contribute further to the tissue reaction.

Hodgkin lymphoma is a cardinal example of a tumor that escapes from the host immune response by expressing proteins that inhibit T cell function. The RS cells of classical Hodgkin lymphoma express high levels of PD ligands, factors that antagonize T cell responses. In many tumors the region on chromosome 9 containing the genes encoding the two PD ligands, PD-L1 and PD-L2, is amplified, an alteration that appears to contribute to their overexpression. The importance of PD ligand expression has been proven in clinical trials of antibodies that block PD-1, which is the T cell receptor for PD ligands (Chapter 6). Most tumors, even those that are resistant to all other therapies, are responsive to PD-1 antibodies, presumably because of the reactivation of a latent host response that was stifled by the PD ligand/PD-1 signaling axis.

Clinical Features. Hodgkin lymphoma, like NHL, usually manifests as painless lymphadenopathy. Although a definitive distinction from NHL can be made only by examination of a tissue biopsy, several clinical features favor the diagnosis of Hodgkin lymphoma (Table 12.9). After the diagnosis is established, staging is used to guide therapy and determine prognosis (Table 12.10). Younger patients with more favorable subtypes tend to present with stage I or stage II disease and usually are free of so-called "B symptoms" (fever, weight loss, night sweats). Patients with advanced disease (stages III and IV) are more likely to exhibit B symptoms as well as pruritus and anemia. Because of the long-term complications of radiotherapy, even patients with stage I disease are now treated with systemic chemotherapy. More advanced disease is generally also treated with chemotherapy, sometimes together with involved field radiotherapy.

The outlook, even for those with advanced disease, is very good. The 5-year survival rate for patients with stage I-A or II-A disease is more than 90%. Even with advanced disease (stage IV-A or IV-B), the overall 5-year disease-free survival rate is around 50%. Among long-term survivors treated with radiotherapy, a higher risk of certain malignancies, including lung cancer and breast cancer, as well as cardiovascular disease, has been reported. These sobering results have spurred development of new regimens that minimize the use of radiotherapy and use less toxic chemotherapy. As already mentioned, anti-PD-1 antibodies have produced excellent responses in patients with relapsed,

Table 12.9 Clinical Differences Between Hodgkin and Non-Hodgkin Lymphomas

Hodgkin Lymphoma	Non-Hodgkin Lymphoma
More often localized to a single axial group of nodes (cervical, mediastinal, paraaortic)	More frequent involvement of multiple peripheral nodes
Orderly spread by contiguity	Noncontiguous spread
Mesenteric nodes and Waldeyer ring rarely involved	Mesenteric nodes and Waldeyer ring commonly involved
Extranodal involvement uncommon	Extranodal involvement common

Table 12.10 Clinical Staging of Hodgkin and Non-Hodgkin Lymphomas (Ann Arbor Classification)[a]

Stage	Distribution of Disease
I	Involvement of a single lymph node region (I) or involvement of a single extralymphatic organ or tissue (I_E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or with involvement of limited contiguous extralymphatic organs or tissue (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (III_S), limited contiguous extralymphatic organ or site (III_E), or both (III_{ES})
IV	Multiple or disseminated foci of involvement of one or more extralymphatic organs or tissues with or without lymphatic involvement

[a]All stages are further divided based on the absence (A) or presence (B) of the following systemic symptoms and signs: significant fever, night sweats, unexplained loss of more than 10% of normal body weight.
From Carbone PT, et al: Symposium (Ann Arbor): staging in Hodgkin disease. *Cancer Res* 31:1707, 1971.

refractory disease and represent a promising immune-based therapy.

Miscellaneous Lymphoid Neoplasms

Among the many other forms of lymphoid neoplasia in the WHO classification, several with distinctive or clinically important features merit brief discussion.

Hairy Cell Leukemia. Hairy cell leukemia is an uncommon, indolent B cell neoplasm characterized by the presence of fine, hairlike cytoplasmic projections. The tumor cells express B cell markers (CD20), surface immunoglobulin, and CD11c and CD103; the latter two antigens are not present on most other B cell tumors, making them diagnostically useful. Virtually all cases are associated with activating mutations in the serine/threonine kinase BRAF, which is also mutated in diverse other cancers (Chapter 6).

Hairy cell leukemia occurs mainly in older males, and its manifestations result from infiltration of bone marrow and spleen. *Splenomegaly,* often massive, is the most common and sometimes only physical finding. *Pancytopenia,* resulting from marrow infiltration and splenic sequestration, is seen in more than half of cases. Lymph node involvement is rare. Leukocytosis is uncommon, being present only in 15% to 20% of patients, but scattered "hairy cells" can be identified in the peripheral blood smear in most cases. The disease is indolent but progressive if untreated; pancytopenia and infections are the major clinical problems. Unlike most other indolent lymphoid neoplasms, hairy cell leukemia is extremely sensitive to chemotherapeutic agents, particularly purine nucleosides. Complete durable responses are the rule and the overall prognosis is excellent. Tumors that fail conventional therapy have excellent responses to BRAF inhibitors, which ultimately may become the treatment of choice.

Mycosis Fungoides and Sézary Syndrome. These tumors of neoplastic CD4+ T cells home to the skin; as a result, they often are referred to as cutaneous T cell lymphoma. Mycosis fungoides usually manifests as a nonspecific erythrodermic rash that progresses with time to a plaque phase and then to a tumor phase. Histologically, neoplastic T cells, often with a cerebriform appearance produced by marked infolding of the nuclear membranes, infiltrate the epidermis and upper dermis. With disease progression, both nodal and visceral dissemination appear. Sézary syndrome is a clinical variant characterized by (1) a generalized exfoliative erythroderma and (2) tumor cells (Sézary cells) in the peripheral blood. Circulating tumor cells also are present in as many as 25% of cases of plaque- or tumor-phase mycosis fungoides. Patients diagnosed with early-phase mycosis fungoides often survive for many years, whereas patients with tumor-phase disease, visceral disease, or Sézary syndrome survive on average for 1 to 3 years.

Adult T Cell Leukemia/Lymphoma. **This neoplasm of CD4+ T cells is caused by a retrovirus, human T cell leukemia virus type 1 (HTLV-1).** HTLV-1 infection is endemic in southern Japan, the Caribbean basin, and West Africa, and occurs sporadically elsewhere, including in the southeastern United States. The pathogenesis of this tumor is discussed in Chapter 6. In addition to lymphoid malignancies, HTLV-1 infection also can cause tropical spastic paraparesis, a progressive demyelinating disease affecting the central nervous system and the spinal cord.

Adult T cell leukemia/lymphoma commonly is associated with skin lesions, lymphadenopathy, hepatosplenomegaly, hypercalcemia, and variable lymphocytosis. In addition to CD4, the leukemic cells express high levels of CD25, the IL-2 receptor α chain. In most cases the tumor is very aggressive and responds poorly to treatment. The median survival time is about 8 months.

Peripheral T Cell Lymphoma. This heterogeneous group of tumors makes up about 10% of adult NHLs. Although several rare distinctive subtypes fall under this heading, most tumors in this group are unclassifiable. In general, these are aggressive tumors that respond poorly to therapy. Moreover, because these are tumors of functional T cells, patients often suffer from symptoms related to tumor-derived inflammatory products, even when the tumor burden is relatively low.

Before ending our review of lymphoid neoplasms, it is worthwhile pausing to summarize the manner in which common driver mutations in specific entities produce changes in cellular behavior that exemplify particular hallmarks of cancer (Fig. 12.25). Such alterations not only highlight important pathogenic principles, but are increasingly the targets of effective therapies, such as antibodies that block PD-1 (Hodgkin lymphoma) and drugs that antagonize BCL2 (follicular lymphoma and other B cell tumors).

SUMMARY

LYMPHOID NEOPLASMS

- Classification is based on cell of origin and stage of differentiation
- Most common types in children are ALLs/lymphoblastic lymphomas derived from precursor B and T cells
- Most common types in adults are non-Hodgkin lymphomas derived from germinal center B cells

Acute Lymphoblastic Leukemia/Lymphoma

- Highly aggressive tumors that manifest with signs and symptoms of bone marrow failure, or as rapidly growing masses
- Tumor cells contain genetic lesions that block differentiation, leading to the accumulation of immature, nonfunctional blasts

Small Lymphocytic Lymphoma/Chronic Lymphocytic Leukemia

- Mature B cell tumor that usually manifests with bone marrow and lymph node involvement
- Indolent course, commonly associated with immune abnormalities, including an increased susceptibility to infection and autoimmune disorders

Follicular Lymphoma

- Tumor cells recapitulate the growth pattern of normal germinal center B cells; most cases are associated with a (14;18) translocation that results in the overexpression of BCL2

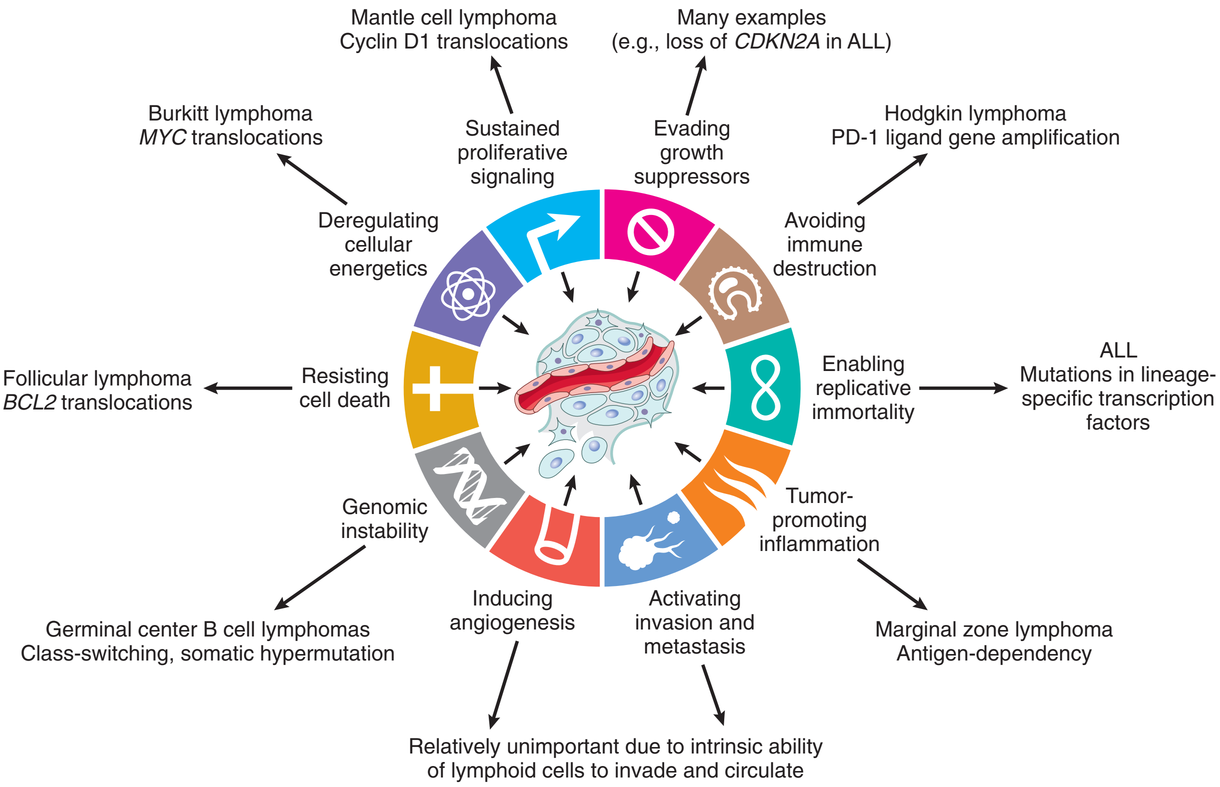

Fig. 12.25 Cancer hallmarks exemplified by particular lymphoid neoplasms. Some of the best characterized pathogenic mechanisms in lymphoid malignancies are summarized here, including dysregulation of MYC in Burkitt lymphoma (leading to Warburg metabolisms and rapid cell growth); dysregulation of BCL2 in follicular lymphoma (leading to resistance to apoptosis); PD-1 ligand gene amplification in Hodgkin lymphoma (leading to evasion of host immunity); events leading to loss of cell cycle control (cyclin D1 rearrangements in mantle cell lymphoma and loss of the *CDKN2A* gene in acute lymphoblastic leukemia [ALL]); mutations in various transcription factors, particularly in ALL, that block differentiation and enhance "leukemia stem cell" self-renewal; and chronic immune stimulation, in marginal zone lymphoma. By contrast, because lymphoid cells normally circulate throughout the body, there is relatively little selective pressure in lymphoid malignancies for aberrations that increase angiogenesis or activate invasion and metastasis.

Mantle Cell Lymphoma

- Mature B cell tumor that usually manifests with advanced disease involving lymph nodes, bone marrow, and extranodal sites such as the gut
- Associated with an (11;14) translocation that results in overexpression of cyclin D1, a regulator of cell cycle progression

Extranodal Marginal Zone Lymphoma

- Mature B cell tumor arising at extranodal sites involved by chronic inflammation resulting from autoimmunity or infection (e.g., *H. pylori*)
- Remains localized for long periods and may regress if the inflammatory stimulus is removed

Diffuse Large B Cell Lymphoma

- Heterogeneous group of mature B cell tumors that shares large cell morphology and aggressive clinical behavior and is the most common type of lymphoma
- Rearrangements or mutations of *BCL6* gene are recognized associations; one-third carry a (14;18) translocation involving *BCL2*

Burkitt Lymphoma

- Very aggressive mature B tumor that usually arises at extranodal sites
- Nearly always associated with translocations involving the *MYC* protooncogene
- Tumor cells often are latently infected by EBV

Multiple Myeloma

- Plasma cell tumor often manifesting with multiple lytic bone lesions associated with pathologic fractures and hypercalcemia
- Neoplastic plasma cells suppress normal humoral immunity and secrete partial immunoglobulins that are nephrotoxic (Bence Jones proteins)

Hodgkin Lymphoma

- Unusual B cell tumor consisting mostly of reactive lymphocytes, macrophages, and stromal cells
- Malignant RS cells make up a minor part of the tumor mass.

Myeloid Neoplasms

Myeloid neoplasms arise from hematopoietic progenitors and typically give rise to proliferations that involve the bone marrow and replace normal marrow elements. There are three broad categories of myeloid neoplasia:

- In *acute myeloid leukemia (AML)*, the neoplastic cells are blocked at an early stage of myeloid cell development. Immature myeloid cells (blasts) accumulate in the

marrow and replace normal elements, and frequently circulate in the peripheral blood.
- In *myeloproliferative neoplasms,* the neoplastic clone continues to undergo terminal differentiation but exhibits increased or dysregulated growth. Commonly, these are associated with an increase in one or more of the formed elements (red cells, platelets, and/or granulocytes) in the peripheral blood.
- In *myelodysplastic syndromes (MDS),* terminal differentiation occurs but in a disordered and ineffective fashion, leading to the appearance of dysplastic marrow precursors and peripheral blood cytopenias.

Although these three categories provide a useful starting point, the divisions between the myeloid neoplasms sometimes blur. Both MDS and myeloproliferative neoplasms often transform to AML, and some neoplasms have features of both myelodysplasia and myeloproliferative neoplasms. Because all myeloid neoplasms arise from early multipotent progenitors, the close relationship among these disorders is not surprising.

It also is now recognized that AML and MDS often arise from an asymptomatic precursor referred to as clonal hematopoieis of indeterminant prognosis (CHIP) CHIP is characterized by normal blood counts despite the presence of one of more clonal acquired "driver" mutations in myeloid cells in the blood and the marrow. CHIP progresses to an overt white cell neoplasm at a frequency of about 1% per year and appears to be an important risk factor for cardiovascular disease (Chapter 10).

Acute Myeloid Leukemia

AML primarily affects older adults; the median age is 50 years. It is very heterogeneous, as discussed later. The clinical signs and symptoms closely resemble those produced by ALL and usually are related to the replacement of normal marrow elements by leukemic blasts. Fatigue, pallor, abnormal bleeding, and infections are common in newly diagnosed patients, who typically present within a few weeks of the onset of symptoms. Splenomegaly and lymphadenopathy generally are less prominent than in ALL, but on rare occasions AML mimics a lymphoma by manifesting as a discrete tissue mass (a so-called "granulocytic sarcoma"). The diagnosis and classification of AML are based on morphologic, histochemical, immunophenotypic, and karyotypic findings. Of these, the karyotype is most predictive of outcome.

Pathogenesis

Most AMLs harbor mutations in genes encoding transcription factors that are required for normal myeloid cell differentiation. These mutations interfere with the differentiation of early myeloid cells, leading to the accumulation of myeloid precursors (blasts) in the marrow. Of particular interest is the (15;17) translocation in acute promyelocytic leukemia, which results in the fusion of the retinoic acid receptor α *(RARA)* gene on chromosome 17 and the *PML* gene on chromosome 15. The chimeric gene produces a PML/RARA fusion protein that blocks myeloid differentiation at the promyelocytic stage, probably in part by inhibiting the function of normal retinoic acid receptors. Remarkably, pharmacologic doses of all-*trans* retinoic acid (ATRA), an analogue of vitamin A (Chapter 7), overcome this block and induce the neoplastic promyelocytes to differentiate into neutrophils rapidly. Because neutrophils die after an average life span of 6 hours, ATRA treatment rapidly clears the tumor. The effect is very specific; AMLs without translocations involving *RARA* do not respond to ATRA. More recently, it has been noted that the combination of ATRA and arsenic trioxide, a salt that induces the degradation of the PML/RARA fusion protein, is even more effective than ATRA alone, producing cures in more than 80% of patients. This is an important example of a highly effective therapy targeted at a tumor-specific molecular defect.

Other work using mice has shown that the mutations in transcription factors found in AML are not sufficient to cause the disease. Putative collaborating mutations in several other tyrosine kinase genes and in the *RAS* gene have been detected.

Sequencing of the AML genomes also has identified frequent mutations in genes that directly impact the epigenome, suggesting that epigenetic alterations have a central role in AML. For example, about 15% to 20% of AMLs are associated with mutations in isocitrate dehydrogenase (IDH). In such tumors, an "oncometabolite" synthesized by the mutated IDH protein blocks the function of enzymes that regulate the epigenome and interferes with myeloid cell differentiation (discussed in Chapter 6). Inhibitors of mutant IDH prevent the production of the oncometabolite and often produce remissions in this particular molecular subtype of AML.

MORPHOLOGY

By definition, in AML myeloid blasts or promyelocytes make up more than 20% of the bone marrow cellularity. **Myeloblasts** (precursors of granulocytes) have delicate nuclear chromatin, three to five nucleoli, and fine azurophilic cytoplasmic granules (Fig. 12.26). **Auer rods,** distinctive red-staining rodlike structures, may be present in myeloblasts or more differentiated cells; they are particularly numerous in acute promyelocytic leukemia (Fig. 12.27). Auer rods are specific for neoplastic myeloblasts and thus are a helpful diagnostic clue when present. In other subtypes of AML, monoblasts, erythroblasts, or megakaryoblasts predominate.

Classification. AMLs are diverse in terms of genetics, cellular lineage, and degree of maturation. The WHO classification relies on all of these features to divide AML into four categories (Table 12.11): (1) AMLs associated with specific genetic aberrations, which are important because they predict outcome and they guide therapy; (2) AMLs with dysplasia, many of which arise from MDSs; (3) AMLs occurring after genotoxic chemotherapy; and (4) AMLs lacking any of the foregoing features. AMLs in the last category are subclassified based on the predominant line of differentiation that the tumor exhibits.

Immunophenotype. The expression of immunologic markers is heterogeneous in AML. Most tumors express some combination of myeloid-associated antigens, such as CD13, CD14, CD15, CD64, or CD117 (KIT). CD34, a marker of hematopoietic stem cells, is often present on myeloblasts. Such markers are helpful in distinguishing AML

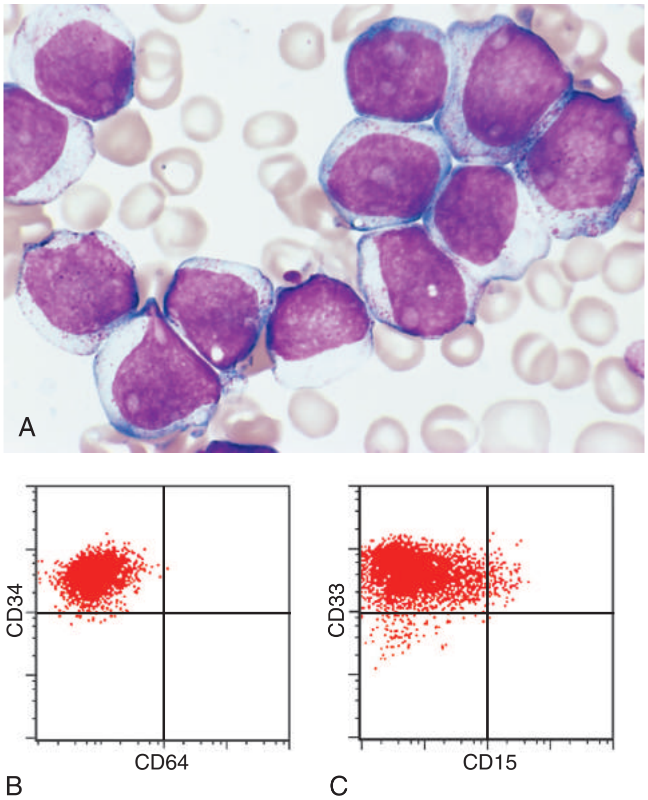

Fig. 12.26 Acute myeloid leukemia (AML). (A) Myeloblasts with delicate nuclear chromatin, prominent nucleoli, and fine azurophilic cytoplasmic granules. (B) and (C) show flow cytometry results for the AML shown in (A). The tumor cells are positive for the stem cell marker CD34 and the myeloid lineage specific markers CD33 and CD15 (subset). *(A, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.* B and C, *Courtesy of Dr. Louis Picker, Oregon Health Science Center, Portland, Oregon.)*

from ALL and in identifying AMLs with only minimal differentiation.

Clinical Features. Most patients present within weeks or a few months of the onset of symptoms with complaints related to anemia, neutropenia, and thrombocytopenia, most notably fatigue, fever, and spontaneous mucosal and cutaneous bleeding. As mentioned earlier, these findings are very similar to those produced by ALL. Thrombocytopenia results in a bleeding diathesis. Cutaneous petechiae and ecchymoses, serosal hemorrhages into the linings of the body cavities and viscera, and mucosal hemorrhages into the gingivae and urinary tract are common. Procoagulants and fibrinolytic factors released by leukemic cells, especially in AML with the t(15;17), exacerbate the bleeding tendency. Infections are frequent and are often caused by opportunists such as fungi, *Pseudomonas,* and commensals. Signs and symptoms related to the involvement of soft tissues are usually less striking in AML than in ALL, but tumors with monocytic differentiation often infiltrate the skin (leukemia cutis) and the gingiva. Central nervous system spread occurs but also is less common than in ALL.

AML remains a devastating disease. Tumors with "good-risk" karyotypic abnormalities (t[8;21], inv[16]) are associated with a 50% chance of long-term disease-free

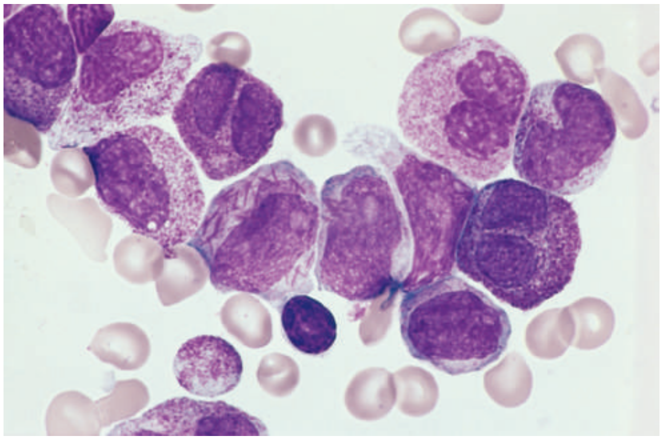

Fig. 12.27 Acute promyelocytic leukemia—bone marrow aspirate. The neoplastic promyelocytes have abnormally coarse and numerous azurophilic granules. Other characteristic findings include a cell in the center of the field with multiple needlelike Auer rods. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

survival, but the overall survival in all patients is only 15% to 30% with conventional chemotherapy. AML associated with *TP53* mutations has emerged as a subtype with a particularly poor prognosis. A bright spot is the improvement in outcomes in acute promyelocytic leukemia brought about by targeted treatment with ATRA and arsenic salts. IDH inhibitors also have produced encouraging results, apparently (like ATRA) by inducing the differentiation of AML blasts. An increasing number of patients with AML are being treated with more aggressive approaches, such as allogeneic hematopoietic stem cell transplantation, which can be curative in some patients.

Myelodysplastic Syndromes

The term *myelodysplastic syndrome* (MDS) refers to a group of clonal stem cell disorders characterized by

Table 12.11 WHO Classification of AML

Class	Prognosis
I. AML With Recurrent Chromosomal Translocations	
AML with t(8;21)(q22;q22); *RUNXT1/RUNX1* fusion gene	Favorable
AML with inv(16)(p13;q22); *CBFB/MYH11* fusion gene	Favorable
AML with t(15;17)(q22;q21.1); *PML/RARA* fusion gene	Favorable
AML with t(11q23;variant); *MLL* fusion genes	Poor
AML with mutated *NPM1*	Variable
II. AML With Multilineage Dysplasia	
With previous MDS	Very poor
Without previous MDS	Poor
III. AML, Therapy-Related	
Alkylating agent–related	Very poor
Epipodophyllotoxin-related	Very poor
IV. AML, Not Otherwise Classified	
Subclasses defined by extent and type of differentiation (e.g., myelocytic, monocytic)	Intermediate

AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome; *NPM1,* nucleophosmin 1; *WHO,* World Health Organization.

maturation defects that are associated with ineffective hematopoiesis and a high risk of transformation to AML. In MDSs, the bone marrow is partly or wholly replaced by the clonal progeny of a transformed multipotent stem cell that retains the capacity to differentiate into red cells, granulocytes, and platelets, but in a manner that is both ineffective and disordered. As a result, the marrow usually is hypercellular or normocellular, but the peripheral blood shows one or more cytopenias. The abnormal stem cell clone in the bone marrow is genetically unstable and prone to the acquisition of additional mutations and the eventual transformation to AML. Most cases are idiopathic, but some develop after chemotherapy with alkylating agents or exposure to ionizing radiation therapy.

Pathogenesis

Important new insights have come from deep sequencing of MDS genomes, which has identified a number of recurrently mutated genes. These genes can be lumped into three major functional categories, as follows:

- *Epigenetic factors*. Frequent mutations are seen involving many of the same epigenetic factors that are mutated in AML, including factors that regulate DNA methylation and histone modifications; thus, like AML, dysregulation of the epigenome appears to be important in the genesis of MDS.
- *RNA splicing factors*. A subset of tumors has mutations involving the RNA splicing machinery that are proposed to drive transformation by altering RNA processing, They are commonly associated with *ring sideroblasts,* a classic form of dysplasia that is seen in a subset of MDS.
- *Transcription factors*. These mutations affect transcription factors that are required for normal myelopoiesis and may contribute to the deranged differentiation that characterizes MDS.

In addition, roughly 10% of MDS cases have loss-of-function mutations in the tumor suppressor gene *TP53,* which correlate with the presence of a complex karyotype and particularly poor clinical outcomes. Both primary MDS and therapy-related MDS are associated with similar *recurrent chromosomal abnormalities, including monosomies 5 and 7, deletions of 5q, 7q, and 20q, and trisomy 8.*

MORPHOLOGY

In MDS, the marrow is populated by abnormal-appearing hematopoietic precursors. Some of the more common abnormalities include **megaloblastoid erythroid precursors** resembling those seen in the megaloblastic anemias, erythroid forms with iron deposits within their mitochondria **(ring sideroblasts)**, granulocyte precursors with **abnormal granules** or nuclear maturation, and small megakaryocytes with single small nuclei or multiple separate nuclei.

Clinical Features. MDS often is described as rare, but actually is about as common as AML, affecting up to 15,000 patients per year in the United States. Most patients present between the ages of 50 and 70. As a result of cytopenias, many suffer from infections, symptoms related to anemia, and hemorrhages. The response to conventional chemotherapy usually is poor, perhaps because MDS arises in a background of stem cell damage. Transformation to AML occurs in 10% to 40% of patients. The prognosis is variable; the median survival time ranges from 9 to 29 months and is worse in cases associated with increased marrow blasts, cytogenetic abnormalities, or *TP53* mutations.

Myeloproliferative Neoplasms

The common pathogenic feature of myeloproliferative neoplasms is the presence of mutated, constitutively activated tyrosine kinases or other acquired aberrations in signaling pathways that lead to growth factor independence. This insight provides a satisfying explanation for the observed overproduction of blood cells and is important therapeutically because of the availability of tyrosine kinase inhibitors. The neoplastic progenitors tend to seed secondary hematopoietic organs (the spleen, liver, and lymph nodes), resulting in hepatosplenomegaly (caused by neoplastic extramedullary hematopoiesis).

Four major diagnostic entities are recognized: chronic myeloid leukemia (CML), polycythemia vera, primary myelofibrosis, and essential thrombocythemia. Their distinctive features are listed below:

- CML is separated from the others by its association with a characteristic abnormality, the BCR-ABL fusion gene, which produces a constitutively active BCR-ABL tyrosine kinase.
- The most common genetic abnormalities in the "BCR-ABL–negative" myeloproliferative neoplasms are activating mutations in the tyrosine kinase JAK2, which occur in virtually all cases of polycythemia vera and about 50% of cases of primary myelofibrosis and essential thrombocythemia
- Some rare myeloproliferative neoplasms are associated with activating mutations in other tyrosine kinases, such as platelet-derived growth factor receptor-α and platelet-derived growth factor receptor-β.

In addition, all myeloproliferative neoplasms have variable propensities to transform to a "spent phase" resembling primary myelofibrosis or to a "blast crisis" identical to acute leukemia, both presumably triggered by the acquisition of other somatic mutations. Only CML, polycythemia vera, and primary myelofibrosis are presented here, as other myeloproliferative neoplasms are too infrequent to merit discussion.

Chronic Myeloid Leukemia

CML principally affects adults between 25 and 60 years of age. The peak incidence is in the fourth and fifth decades of life. About 4500 new cases are diagnosed per year in the United States.

Pathogenesis

CML is distinguished from other myeloproliferative neoplasms by the presence of a chimeric *BCR-ABL* gene derived from portions of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. In about 95% of cases, the *BCR-ABL* gene is the product of a balanced (9;22) translocation that moves *ABL* from chromosome 9 to a position on chromosome 22 adjacent to *BCR*. In the remaining

5% of cases, a *BCR-ABL* fusion gene is created by cytogenetically cryptic or complex rearrangements involving more than two chromosomes. The *BCR-ABL* fusion gene is present in granulocytic, erythroid, megakaryocytic, and B cell precursors, and in some cases T cell precursors as well, indicating that the tumor arises from a transformed hematopoietic stem cell. Although the Ph chromosome is highly characteristic of CML, it also is present in 25% of adult B cell–ALLs and a small subset of AMLs.

As described in Chapter 6, the *BCR-ABL* gene encodes a fusion protein consisting of portions of BCR and the tyrosine kinase domain of ABL. Normal myeloid progenitors depend on signals generated by growth factors and their receptors for growth and survival. **The growth factor dependence of CML progenitors is greatly decreased by constitutive signals generated by BCR-ABL that mimic the effects of growth factor receptor activation.** Importantly, because BCR-ABL does not inhibit differentiation, the early disease course is marked by excessive production of relatively normal blood cells, particularly granulocytes and platelets.

MORPHOLOGY

The peripheral blood findings are highly characteristic. The leukocyte count is elevated, often exceeding 100,000 cells/μL. **The circulating cells are predominantly neutrophils, metamyelocytes, and myelocytes** (Fig. 12.28), but **basophils** and **eosinophils** are also prominent and platelets are usually increased. The bone marrow is hypercellular owing to increased numbers of maturing granulocytic and megakaryocytic precursors. The red pulp of the enlarged spleen resembles bone marrow because of the presence of extensive **extramedullary hematopoiesis.** This burgeoning proliferation often compromises the local blood supply, leading to **splenic infarcts.**

Clinical Features

The onset of CML is insidious, as the initial symptoms usually are nonspecific (e.g., easy fatigability, weakness, weight loss). Sometimes the first symptom is a dragging sensation in the abdomen caused by splenomegaly. On occasion it may be necessary to distinguish CML from a *lekemoid reaction* a dramatic elevation of the granulocyte count in response to infection, stress, chronic inflammation, and certain neoplasms. This distinction can be achieved definitively by testing for the presence of the BCR-ABL fusion gene, which can be done by karyotyping, fluorescence in situ hybridization, or PCR assay.

The natural history of CML initially is one of slow progression. Even without treatment, the median survival is 3 years. After a variable (and unpredictable) period, approximately half of CML cases enter an accelerated phase marked by increasing anemia and new thrombocytopenia, the appearance of additional cytogenetic abnormalities, and finally transformation into a picture resembling acute leukemia (blast crisis). In the remaining 50% of cases, blast crisis occurs abruptly, without an accelerated phase. Of note, in 30% of cases the blast crisis resembles precursor-B cell ALL, further attesting to the origin of CML from hematopoietic stem cells. In the remaining 70% of cases, the blast crisis resembles AML. Less commonly, CML progresses to a phase of extensive bone marrow fibrosis resembling primary myelofibrosis.

Fortunately for those affected, the natural history of CML has been altered dramatically by the emergence of targeted therapy. Treatment with tyrosine kinase inhibitors, particularly in patients with early disease, induces sustained remissions with manageable toxicity and prevents progression to blast crisis, apparently by suppressing the proliferative drive that leads to the acquisition of additional mutations. When patients on tyrosine kinase inhibitors relapse, their tumors frequently are found to have acquired mutations in the kinase domain of BCR-ABL that prevent the drugs from binding. The selective outgrowth of these cells is explained by the powerful antitumor effects of BCR-ABL inhibitors, and indicates that many resistant tumors are still "addicted" to the progrowth signals created by BCR-ABL. In some instances resistant tumors can be treated with "third-generation" BCR-ABL inhibitors. For others, hematopoietic stem cell transplantation offers a chance of cure, but carries with it substantial risks, particularly in the aged.

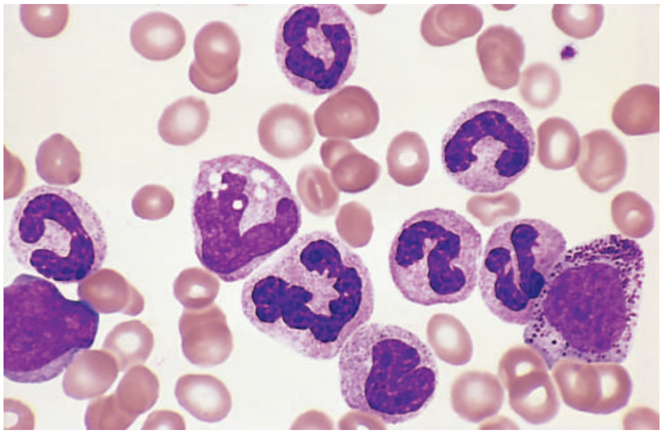

Fig. 12.28 CML—peripheral blood smear. Granulocytic forms at various stages of differentiation are present. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Polycythemia Vera

Polycythemia vera is strongly associated with activating point mutations in the tyrosine kinase JAK2. JAK2 normally acts in the signaling pathways downstream of the erythropoietin receptor and other growth factor receptors. The most common JAK2 mutation, sharply lowers the dependence of hematopoietic cells on growth factors for growth and survival. This produces excessive proliferation of erythroid, granulocytic, and megakaryocytic elements (panmyelosis), but most clinical signs and symptoms are related to an absolute increase in red cell mass. Polycythemia vera must be distinguished from relative polycythemia, which results from hemoconcentration. Unlike reactive forms of absolute polycythemia, polycythemia vera is associated with low levels of serum erythropoietin, which is a reflection of the growth factor–independent growth of the neoplastic clone.

MORPHOLOGY

The major anatomic changes in polycythemia vera stem from increases in blood volume and viscosity brought about by the polycythemia. **Congestion** of many tissues is characteristic. The liver is enlarged and often contains small foci of extramedullary hematopoiesis. The spleen usually is slightly enlarged (250 to 300 g) because of vascular congestion. As a result of the increased viscosity and vascular stasis, **thromboses and infarctions are common,** particularly in the heart, spleen, and kidneys. Hemorrhages also occur in about a third of the patients. These most often affect the gastrointestinal tract, oropharynx, or brain and may occur spontaneously or following some minor trauma or surgical procedure. Platelets produced from the neoplastic clone often are dysfunctional, a derangement that contributes to the elevated risk of thrombosis and bleeding. As in CML, the peripheral blood often shows **basophilia.**

The bone marrow is hypercellular owing to increased numbers of erythroid, myeloid, and megakaryocytic forms. In addition, some degree of marrow fibrosis is present in 10% of patients at the time of diagnosis. In a subset of patients, this progresses to a spent phase where the marrow is largely replaced by fibroblasts and collagen.

Clinical Features

Polycythemia vera appears insidiously, usually in late middle age. Patients are plethoric and often somewhat cyanotic. Histamine released from the neoplastic basophils may contribute to pruritus and also may account for the increased incidence of peptic ulceration. Other complaints are referable to the thrombotic and hemorrhagic tendencies and to hypertension. Headache, dizziness, gastrointestinal symptoms, hematemesis, and melena are common. Because of the high rate of cell turnover, symptomatic gout is seen in 5% to 10% of cases.

The diagnosis usually is made in the laboratory. Red cell counts range from 6 to 10 million/μL, and the hematocrit is often 60% or greater. The granulocyte count can be as high as 50,000 cells/μL, and the platelet count is often more than 400,000/μL. Basophilia is common. The platelets are functionally abnormal in most cases, and giant platelets and megakaryocyte fragments are often seen in the blood. About 30% of patients develop thrombotic complications, usually affecting the brain or heart. Hepatic vein thrombosis giving rise to *Budd-Chiari syndrome* (Chapter 15) is an uncommon but grave complication. Minor hemorrhages (e.g., epistaxis and bleeding from gums) are common and life-threatening hemorrhages that occur in 5% to 10% of patients. In those receiving no treatment, death occurs from vascular complications within months; however, the median survival is increased to about 10 years by lowering the red cell count to near normal through repeated phlebotomy.

Unfortunately, prolonged survival has shown a propensity for polycythemia vera to evolve to a "spent phase" resembling primary myelofibrosis. After an average interval of 10 years, 15% to 20% of cases undergo such a transformation. Owing to the extensive marrow fibrosis, hematopoiesis shifts to the spleen, which enlarges markedly. Inhibitors that target JAK2 have been approved for treatment of the spent phase of polycythemia vera and lead to some improvement in most patients. Transformation to a "blast crisis" identical to AML also occurs, but much less frequently than in CML.

Primary Myelofibrosis

The hallmark of primary myelofibrosis is the development of obliterative marrow fibrosis, which reduces bone marrow hematopoiesis and leads to cytopenias and extensive extramedullary hematopoiesis. Histologically, the appearance is identical to the spent phase that occurs occasionally late in the course of other myeloproliferative disorders. This similarity also extends to the underlying pathogenesis.

JAK-STAT signaling seems to be the underlying driver in almost all cases. Thus, JAK2 mutations are present in 50% to 60% of cases and activating mutations in MPL, the thrombopoietin receptor, are seen in an additional 1% to 5% of cases. Most of the remaining cases have other mutations, which also are hypothesized to stimulate increased JAK-STAT signaling. Why JAK2 mutations are associated with polycythemia vera in some patients and primary myelofibrosis in others is not understood; differences in the cell of origin and the genetic backgrounds that give rise to these two disorders are suspected.

It is believed that the characteristic marrow fibrosis is caused by the inappropriate release of fibrogenic factors from neoplastic megakaryocytes. Two factors synthesized by megakaryocytes have been implicated: *platelet-derived growth factor* and *TGF-β*. As you recall, platelet-derived growth factor and TGF-β are fibroblast mitogens. In addition, TGF-β promotes collagen deposition and causes angiogenesis, both of which are observed in myelofibrosis.

As marrow fibrosis progresses, displaced hematopoietic stem cells take up residence in niches in secondary hematopoietic organs, such as the spleen, the liver, and the lymph nodes, leading to the appearance of extramedullary hematopoiesis. For incompletely understood reasons, red cell production at extramedullary sites is disordered. This factor and the concomitant suppression of marrow function result in moderate to severe anemia.

MORPHOLOGY

The peripheral blood smear is markedly abnormal (Fig. 12.29). Red cells often exhibit bizarre shapes **(poikilocytes, teardrop cells)**, and nucleated erythroid precursors are commonly seen along with immature white cells (myelocytes and metamyelocytes), a combination of findings referred to as **leukoerythroblastosis**. Abnormally large platelets often are present as well. The bone marrow in advanced cases is hypocellular and diffusely fibrotic, whereas early in the course it may be hypercellular and have only focal areas of fibrosis. Throughout the course, marrow megakaryocytes are present in clusters and have characteristic hyperchromatic nuclei with "cloudlike" outlines. Marked **splenomegaly** resulting from extensive extramedullary hematopoiesis, often associated with **subcapsular infarcts,** also is typical. The spleen may weigh as much as 4000 g, roughly twenty times its normal weight. Moderate **hepatomegaly**, also due to extramedullary hematopoiesis, is commonplace. Lymph nodes also are involved by extramedullary hematopoiesis, but not to a degree sufficient to cause appreciable enlargement.

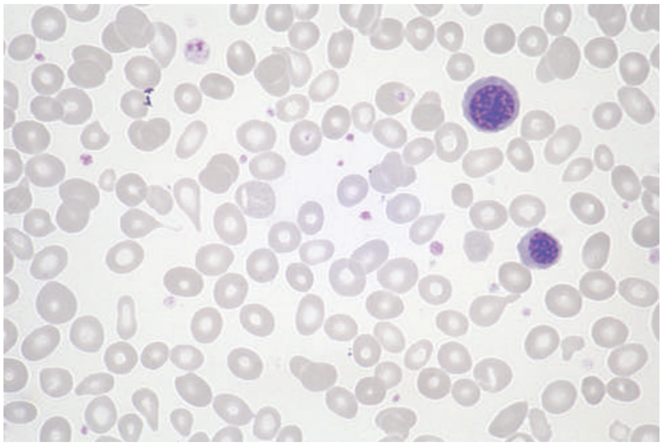

Fig. 12.29 Primary myelofibrosis—peripheral blood smear. Two nucleated erythroid precursors and several teardrop-shaped red cells (dacryocytes) are evident. Immature myeloid cells were present in other fields. An identical histologic picture can be seen in other diseases producing marrow distortion and fibrosis.

Clinical Features

Primary myelofibrosis usually occurs in individuals older than 60 years who come to attention because of progressive anemia and splenomegaly. Nonspecific symptoms such as fatigue, weight loss, and night sweats are common. Hyperuricemia and secondary gout resulting from a high rate of cell turnover also are frequently seen.

Laboratory studies typically show a moderate to severe normochromic normocytic anemia accompanied by *leukoerythroblastosis*. The white cell count is usually normal or mildly reduced, but can be elevated early in the course. The platelet count is usually normal or elevated at diagnosis, but thrombocytopenia often supervenes as the disease progresses. These blood findings are not specific, and bone marrow biopsy is essential for diagnosis.

Primary myelofibrosis is more difficult to treat than polycythemia vera and CML. The median survival is in the range of 4 to 5 years. Threats to life include infection, thrombosis and bleeding related to platelet abnormalities, and transformation to AML, which occurs in 5% to 20% of cases. JAK2 inhibitors are effective at decreasing the splenomegaly and constitutional symptoms, even in those without JAK2 mutations, presumably because increased JAK/STAT signaling is common to all molecular subtypes. Hematopoietic stem cell transplantation may be curative in those young and fit enough to withstand the procedure.

SUMMARY

MYELOID NEOPLASMS

Myeloid tumors occur mainly in adults and fall into three major groups:

- **AML**
  - Aggressive tumors comprised of immature myeloid lineage blasts, which replace the marrow and suppress normal hematopoiesis
  - Associated with diverse acquired mutations that lead to expression of abnormal transcription factors, which interfere with myeloid differentiation
- **MDS**
  - Myeloid tumors characterized by disordered and ineffective hematopoiesis
  - Manifest with one or more cytopenias and progress in 10% to 40% of cases to AML
- **Myeloproliferative neoplasms**
  - Myeloid tumors in which production of formed myeloid elements is initially increased, leading to high blood counts and extramedullary hematopoiesis
  - Commonly associated with acquired mutations that lead to constitutive activation of tyrosine kinases, which mimic signals from normal growth factors. The most common pathogenic kinases are BCR-ABL (associated with CML) and mutated JAK2 (associated with polycythemia vera and primary myelofibrosis).
  - All can transform to acute leukemia and to a spent phase of marrow fibrosis associated with anemia, thrombocytopenia, and splenomegaly.

Histiocytic Neoplasms

Langerhans Cell Histiocytoses

The term *histiocytosis* is an "umbrella" designation for a variety of proliferative disorders of dendritic cells or macrophages. Some, such as very rare histiocytic lymphomas, are highly malignant neoplasms. Others, such as most histiocytic proliferations in lymph nodes, are completely benign and reactive. Between these two extremes lie a group of relatively rare tumors comprised of Langerhans cells, the *Langerhans cell histiocytoses*. As described in Chapter 5, Langerhans cells are immature dendritic cells found in the epidermis; similar cells are found in many other organs, and they function to capture antigens and display them to T cells.

Langerhans cell proliferations take on different clinical forms, but all are believed to be variations of the same basic disorder. The proliferating Langerhans cells express MHC class II antigens, CD1a, and langerin. Langerin is a transmembrane protein found in *Birbeck granules,* cytoplasmic pentalaminar rodlike tubular structures that in electron micrographs have a characteristic periodicity and sometimes a dilated terminal end ("tennis racket" appearance). Under the light microscope, the proliferating Langerhans cells do not resemble their normal dendritic counterparts. Instead, they have abundant, often vacuolated cytoplasm and vesicular nuclei, an appearance more akin to that of tissue macrophages (called histiocytes by morphologists)—hence the term *Langerhans cell histiocytosis.*

Langerhans cell histiocytoses can be grouped into two major relatively distinctive clinicopathologic entities.

- *Multisystem Langerhans cell histiocytosis (Letterer-Siwe disease)* usually occurs in children younger than 2 years of age. It typically manifests with multifocal cutaneous lesions that grossly resemble seborrheic skin eruptions and are composed of Langerhans cells. Most affected patients have hepatosplenomegaly, lymphadenopathy, pulmonary lesions, and (later in the course) destructive

osteolytic bone lesions. Extensive marrow infiltration often leads to pancytopenia and predisposes the patient to recurrent bacterial infections. The disease is rapidly fatal if untreated. With intensive chemotherapy, 50% of patients survive 5 years.

- *Unisystem Langerhans cell histiocytosis (eosinophilic granuloma)* may be unifocal or multifocal. It is characterized by expanding accumulations of Langerhans cells, usually within the medullary cavities of bones or less commonly in the skin, lungs, or stomach. The Langerhans cells are admixed with variable numbers of lymphocytes, plasma cells, neutrophils, and eosinophils, which are usually prominent. Virtually any bone may be involved; the calvaria, ribs, and femur are most commonly affected. *Unifocal disease* most often involves a single bone. It may be asymptomatic or cause pain, tenderness, and pathologic fracture. It is an indolent disorder that may heal spontaneously or be cured by local excision or irradiation. *Multifocal unisystem disease* usually affects children and typically manifests with multiple erosive bony masses that sometimes extend into soft tissues. In about 50% of cases, involvement of the posterior pituitary stalk of the hypothalamus leads to diabetes insipidus. The combination of calvarial bone defects, diabetes insipidus, and exophthalmos is referred to as the *Hand-Schüller-Christian triad.* Many patients experience spontaneous regressions; others are treated effectively with chemotherapy.

A clue to the pathogenesis of Langerhans cell tumors lies in the discovery that the different clinical forms are frequently associated with an acquired mutation in the serine/threonine kinase BRAF, that leads to hyperactivity of the kinase. This same mutation is found in a variety of other tumors, including hairy cell leukemia (described earlier), benign nevi, malignant melanoma, papillary thyroid carcinoma, and some colon cancers (Chapter 6). BRAF is a component of the RAS signaling pathway that drives cellular proliferation and survival, effects that likely contribute to the growth of neoplastic Langerhans cells.

Bleeding Disorders

Bleeding disorders are characterized clinically by abnormal bleeding, which can appear spontaneously or follow some inciting event (e.g., trauma or surgery). As described in Chapter 4, normal clotting involves the vessel wall, the platelets, and the clotting factors. It follows that abnormalities in any of these components can lead to clinically significant bleeding. A review of the laboratory tests used in the evaluation of patients with a suspected bleeding disorder, along with the principles involved, is presented next, followed by consideration of specific disorders of coagulation. We finish with a discussion of a few clinically important complications of blood product transfusion.

The most important tests for investigation of suspected coagulopathies include the following:

- *Prothrombin time* (PT). This test assesses the extrinsic and common coagulation pathways. It measures the time (in seconds) needed for plasma to clot after addition of tissue thromboplastin (e.g., brain extract) and Ca^{2+} ions. A prolonged PT can result from a deficiency of factor V, VII, or X; prothrombin; or fibrinogen or the presence of an acquired inhibitor (typically an antibody) that interferes with the extrinsic pathway.
- *Partial thromboplastin time* (PTT). This test assesses the intrinsic and common coagulation pathways. It measures the time (in seconds) needed for the plasma to clot after the addition of kaolin, cephalin, and Ca^{2+}. Kaolin activates the contact-dependent factor XII and cephalin substitutes for platelet phospholipids. Prolongation of PTT can be caused by a deficiency of factor V, VIII, IX, X, XI, or XII; prothrombin; or fibrinogen or the presence of an acquired inhibitor that interferes with the intrinsic pathway.
- *Platelet count.* This is obtained on anti-coagulated blood using an electronic particle counter. The reference range is 150,000 to 450,000/μL. Counts outside this range must be confirmed by a visual inspection of a peripheral blood smear.
- *Tests of platelet function.* At present no single test provides an adequate assessment of the complex functions of platelets. Aggregation tests that measure the response of platelets to certain agonists and qualitative and quantitative tests of von Willebrand factor (vWF) (which you will recall is required for platelet adherence to subvascular collagen) are both commonly used in clinical practice. An old test, the bleeding time, has some value but is time-consuming and difficult to standardize and is therefore performed only rarely. Newer instrument-based assays that provide quantitative measures of platelet function are being evaluated but are not yet available for routine use in the clinic.

In addition, more specialized tests are available that measure the levels of specific clotting factors and fibrin split products or assess the presence of circulating anti-coagulants.

Bleeding disorders may stem from abnormalities of vessels, platelets, or coagulation factors, alone or in combination. Bleeding resulting from *vascular fragility* is seen with vitamin C deficiency (scurvy) (Chapter 8), systemic amyloidosis (Chapter 5), chronic glucocorticoid use, rare inherited conditions affecting the connective tissues, and a large number of infectious and hypersensitivity vasculitides. Some of these conditions are discussed in other chapters; others are beyond the scope of this book. Bleeding that results purely from vascular fragility is characterized by the “spontaneous” appearance of petechiae and ecchymoses in the skin and mucous membranes (probably resulting from minor trauma). In most instances laboratory tests of coagulation are normal.

Bleeding also can be triggered by systemic conditions that inflame or damage endothelial cells. If severe

enough, such insults convert the vascular lining to a prothrombotic surface that activates coagulation throughout the circulatory system, a condition known as *disseminated intravascular coagulation* (DIC) (discussed in the next section). Paradoxically, in DIC, platelets and coagulation factors often are used up faster than they can be replaced, resulting in deficiencies that may lead to severe bleeding (a condition referred to as *consumptive coagulopathy*).

Deficiencies of platelets (thrombocytopenia) also are an important cause of bleeding. These occur in a variety of clinical settings that are discussed later. Other bleeding disorders stem from qualitative defects in platelet function. Such defects may be acquired, as in uremia and certain myeloproliferative disorders and after aspirin ingestion; or inherited, as in von Willebrand disease and other rare congenital disorders. The clinical signs of inadequate platelet function include easy bruising, nosebleeds, excessive bleeding from minor trauma, and menorrhagia.

In bleeding disorders stemming from defects in one or more coagulation factors, the PT, PTT, or both are prolonged. Unlike platelet defects, petechiae and mucosal bleeding are usually absent. Instead, hemorrhages tend to occur in parts of the body that are subject to trauma, such as the joints of the lower extremities. Massive hemorrhage may occur after surgery, dental procedures, or severe trauma. This category includes the hemophilias, an important group of inherited coagulation disorders.

It is not uncommon for bleeding to occur as a consequence of a mixture of defects. This is the case in DIC, in which both thrombocytopenia and coagulation factor deficiencies contribute to bleeding, and in von Willebrand disease, a fairly common inherited disorder in which both platelet function and (to a lesser degree) coagulation factor function are abnormal.

With the foregoing overview as background, we now turn to specific bleeding disorders.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

DIC occurs as a complication of a wide variety of disorders; it is caused by the systemic activation of coagulation and results in the formation of thrombi throughout the microcirculation. As a consequence, platelets and coagulation factors are consumed and, secondarily, fibrinolysis is activated. Thus, DIC can give rise either to tissue hypoxia and microinfarcts caused by myriad microthrombi or to a bleeding disorder related to pathologic activation of fibrinolysis and the depletion of the elements required for hemostasis (hence the term *consumptive coagulopathy*). This entity probably causes bleeding more commonly than all of the congenital coagulation disorders combined.

Pathogenesis

Before discussing specific disorders associated with DIC, we must first consider in a general way the pathogenic mechanisms by which intravascular clotting occurs. Reference to earlier comments on normal blood coagulation (Chapter 4) may be helpful at this point. It suffices to recall that clotting can be initiated by either the extrinsic pathway, which is triggered by the release of tissue factor (tissue thromboplastin); or the intrinsic pathway, which involves the activation of factor XII by surface contact, collagen, or other negatively charged substances. Both pathways lead to the generation of thrombin. Clotting normally is limited by the rapid clearance of activated clotting factors by the macrophages and the liver, endogenous anticoagulants (e.g., protein C), and the concomitant activation of fibrinolysis.

DIC usually is triggered by either (1) the release of tissue factor or thromboplastic substances into the circulation or (2) widespread endothelial cell damage (Fig. 12.30). Thromboplastic substances can be released into the circulation from a variety of sources—for example, the placenta in obstetric complications or certain types of cancer cells, particularly those of acute promyelocytic leukemia and adenocarcinomas. Cancer cells may also provoke coagulation in other ways, such as by releasing proteolytic enzymes and by expressing tissue factor. In gram-negative and gram-positive sepsis (important causes of DIC), endotoxins or exotoxins stimulate the release of tissue factor from monocytes. Activated monocytes also release IL-1 and tumor necrosis factor, both of which stimulate the expression of tissue factor on endothelial cells and simultaneously decrease the expression of thrombomodulin. The latter, as discussed, activates protein C, an anticoagulant (Chapter 4). The net result of these alterations is the enhanced generation of thrombin and the blunting of inhibitory pathways that limit coagulation.

Severe endothelial cell injury can initiate DIC by causing the release of tissue factor and by exposing subendothelial collagen and vWF. However, even subtle forms of endothelial damage can unleash procoagulant activity by stimulating tissue factor expression on endothelial cell surfaces. Widespread endothelial injury can be produced by the deposition of antigen-antibody complexes (e.g., in systemic lupus erythematosus), by temperature extremes (e.g., after heat stroke or burn injury), or by infections (e.g., resulting from meningococci or rickettsiae). As discussed in Chapter 4, endothelial injury is an important consequence of systemic inflammatory response syndrome (SIRS) triggered by sepsis and other systemic insults, and, not surprisingly, DIC is a frequent complication of SIRS.

Disorders associated with DIC are listed in Table 12.12. Of these, *DIC is most often associated with sepsis, obstetric complications, malignancy, and major trauma (especially to the brain)*. The initiating events in these conditions are multiple and often interrelated. For example, in obstetric conditions, tissue factor derived from the placenta, retained dead fetus, or amniotic fluid enters the circulation; however, shock, hypoxia, and acidosis often coexist and can lead to widespread endothelial injury. Trauma to the brain releases fat and phospholipids, which act as contact factors and thereby activate the intrinsic arm of the coagulation cascade.

Whatever the pathogenic mechanism, DIC has two consequences. First, there is widespread fibrin deposition within the microcirculation. The associated obstruction leads to ischemia in the more severely affected or vulnerable organs and hemolysis as red cells are traumatized while passing through vessels narrowed by fibrin thrombi *(microangiopathic hemolytic anemia)*. Second, because of the depletion of platelets and clotting factors and the secondary

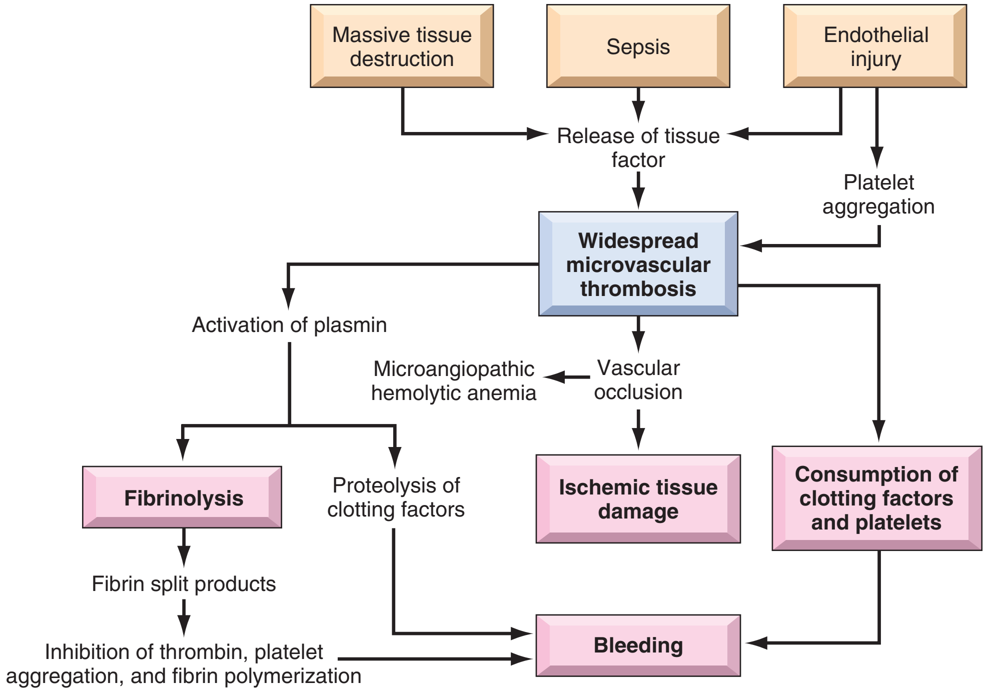

Fig. 12.30 Pathophysiology of disseminated intravascular coagulation.

release of plasminogen activators, there is a superimposed bleeding tendency. Plasmin cleaves not only to fibrin (fibrinolysis) but also to factors V and VIII, thereby reducing their concentration further. In addition, fibrinolysis creates fibrin degradation products. These inhibit platelet aggregation, have anti-thrombin activity, and impair fibrin polymerization, all of which contribute to the hemostatic failure (Fig. 12.30).

Table 12.12 Major Disorders Associated With Disseminated Intravascular Coagulation

Obstetric Complications
Abruptio placentae
Retained dead fetus
Septic abortion
Amniotic fluid embolism
Toxemia
Infections
Sepsis (gram-negative and gram-positive)
Meningococcemia
Rocky Mountain spotted fever
Histoplasmosis
Aspergillosis
Malaria
Neoplasms
Carcinomas of pancreas, prostate, lung, and stomach
Acute promyelocytic leukemia
Massive Tissue Injury
Trauma
Burns
Extensive surgery

MORPHOLOGY

In DIC, **microthrombi** are most often found in the arterioles and capillaries of the kidneys, adrenals, brain, and heart, but no organ is spared. The glomeruli contain small fibrin thrombi. These may be associated with only a subtle, reactive swelling of the endothelial cells or varying degrees of focal glomerulitis. The microvascular occlusions give rise to small infarcts in the renal cortex. In severe cases the ischemia can destroy the entire cortex and cause bilateral renal cortical necrosis. Involvement of the adrenal glands can produce the **Waterhouse-Friderichsen syndrome** (Chapter 20). Microinfarcts also are commonly encountered in the brain and are often surrounded by microscopic or gross foci of hemorrhage. These can give rise to bizarre neurologic signs. Similar changes are seen in the heart and often in the anterior pituitary. DIC may contribute to the development of **Sheehan postpartum pituitary necrosis** (Chapter 19). The bleeding tendency associated with DIC is manifested not only by larger-than-expected hemorrhages near foci of infarction but also by diffuse petechiae and ecchymoses on the skin, serosal linings of the body cavities, epicardium, endocardium, lungs, and mucosal lining of the urinary tract.

Clinical Features

As might be imagined, depending on the balance between clotting and bleeding tendencies, the range of possible clinical manifestations is enormous. In general, acute DIC (e.g., that associated with obstetric complications) is dominated by bleeding, whereas chronic DIC (e.g., as occurs in those with cancer) tends to manifest with signs and symptoms related to thrombosis. The abnormal clotting usually is confined to the microcirculation, but large vessels are involved on occasion. The manifestations may be minimal, or there may be shock, acute renal failure, dyspnea,

cyanosis, convulsions, and coma. Most often, the onset of DIC is announced by prolonged and copious postpartum bleeding or the presence of petechiae and ecchymoses on the skin. These may be the only manifestations, or there may be severe hemorrhage into the gut or urinary tract. Laboratory evaluation shows thrombocytopenia and prolongation of the PT and the PTT (from depletion of platelets, clotting factors, and fibrinogen). Fibrin split products are increased in the plasma.

The prognosis varies widely depending on the nature of the underlying disorder and the severity of the intravascular clotting and fibrinolysis. Acute DIC can be life threatening and must be treated aggressively with anticoagulants such as heparin or the coagulants contained in fresh frozen plasma. Conversely, chronic DIC is sometimes identified unexpectedly by laboratory testing. In either circumstance, definitive treatment must be directed at the underlying cause.

THROMBOCYTOPENIA

Isolated thrombocytopenia is associated with a bleeding tendency and *normal coagulation tests*. A count less than 150,000 platelets/μL generally is considered thrombocytopenia. However, only when platelet counts fall to 20,000 to 50,000 platelets/μL is there an increased risk of posttraumatic bleeding, and spontaneous bleeding is unlikely until counts fall below 5000 platelets/μL. Most bleeding occurs from small, superficial blood vessels and produces *petechiae* or large *ecchymoses* in the skin, the mucous membranes of the gastrointestinal and urinary tracts, and other sites. Larger hemorrhages into the central nervous system are a major hazard in those with markedly depressed platelet counts.

The major causes of thrombocytopenia are listed in Table 12.13. Clinically important thrombocytopenia is confined to disorders with reduced production or increased destruction of platelets. When the cause is the accelerated destruction of platelets, the bone marrow usually shows a compensatory increase in the number of megakaryocytes. Also of note, thrombocytopenia is one of the most common hematologic manifestations of AIDS. It can occur early in the course of HIV infection and has a multifactorial basis, including immune complex–mediated platelet destruction, anti-platelet autoantibodies, and HIV-mediated suppression of megakaryocyte development and survival.

Table 12.13 Causes of Thrombocytopenia

Decreased Production of Platelets
Generalized Bone Marrow Dysfunction
Aplastic anemia: congenital and acquired Marrow infiltration: leukemia, disseminated cancer
Selective Impairment of Platelet Production
Drug-induced: alcohol, thiazides, cytotoxic drugs Infections: measles, HIV infection
Ineffective Megakaryopoiesis
Megaloblastic anemia Paroxysmal nocturnal hemoglobinuria
Decreased Platelet Survival
Immunologic Destruction
Autoimmune: ITP, systemic lupus erythematosus Isoimmune: posttransfusion and neonatal Drug-associated: quinidine, heparin, sulfa compounds Infections: infectious mononucleosis, HIV infection, cytomegalovirus infection
Nonimmunologic Destruction
Disseminated intravascular coagulation TTP Giant hemangiomas Microangiopathic hemolytic anemias
Sequestration
Hypersplenism
Dilutional
Multiple transfusions (e.g., for massive blood loss)

DIC, Disseminated intravascular coagulation; *HIV*, human immunodeficiency virus; *ITP*, immune thrombocytopenic purpura; *TTP*, thrombotic thrombocytopenic purpura.

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) includes two clinical subtypes. *Chronic ITP* is a relatively common disorder that tends to affect women between the ages of 20 and 40 years. *Acute ITP* is a self-limited form seen mostly in children after viral infections.

Antibodies directed against platelet membrane glycoproteins IIb/IIIa or Ib/IX complexes can be detected in roughly 80% of cases of chronic ITP. The spleen is an important site of anti-platelet antibody production and the major site of destruction of the IgG-coated platelets. Although splenomegaly is not a feature of uncomplicated chronic ITP, the importance of the spleen in the premature destruction of platelets is proved by the benefits of splenectomy, which normalizes the platelet count and induces a complete remission in more than two-thirds of patients. The bone marrow usually contains increased numbers of megakaryocytes, a finding common to all forms of thrombocytopenia caused by accelerated platelet destruction.

The onset of chronic ITP is insidious. Common findings include petechiae, easy bruising, epistaxis, gum bleeding, and hemorrhages after minor trauma. Fortunately, more serious intracerebral or subarachnoid hemorrhages are uncommon. The diagnosis rests on the clinical features, the presence of thrombocytopenia, examination of the marrow, and the exclusion of secondary ITP. Reliable clinical tests for anti-platelet antibodies are not available. Treatment usually involves the use of immunosuppressive agents and, in some cases, splenectomy.

Heparin-Induced Thrombocytopenia

This special type of drug-induced thrombocytopenia (discussed in more detail in Chapter 4) merits brief mention because of its clinical importance. Moderate to severe thrombocytopenia develops in 3% to 5% of patients after 1 to 2 weeks of treatment with unfractionated heparin. The disorder is caused by IgG antibodies that bind to platelet factor 4 on platelet membranes in a heparin-dependent fashion. Resultant activation of the platelets induces their aggregation, thereby exacerbating the condition that heparin is used to treat—thrombosis. Both venous and arterial thromboses

occur, even in the setting of marked thrombocytopenia, and may cause severe morbidity (e.g., loss of limbs) and death. Cessation of heparin therapy breaks the cycle of platelet activation and consumption. The risk of this complication is lowered (but not prevented entirely) by use of low-molecular-weight heparin preparations.

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

The term *thrombotic microangiopathies* encompasses a spectrum of clinical syndromes that include thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS). As originally defined, TTP is associated with the pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, transient neurologic deficits, and renal failure. HUS also is associated with microangiopathic hemolytic anemia and thrombocytopenia but is distinguished from TTP by the absence of neurologic symptoms, the dominance of acute renal failure, and frequent occurrence in children (Chapter 14). Clinical experience has blurred these distinctions, as many adults with TTP lack one or more of the five criteria, and some patients with HUS have fever and neurologic dysfunction. Fundamental to both conditions is the widespread formation of platelet-rich thrombi in the microcirculation. The consumption of platelets leads to thrombocytopenia, and the narrowing of blood vessels by the platelet-rich thrombi results in a microangiopathic hemolytic anemia. All of the thrombotic microangiopathies produce renal damage of variable severity, and their pathogenesis is discussed in greater detail in Chapter 14.

It is important to note that although DIC and the thrombotic microangiopathies share features such as microvascular occlusion and microangiopathic hemolytic anemia, they are pathogenically distinct. Furthermore, unlike in DIC, in TTP and HUS activation of the coagulation cascade is not of primary importance, and so the results of laboratory tests of coagulation (e.g., the PT and PTT tests) usually are normal.

COAGULATION DISORDERS

Coagulation disorders result from either congenital or acquired deficiencies of clotting factors. Acquired deficiencies are most common and often involve several factors simultaneously. As discussed in Chapter 8, vitamin K is required for the synthesis of prothrombin and clotting factors VII, IX, and X, and its deficiency causes a severe coagulation defect. The liver synthesizes several coagulation factors and also removes many activated coagulation factors from the circulation; thus, hepatic parenchymal diseases are common causes of complex hemorrhagic diatheses. As already discussed, DIC also may lead to multiple concomitant factor deficiencies. Rarely, autoantibodies may cause acquired deficiencies limited to a single factor.

Hereditary deficiencies of many coagulation factors also have been identified. Hemophilia A (a deficiency of factor VIII) and hemophilia B (Christmas disease, a deficiency of factor IX) are X-linked traits, whereas other deficiencies are autosomal recessive disorders. Of the inherited deficiencies, only von Willebrand disease, hemophilia A, and hemophilia B are sufficiently common to warrant further consideration.

Deficiencies of Factor VIII–von Willebrand Factor Complex

Hemophilia A and von Willebrand disease are caused by qualitative or quantitative defects involving the factor VIII–vWF complex. As background for subsequent discussion of these disorders, it is useful to review the structure and function of these two proteins (Fig. 12.31).

As described earlier, factor VIII is an essential cofactor for factor IX, which activates factor X in the intrinsic coagulation pathway. Circulating factor VIII binds noncovalently to vWF, which exists as large multimers of up to

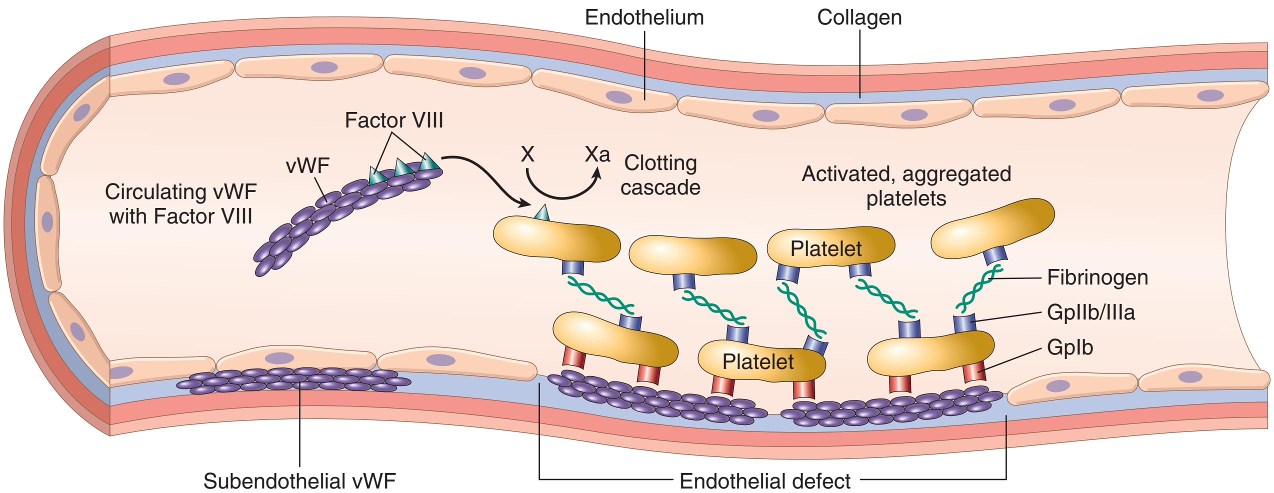

Fig. 12.31 Structure and function of factor VIII–von Willebrand factor (vWF) complex. Factor VIII and vWF circulate as a complex. vWF also is present in the subendothelial matrix of normal blood vessels. Factor VIII takes part in the coagulation cascade by activating factor X by means of factor IX *(not shown)*. vWF causes adhesion of platelets to subendothelial collagen, primarily through the glycoprotein Ib (GpIb) platelet receptor.

20 Megadaltons in weight. Endothelial cells are the major source of plasma vWF, whereas most factor VIII is synthesized in the liver. vWF is found in the plasma (in association with factor VIII), in platelet granules, in endothelial cells within cytoplasmic vesicles called Weibel-Palade bodies, and in the subendothelium, where it binds to collagen.

When endothelial cells are stripped away by trauma or injury, subendothelial vWF is exposed and binds platelets, mainly through glycoprotein Ib and to a lesser degree through glycoprotein IIb/IIIa (Fig. 12.31). The most important function of vWF is to facilitate the adhesion of platelets to damaged blood vessel walls, a crucial early event in the formation of a hemostatic plug. Inadequate platelet adhesion is believed to underlie the bleeding tendency in von Willebrand disease. In addition to its role in platelet adhesion, vWF also stabilizes factor VIII; thus, vWF deficiency leads to a secondary deficiency of factor VIII.

The various forms of von Willebrand disease are diagnosed by measuring the quantity, size, and function of vWF. vWF function is assessed using the *ristocetin platelet agglutination test*. Ristocetin somehow "activates" the bivalent binding of vWF and platelet membrane glycoprotein Ib, creating interplatelet "bridges" that cause platelets to clump (agglutination), an event that can be measured easily. Thus, ristocetin-dependent platelet agglutination serves as a useful bioassay for vWF.

With this background we now turn to the discussion of diseases resulting from deficiencies of factor VIII–vWF complex.

von Willebrand Disease

von Willebrand disease is transmitted as an autosomal dominant disorder. It usually presents as spontaneous bleeding from mucous membranes, excessive bleeding from wounds, and menorrhagia. It is underrecognized, as the diagnosis requires sophisticated tests and the clinical manifestations often are quite mild. Actually, this disease is surprisingly prevalent, particularly in persons of European descent. **It is estimated that approximately 1% of people in the United States have von Willebrand disease, making it the most common inherited bleeding disorder.**

People with von Willebrand disease have compound defects in platelet function and coagulation, but in most cases only the platelet defect produces clinical findings. The exceptions are rare in patients with homozygous von Willebrand disease, in whom there is a concomitant deficiency of factor VIII severe enough to produce features resembling those of hemophilia (described later).

The effects of the causative mutations vary, allowing von Willebrand disease to be divided into several subtypes

- *Type 1* is the classic and most common variant of von Willebrand disease. It is an autosomal dominant disorder in which the quantity of circulating vWF is reduced. There is also a measurable but clinically insignificant decrease in factor VIII levels.
- *Type II* is divided into several subtypes characterized by the selective loss of high–molecular-weight multimers of vWF. Because these large multimers are the most active form, there is a functional deficiency of vWF. In type IIA, the high-molecular-weight multimers are not synthesized, leading to a true deficiency. In type IIB, abnormal "hyperfunctional" high-molecular-weight multimers are synthesized that are rapidly removed from the circulation. These high-molecular-weight multimers cause spontaneous platelet aggregation (a situation reminiscent of the very-high–molecular-weight multimer aggregates seen in TTP); indeed, some people with type IIB von Willebrand disease have mild chronic thrombocytopenia, presumably resulting from platelet consumption.

Hemophilia A—Factor VIII Deficiency

Hemophilia A is the most common hereditary cause of serious bleeding. It is an X-linked recessive disorder caused by reduced factor VIII activity. It primarily affects males. Much less commonly, excessive bleeding occurs in heterozygous females, presumably due to preferential inactivation of the X chromosome carrying the normal factor VIII gene (unfavorable lyonization). Approximately 30% of cases are caused by new mutations; in the remainder, there is a positive family history. Severe hemophilia A is observed in people with marked deficiencies of factor VIII (activity levels < 1% of normal). Milder deficiencies may only become apparent in the face of trauma or other hemostatic stressses. The varying degrees of factor VIII deficiency are explained by the existence of many different causative mutations, including deletions, inversions, and splice junction mutations. In about 10% of patients, the factor VIII concentration is normal by immunoassay, but the coagulant activity is low because of a mutation in factor VIII that causes a loss of function.

In symptomatic cases there is a tendency toward easy bruising and massive hemorrhage after trauma or operative procedures. In addition, "spontaneous" hemorrhages frequently are encountered in tissues that normally are subject to mechanical stress, particularly the joints, where recurrent bleeds *(hemarthroses)* lead to progressive deformities that can be crippling. Petechiae are characteristically absent. Specific assays for factor VIII are used to confirm the diagnosis of hemophilia A. Typically, patients with hemophilia A have a prolonged PTT that is corrected by mixing the patient's plasma with normal plasma. Specific factor assays are then used to confirm the deficiency of factor VIII. In approximately 15% of those with severe hemophilia A, replacement therapy is complicated by the development of neutralizing antibodies against factor VIII, probably because factor VIII is seen by the immune system as a "foreign" antigen. In these persons, the PTT fails to correct in mixing studies.

Hemophilia A is treated with factor VIII infusions. Historically, factor VIII was prepared from human plasma, carrying with it the risk of transmission of viral diseases. As mentioned in Chapter 5, before 1985 thousands of hemophiliacs received factor VIII preparations contaminated with HIV and subsequently developed AIDS. The availability and widespread use of recombinant factor VIII and more highly purified factor VIII concentrates have now eliminated the infectious risk of factor VIII replacement therapy.

Hemophilia B—Factor IX Deficiency

Severe factor IX deficiency is an X-linked disorder that is indistinguishable clinically from hemophilia A but is much less common. The PTT is prolonged. The diagnosis is made using specific assays of factor IX. It is treated by infusion of recombinant factor IX.

SUMMARY

BLEEDING DISORDERS

Disseminated Intravascular Coagulation

- Syndrome in which systemic activation of the coagulation leads to consumption of coagulation factors and platelets
- Can be dominated by bleeding, vascular occlusion and tissue hypoxemia, or both
- Common triggers: sepsis, major trauma, certain cancers, obstetric complications

Immune Thrombocytopenic Purpura

- Caused by autoantibodies against platelet antigens
- May be triggered by drugs, infections, or lymphomas, or may be idiopathic

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

- Both manifest with thrombocytopenia, microangiopathic hemolytic anemia, and renal failure; fever and CNS involvement are more typical of TTP.
- *TTP:* Caused by acquired or inherited deficiencies of ADAMTS 13, a plasma metalloprotease that cleaves very-high-molecular-weight multimers of vWF. Deficiency of ADAMTS 13 results in abnormally large vWF multimers that activate platelets.
- *Hemolytic uremic syndrome:* Caused by deficiencies of complement regulatory proteins or agents that damage endothelial cells, such as a Shiga-like toxin elaborated by *E. coli* strain O157:H7. The endothelial injury initiates platelet activation, platelet aggregation, and microvascular thrombosis.

von Willebrand Disease

- Autosomal dominant disorder caused by mutations in vWF, a large protein that promotes the adhesion of platelets to subendothelial collagen.
- Typically causes a mild to moderate bleeding disorder resembling that associated with thrombocytopenia.

Hemophilia

- *Hemophilia A:* X-linked disorder caused by mutations in factor VIII. Affected males typically present with severe bleeding into soft tissues and joints and have a PTT.
- *Hemophilia B:* X-linked disorder caused by mutations in coagulation factor IX. It is clinically identical to hemophilia A.

Complications of Transfusion

Blood products often are rightly called "the gift of life," permitting people to survive traumatic injuries and procedures such as hematopoietic stem cell transplantation and complex surgical procedures that would otherwise prove fatal. Over 5 million red cell transfusions are given in U.S. hospitals each year. Thanks to improved screening of donors, blood products (packed red blood cells, platelets, and fresh-frozen plasma) are safer than ever before.

Nevertheless, complications still occur. Most are minor and transient. The most common is referred to as a *febrile nonhemolytic reaction*, which takes the form of fever and chills, sometimes with mild dyspnea, within 6 hours of a transfusion of red cells or platelets. It is thought that these reactions are caused by inflammatory mediators derived from donor leukocytes. The frequency of these reactions increases with the storage age of the product and is decreased by measures that limit donor leukocyte contamination. Symptoms respond to anti-pyretics and are short-lived.

Other transfusion reactions are uncommon or rare, but can have severe and sometimes fatal consequences, and therefore merit brief discussion.

ALLERGIC REACTIONS

Severe, potentially fatal allergic reactions may occur when blood products containing certain antigens are given to previously sensitized recipients. These are most likely to occur in patients with IgA deficiency, which has a frequency of 1:300 to 1:500 people. The reaction is triggered by IgG antibodies that recognize IgA in the infused blood product. Fortunately, most patients with IgA deficiency do not develop such antibodies, and these severe reactions are rare, occurring in 1 in 20,000 to 1 in 50,000 transfusions. *Urticarial allergic reactions* may be triggered by the presence of an allergen in the donated blood product that is recognized by IgE antibodies in the recipient. These are more common, occurring in 1% to 3% of transfusions, but they are generally mild.

HEMOLYTIC REACTIONS

***Acute hemolytic reactions* usually are caused by preformed IgM antibodies against donor red cells that fix complement.** They most commonly stem from an error in patient identification or tube labeling that allows a patient to receive an ABO incompatible unit of blood. Preexisting "natural" IgM antibodies, usually against blood group antigens A or B, bind to red cells and rapidly induce complement-mediated lysis, intravascular hemolysis, and hemoglobinuria associated with fever, shaking chills, and flank pain. The direct Coombs test is positive unless all of the donor red cells have lysed. The signs and symptoms are due to complement activation rather than hemolysis per se, as osmotic lysis of red cells (e.g., by mistakenly infusing red cells and 5% dextrose in water simultaneously) produces hemoglobinuria without any other symptoms. In severe cases the process may rapidly progress to DIC, shock, renal failure, and death.

***Delayed hemolytic reactions* are caused by antibodies that recognize red cell antigens that the recipient was sensitized to previously, for example, through a**

previous blood transfusion. These are typically caused by IgG antibodies and are associated with a positive direct Coombs test and laboratory features of hemolysis (e.g., low haptoglobin and elevated LDH). Antibodies to antigens such as Rh, Kell, and Kidd sometimes fix complement, resulting in severe and potentially fatal reactions identical to those seen with ABO mismatches. Other antibodies that do not fix complement typically result in extravascular hemolysis and relatively minor signs and symptoms.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (**TRALI**) **is a severe, frequently fatal complication in which factors in a transfused blood product trigger the activation of neutrophils in the lung microvasculature.** The incidence is low, probably less than 1 per 10,000 transfusions. Current thinking about TRALI favors a "two hit" hypothesis. The first hit is an exposure that activates endothelial cells in pulmonary capillaries. This "priming" event has diverse causes, including smoking, sepsis, and shock, and leads to sequestration of neutrophils. The primed neutrophils are then activated by a factor present in the transfused blood product, which constitutes the second hit.

The leading "second hit" candidate is an antibody in the transfused blood product that recognizes antigens expressed on neutrophils. By far the most common antibodies associated with TRALI are those that bind major histocompatibility complex (MHC) class I antigens. These antibodies are often found in multiparous women, in whom they are generated in response to foreign MHC antigens expressed by the fetus. Indeed, measures to exclude multiparous women from plasma donation have resulted in the incidence of TRALI being cut in half. The presentation is dramatic, with sudden onset of respiratory failure associated with diffuse bilateral pulmonary infiltrates during or soon after a transfusion. The treatment is largely supportive and the outcome is guarded; mortality is 5% in uncomplicated cases and up to 67% in those who are severely ill.

INFECTIOUS COMPLICATIONS

Virtually any infectious agent can be transmitted through blood products, but bacterial and viral infections are most likely to be so. Significant bacterial contamination (sufficient to produce symptoms) is much more common in platelet preparations than red cell preparations, because of the fact that platelets (unlike red cells) must be stored at room temperature, which favors growth of bacterial contaminants. Rates of bacterial infection secondary to platelet transfusion can be as high as 1 in 5000. Many of the symptoms (fever, chills, hypotension) resemble those of transfusion reactions, and it may be necessary to start broad-spectrum antibiotics prospectively in symptomatic patients while awaiting laboratory results.

Advances in donor selection, donor screening, and infectious disease testing have dramatically decreased the incidence of viral transmission by blood products. However on rare occasions when the donor is acutely infected, there can still be transfusion-related transmission of viruses. Rates of transmission of HIV, hepatitis C, and hepatitis B are estimated to be 1 in 2 million, 1 in 1 million, and 1 in 500,000, respectively. There also remains a low risk of "exotic" infectious agents such as West Nile virus, trypanosomiasis, and babesiosis.

Disorders of the Spleen and Thymus

SPLENOMEGALY

The spleen is frequently involved in a wide variety of systemic diseases. In virtually all instances the spleen responds by enlarging (splenomegaly), an alteration that produces a set of stereotypical signs and symptoms. Evaluation of splenic enlargement is aided by recognition of the usual limits of splenomegaly produced by specific disorders. It would be erroneous to attribute an enlarged spleen pushing into the pelvis to vitamin B_{12} deficiency, or to entertain a diagnosis of CML in the absence of splenomegaly. Disorders may be grouped according to the degree of splenomegaly that they characteristically produce:

- *Massive splenomegaly* (weight > 1000 g)
  Myeloproliferative neoplasms (CML, primary myelofibrosis); certain indolent leukemias (CLL and hairy cell leukemia); many lymphomas; infectious diseases (e.g., malaria); Gaucher disease
- *Moderate splenomegaly* (weight 500–1000 g)
  Chronic congestive splenomegaly (portal hypertension or splenic vein obstruction); acute leukemias; disorders with extravascular hemolysis (hereditary spherocytosis, thalassemia major, autoimmune hemolytic anemia; amyloidosis; Niemann-Pick disease; many infections, including infective endocarditis, tuberculosis, and typhoid; sarcoidosis; metastatic carcinoma or sarcoma
- *Mild splenomegaly* (weight < 500 g)
  Acute splenitis; acute splenic congestion; infectious mononucleosis; miscellaneous disorders, including septicemia, systemic lupus erythematosus, and intraabdominal infections

The microscopic changes associated with these diseases are discussed in the relevant sections of this and other chapters.

A chronically enlarged spleen often removes excessive numbers of one or more of the formed elements of blood, resulting in anemia, leukopenia, or thrombocytopenia. This is referred to as *hypersplenism*, a state that can be associated with many of the diseases listed previously. In addition, platelets are particularly susceptible to sequestration in the interstices of the red pulp; as a result, *thrombocytopenia* is

more prevalent and severe in persons with splenomegaly than is anemia or neutropenia.

DISORDERS OF THE THYMUS

As is well known, the thymus has a crucial role in T cell differentiation. It is not surprising, therefore, that the thymus can be involved by lymphomas, particularly those of T cell lineage (discussed earlier in this chapter). The focus here is on the two most frequent (albeit still uncommon) disorders of the thymus: thymic hyperplasia and thymoma.

Thymic Hyperplasia

Thymic enlargement often is associated with the presence of lymphoid follicles, or germinal centers, within the medulla. These germinal centers contain reactive B cells, which are only present in small numbers in normal thymuses. Thymic follicular hyperplasia is found in most patients with *myasthenia gravis* and sometimes also occurs in other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis. The relationship between the thymus and myasthenia gravis is discussed in Chapter 22. Of significance, removal of the hyperplastic thymus is often beneficial early in the disease.

Thymoma

Thymomas are tumors of thymic epithelial cells. Several classification systems for thymoma based on cytologic and biologic criteria have been proposed. One simple and clinically useful classification is as follows:

- Benign or encapsulated thymoma: cytologically and biologically benign
- Malignant thymoma
  - *Type I*: cytologically benign but infiltrative and locally aggressive
  - *Type II* (thymic carcinoma): cytologically and biologically malignant

MORPHOLOGY

Macroscopically, thymomas are lobulated, firm, gray-white masses up to 15 to 20 cm in dimension. Most appear encapsulated, but 20% to 25% penetrate the capsule and infiltrate perithymic tissues. Microscopically, virtually all thymomas are composed of a mixture of epithelial tumor cells and nonneoplastic thymocytes (immature T cells). In **benign thymomas,** the epithelial cells are spindled or elongated and resemble those that normally populate the medulla. As a result, these are sometimes referred to as **medullary thymomas.** In other tumors, there is an admixture of the plumper, rounder, cortical-type epithelial cells; this pattern is sometimes referred to as a mixed thymoma. The medullary and mixed patterns account for 60% to 70% of all thymomas.

Malignant thymoma type I is cytologically bland but locally invasive; it accounts for 20% to 25% of all thymomas. These tumors also occasionally (and unpredictably) metastasize. They are composed of varying proportions of epithelial cells and reactive thymocytes. The epithelial cells usually have abundant cytoplasm and rounded vesicular nuclei, an appearance similar to normal thymic cortical epithelial cells; spindled epithelial cells are sometimes present as well. The epithelial cells often palisade around blood vessels. The critical distinguishing feature is the penetration of the capsule with the invasion of surrounding structures.

Malignant thymoma type II is perhaps better thought of as a form of thymic carcinoma. These tumors account for about 5% of thymomas. Macroscopically, they usually are fleshy, obviously invasive masses that often metastasize to such sites as the lungs. Microscopically, most resemble squamous cell carcinoma.

Clinical Features

Thymomas are rare. They may arise at any age, but most occur in middle-aged adults. In a large series about 30% were asymptomatic; 30% to 40% produced local manifestations such as cough, dyspnea, and superior vena cava syndrome; and the remainder were associated with a systemic disease, most commonly myasthenia gravis, in which a concomitant thymoma is discovered in 15% to 20% of patients. Removal of the tumor often leads to improvement of the neuromuscular disorder. In addition to myasthenia gravis , thymomas may be associated with several other pareneoplastic syndromes. These include in rough order of frequency , pure red cell aplasia, hypogammaglobulinemia, and multi organ autoimmunity. The latter bears resemblance with graft versus host disease.

CHAPTER

Lung 13

CHAPTER OUTLINE

The major function of the lung is to replenish oxygen and remove carbon dioxide from blood. Developmentally, the respiratory system is an outgrowth from the ventral wall of the foregut. The midline trachea develops two lateral outpouchings, the lung buds. The right lung bud eventually divides into three main bronchi, and the left into two main bronchi, thus giving rise to three lobes on the right and two on the left. The main bronchi branch dichotomously, giving rise to progressively smaller airways, termed *bronchioles,* which are distinguished from bronchi by the lack of cartilage and submucosal glands within their walls. Additional branching of bronchioles leads to *terminal bronchioles*; the part of the lung distal to the terminal bronchiole is called an *acinus*. Pulmonary acini are composed of *respiratory bronchioles* (emanating from the terminal bronchiole) that proceed into *alveolar ducts,* which immediately branch into *alveolar sacs,* the blind ends of the respiratory passages, whose walls are formed entirely of *alveoli,* the ultimate site of gas exchange. The alveolar walls (or alveolar septa) consist of the following components, proceeding from blood to air (Fig. 13.1):

- *The capillary endothelium and basement membrane.*
- *The pulmonary interstitium,* composed of fine elastic fibers, small bundles of collagen, a few fibroblast-like cells, smooth muscle cells, mast cells, and rare mononuclear cells.
- *Alveolar epithelium,* consisting of a continuous layer of two principal cell types: flattened, plate-like type I pneumocytes covering 95% of the alveolar surface; and rounded type II pneumocytes. The latter synthesize pulmonary surfactant and are the main cell type involved in repair of alveolar epithelium after damage to type I pneumocytes.

A few alveolar macrophages usually lie free within the alveolar space. In the city dwellers, these macrophages often contain phagocytosed carbon particles.

Lung diseases can broadly be divided into those affecting (1) the airways, (2) the interstitium, and (3) the pulmonary vascular system. This division into discrete compartments is, of course, deceptively simple. In reality, disease in one compartment often causes secondary alterations of morphology and function in others.

ATELECTASIS (COLLAPSE)

Atelectasis, also known as collapse, is loss of lung volume caused by inadequate expansion of air spaces. It results in shunting of inadequately oxygenated blood from pulmonary arteries into veins, thus giving rise to a ventilation-perfusion imbalance and hypoxia. On the basis of the

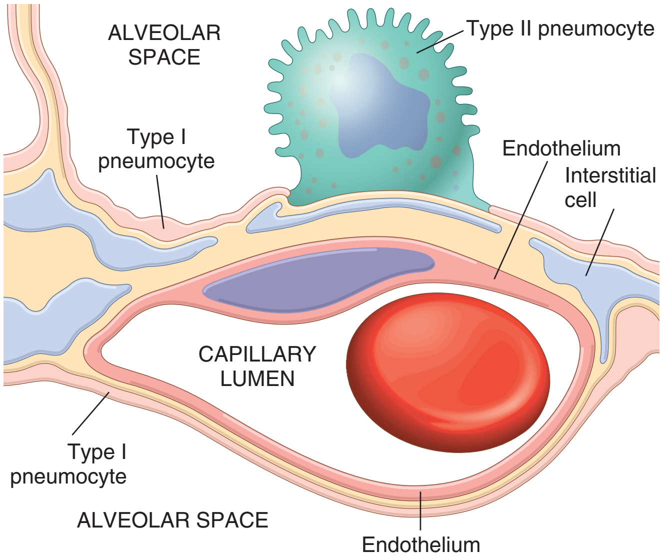

Fig. 13.1 Microscopic structure of the alveolar wall. Note that the basement membrane *(yellow)* is thin on one side and widened where it is continuous with the interstitial space.

underlying mechanism and the distribution of alveolar collapse, atelectasis is classified into three forms

- *Resorption atelectasis* occurs when an obstruction prevents air from reaching distal airways. Any air present gradually becomes absorbed, and alveolar collapse follows. The most common cause of resorption collapse is obstruction of a bronchus. Resorption atelectasis most frequently occurs postoperatively due to intrabronchial mucous or mucopurulent plugs, but also may result from foreign body aspiration (particularly in children), bronchial asthma, bronchiectasis, chronic bronchitis, or intrabronchial tumor, in which it may be the first sign of malignancy.
- *Compression atelectasis* is usually associated with accumulation of fluid, blood, or air within the pleural cavity. A frequent cause is pleural effusions occurring in the setting of congestive heart failure. Leakage of air into the pleural cavity (pneumothorax) also leads to compression atelectasis. Basal atelectasis resulting from a failure to breath deeply commonly occurs in bedridden patients, in patients with ascites, and during and after surgery.
- *Contraction atelectasis* (or cicatrization atelectasis) occurs when local or diffuse fibrosis affecting the lung or the pleura hamper lung expansion.

Atelectasis (except when caused by contraction) is potentially reversible and should be treated promptly to prevent hypoxemia and superimposed infection of the collapsed lung.

ACUTE RESPIRATORY DISTRESS SYNDROME

The epidemiology and definition of acute respiratory distress syndrome (ARDS) are evolving. Formerly considered to be the severe end of a spectrum of acute lung injury, it is now defined as respiratory failure occurring within 1 week of a known clinical insult with bilateral opacities on chest imaging, not fully explained by effusions, atelectasis, cardiac failure, or fluid overload. It is graded based on the severity of the changes in arterial blood oxygenation. Causes are diverse; the shared feature is that all lead to extensive bilateral injury to alveoli.

Severe ARDS is characterized by rapid onset of life-threatening respiratory insufficiency, cyanosis, and severe arterial hypoxemia that is refractory to oxygen therapy. The histologic manifestation of ARDS in the lungs is known as *diffuse alveolar damage (DAD).* ARDS may occur in a multitude of clinical settings and is associated with primary pulmonary diseases and severe systemic inflammatory disorders such as sepsis. The most frequent triggers of ARDS are pneumonia (35%–45%) and sepsis (30%–35%), followed by aspiration, trauma (including brain injury, abdominal surgery, and multiple fractures), pancreatitis, and transfusion reactions. ARDS should not be confused with respiratory distress syndrome of the newborn; the latter is caused by a deficiency of surfactant caused by prematurity.

Pathogenesis

In ARDS, the integrity of the alveolar-capillary membrane is compromised by endothelial and epithelial injury. Most work suggests that ARDS stems from an inflammatory reaction initiated by a variety of pro-inflammatory mediators (Fig. 13.2). As early as 30 minutes after an acute insult, there is increased synthesis of interleukin 8 (IL-8), a potent neutrophil chemotactic and activating agent, by pulmonary macrophages. Release of IL-8 and other factors, such as IL-1 and tumor necrosis factor (TNF), leads to endothelial activation and sequestration and activation of neutrophils in pulmonary capillaries. Neutrophils are thought to have an important role in the pathogenesis of ARDS. Histologic examination of lungs early in the disease process shows increased numbers of neutrophils within the vascular space, the interstitium, and the alveoli. Activated neutrophils release a variety of products (e.g., reactive oxygen species, proteases) that damage the alveolar epithelium and endothelium. The assault on the endothelium and epithelium causes vascular leakiness and loss of surfactant that render the alveolar unit unable to expand. Of note, the destructive forces unleashed by neutrophils can be counteracted by an array of endogenous anti-proteases and anti-oxidants that are upregulated by proinflammatory cytokines. In the end, it is the balance between the destructive and protective factors that determines the degree of tissue injury and clinical severity of the ARDS.

MORPHOLOGY

In the **acute phase of ARDS,** the lungs are dark red, firm, airless, and heavy. Microscopic examination reveals capillary congestion, necrosis of alveolar epithelial cells, interstitial and intra-alveolar edema and hemorrhage, and (particularly with sepsis) collections of neutrophils in capillaries. The most characteristic finding is the presence of **hyaline membranes,** particularly

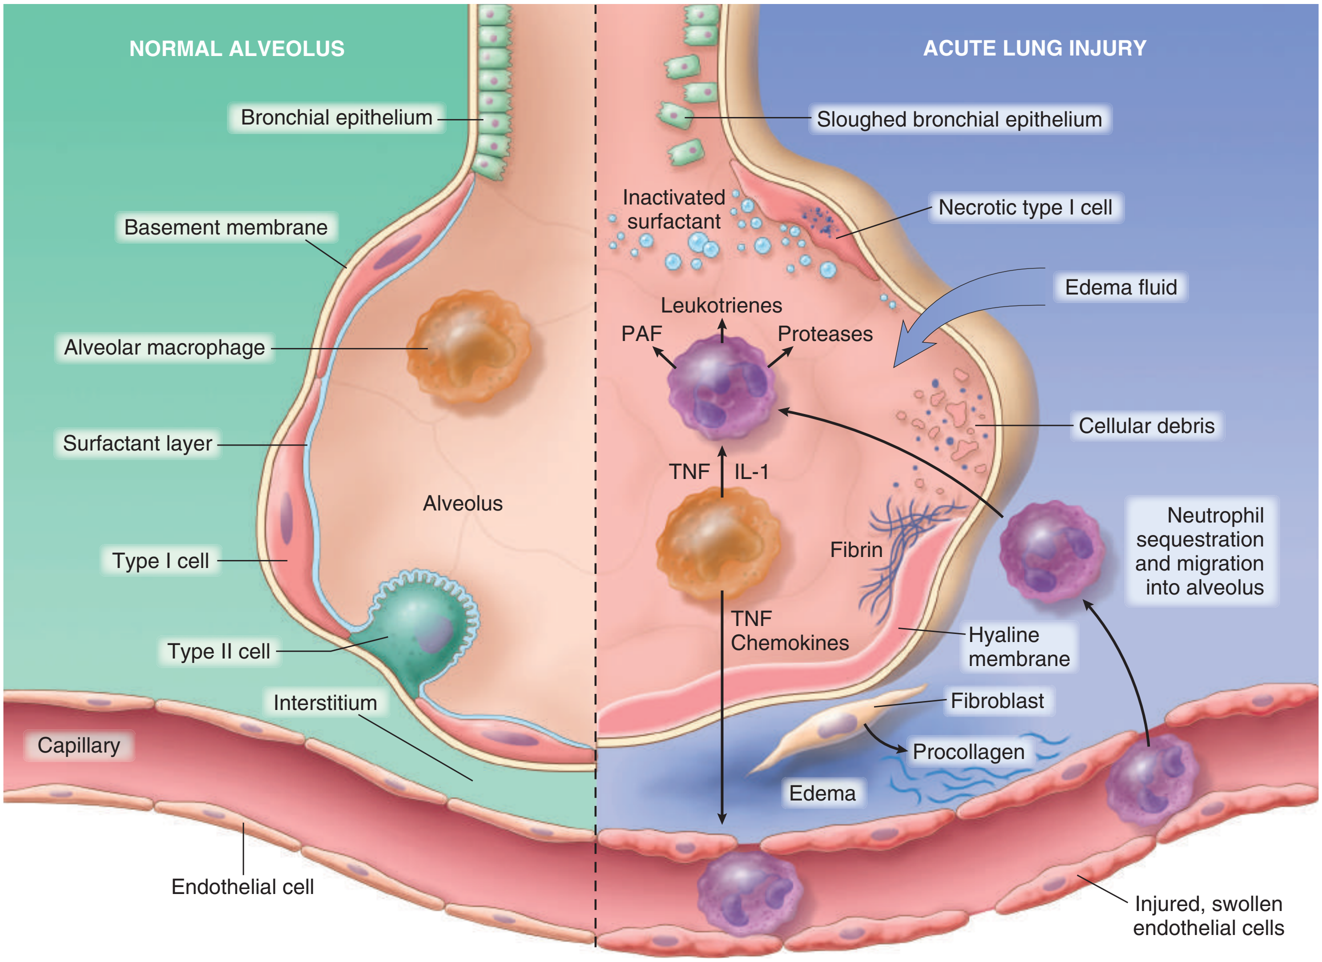

Fig. 13.2 The normal alveolus *(left)* and the injured alveolus in the early phase of acute lung injury and the acute respiratory distress syndrome. Under the influence of proinflammatory cytokines such as interleukins IL-8 and IL-1 and tumor necrosis factor (TNF) (released by macrophages), neutrophils are sequestered in the pulmonary microvasculature and then egress into the alveolar space, where they undergo activation. Activated neutrophils release leukotrienes, oxidants, proteases, and platelet-activating factor (PAF), which contribute to local tissue damage, accumulation of edema fluid, surfactant inactivation, and hyaline membrane formation. Subsequently, the release of macrophage-derived fibrogenic cytokines such as transforming growth factor-β (TGF-β) and platelet-derived growth factor (PGDF) stimulate fibroblast growth and collagen deposition associated with the healing phase of injury. *(Modified from Ware LB: Pathophysiology of acute lung injury and the acute respiratory distress syndrome,* Semin Respir Crit Care Med *27:337, 2006.)*

lining the distended alveolar ducts (Fig. 13.3). Such membranes consist of fibrin-rich edema fluid admixed with remnants of necrotic epithelial cells. Overall, the picture is remarkably similar to that seen in respiratory distress syndrome of the newborn (Chapter 6). In the **organizing stage,** type II pneumocytes proliferate vigorously in an attempt to regenerate the alveolar lining. Resolution is unusual; more commonly, the fibrin-rich exudates organize into intraalveolar fibrosis. Marked thickening of the alveolar septa ensues due to proliferation of interstitial cells and deposition of collagen.

Clinical Features

The clinical syndrome of acute lung injury or ARDS affects approximately 190,000 patients per year in the United States. In 85% of cases, it develops within 72 hours of the initial insult. The overall hospital mortality rate is 38.5% (27%, 32%, and 45% for mild, moderate, and severe ARDS, respectively). Predictors of poor prognosis include advanced age, bacteremia (sepsis), and the development of multiorgan failure. Most patients who survive the acute insult recover normal respiratory function within 6 to 12 months, but the rest develop diffuse interstitial fibrosis leading to chronic respiratory insufficiency.

SUMMARY

ACUTE RESPIRATORY DISTRESS SYNDROME

- ARDS is a clinical syndrome of progressive respiratory insufficiency caused by diffuse alveolar damage in the setting of sepsis, severe trauma, or diffuse pulmonary infection.
- Neutrophils and their products have a crucial role in the pathogenesis of ARDS by causing endothelial and epithelial injury.
- The characteristic histologic picture is that of alveolar edema, epithelial necrosis, accumulation of neutrophils, and presence of hyaline membranes lining the alveolar wall and ducts.

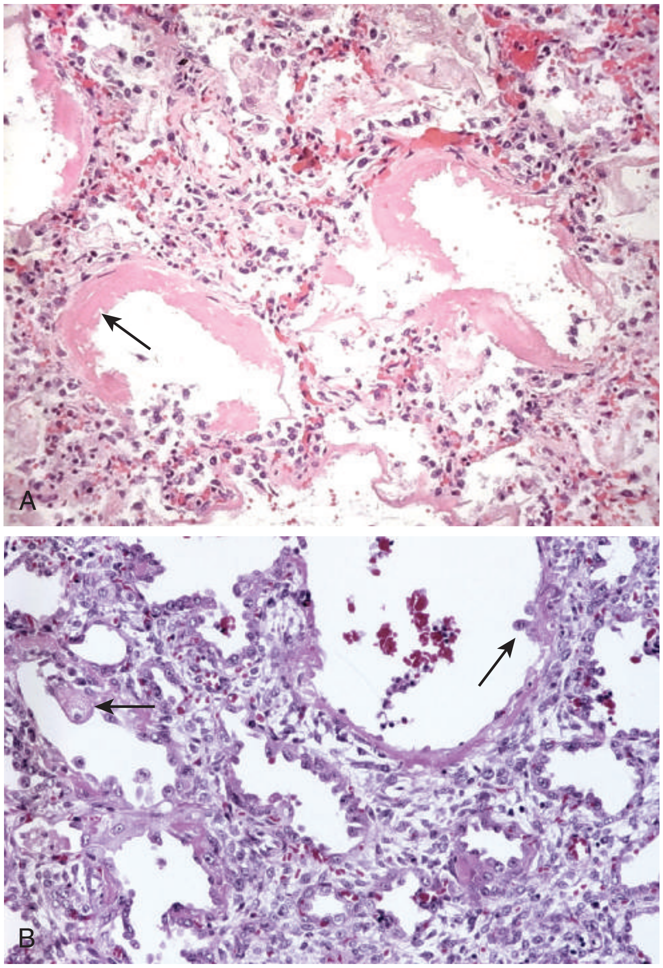

Fig. 13.3 Acute lung injury and acute respiratory distress syndrome. (A) Diffuse alveolar damage in the acute phase. Some alveoli are collapsed, while others are distended; many are lined by bright pink hyaline membranes *(arrow)*. (B) The healing stage is marked by resorption of hyaline membranes and thickening of alveolar septa by inflammatory cells, fibroblasts, and collagen. Numerous reactive type II pneumocytes also are seen at this stage *(arrows)*, associated with regeneration and repair.

OBSTRUCTIVE VERSUS RESTRICTIVE PULMONARY DISEASES

Diffuse pulmonary diseases can be classified into two categories: (1) obstructive (airway) disease, characterized by an increase in resistance to air flow caused by partial or complete obstruction at any level; and (2) restrictive disease, characterized by reduced expansion of lung parenchyma and decreased total lung capacity.

The major diffuse obstructive disorders are emphysema, chronic bronchitis, bronchiectasis, and asthma. In patients with these diseases, forced vital capacity (FVC) is either normal or slightly decreased, while the expiratory flow rate, usually measured as the forced expiratory volume at 1 second (FEV_1), is significantly decreased. Thus, the ratio of FEV to FVC is characteristically decreased. Expiratory obstruction may result from anatomic airway narrowing, classically observed in asthma, or from loss of elastic recoil, characteristic of emphysema.

By contrast, in diffuse restrictive diseases, FVC is reduced and the expiratory flow rate is normal or reduced proportionately. Hence, the ratio of FEV to FVC is near normal. Restrictive defects occur in two general conditions: (1) chest wall disorders in the presence of normal lungs (e.g., with severe obesity, diseases of the pleura, and neuromuscular disorders, such as the Guillain-Barré syndrome [Chapter 22], that affect the respiratory muscles) and (2) acute or chronic interstitial lung diseases. The classic acute restrictive disease is ARDS, discussed earlier. Chronic restrictive diseases (discussed later) include the pneumoconioses, interstitial fibrosis of unknown etiology, and infiltrative conditions such as sarcoidosis.

OBSTRUCTIVE LUNG (AIRWAY) DISEASES

In their prototypical forms, the four disorders in this group—emphysema, chronic bronchitis, asthma, and bronchiectasis—have distinct clinical and anatomic characteristics (Table 13.1), but overlaps between emphysema, chronic bronchitis, and asthma are common.

It should be noted that emphysema is defined on the basis of morphologic and radiologic features, whereas chronic bronchitis is defined on the basis of clinical features (described later). The anatomic distribution of these disorders also is somewhat different, as chronic bronchitis initially involves the large airways, whereas emphysema affects the acinus. In severe or advanced cases of both, small airway disease (chronic bronchiolitis) is also present. Although emphysema may exist without chronic bronchitis (particularly in inherited α1-anti-trypsin deficiency, discussed later) and vice versa, the two diseases usually coexist. This is almost certainly because cigarette smoking is the major underlying cause of both. In view of their propensity to coexist, emphysema and chronic bronchitis often are grouped together under the rubric of *chronic obstructive pulmonary disease (COPD)*. COPD affects more than 10% of the U.S. adult population and is the fourth leading cause of death in this country. The largely irreversible airflow obstruction of COPD distinguishes it from asthma, which, as discussed later, is characterized by reversible airflow obstruction (Fig. 13.4).

Emphysema

Emphysema is characterized by permanent enlargement of the air spaces distal to the terminal bronchioles, accompanied by destruction of their walls without significant fibrosis. It is classified according to its anatomic distribution. As discussed earlier, the acinus is the structure distal to terminal bronchioles, and a cluster of three to five acini is called a *lobule* (Fig. 13.5A). There are four major types of emphysema: (1) centriacinar, (2) panacinar, (3) distal acinar, and (4) irregular. Only the first two types cause significant airway obstruction, with centriacinar emphysema being about 20 times more common than panacinar disease.

- *Centriacinar (centrilobular) emphysema.* **The distinctive feature of centriacinar emphysema is that the central or proximal parts of the acini, formed by respiratory**

Table 13.1 Disorders Associated With Airflow Obstruction: The Spectrum of Chronic Obstructive Pulmonary Disease

Clinical Entity	Anatomic Site	Major Pathologic Changes	Etiology	Signs/Symptoms
Chronic bronchitis	Bronchus	Mucous gland hypertrophy and hyperplasia, hypersecretion	Tobacco smoke, air pollutants	Cough, sputum production
Bronchiectasis	Bronchus	Airway dilation and scarring	Persistent or severe infections	Cough, purulent sputum, fever
Asthma	Bronchus	Smooth muscle hypertrophy and hyperplasia, excessive mucus, inflammation	Immunologic or undefined causes	Episodic wheezing, cough, dyspnea
Emphysema	Acinus	Air space enlargement, wall destruction	Tobacco smoke	Dyspnea
Small airway disease, bronchiolitis*	Bronchiole	Inflammatory scarring, partial obliteration of bronchioles	Tobacco smoke, air pollutants	Cough, dyspnea

*Can be present in all forms of obstructive lung disease or by itself.

bronchioles, are affected, while distal alveoli are spared. Thus, both emphysematous and normal air spaces exist within the same acinus and lobule (see Fig. 13.5B). The lesions are more common and severe in the upper lobes, particularly in the apical segments. In severe centriacinar emphysema, the distal acinus also becomes involved, and thus, the differentiation from panacinar emphysema becomes difficult. This type of emphysema is most common in cigarette smokers, often in association with chronic bronchitis.

- *Panacinar (panlobular) emphysema.* **In panacinar (panlobular) emphysema, the acini are uniformly enlarged,** from the level of the respiratory bronchiole to the terminal blind **alveoli** (see Fig. 13.5C). In contrast to centriacinar emphysema, panacinar emphysema occurs more commonly in the lower lung zones and is associated with α1-anti-trypsin deficiency.
- *Distal acinar (paraseptal) emphysema.* **In this form of emphysema, the proximal portion of the acinus is normal but the distal part is primarily involved.** The emphysema is more striking adjacent to the pleura, along the lobular connective tissue septa, and at the margins of the lobules. It occurs adjacent to areas of fibrosis, scarring, or atelectasis and is usually more severe in the upper half of the lungs. The characteristic finding is the presence of multiple, contiguous, enlarged air spaces ranging in diameter from less than 0.5 mm to more than 2.0 cm, sometimes forming cystic structures that, with progressive enlargement, give rise to *bullae.* The cause of this type of emphysema is unknown; it comes to attention most often in young adults who present with spontaneous pneumothorax.

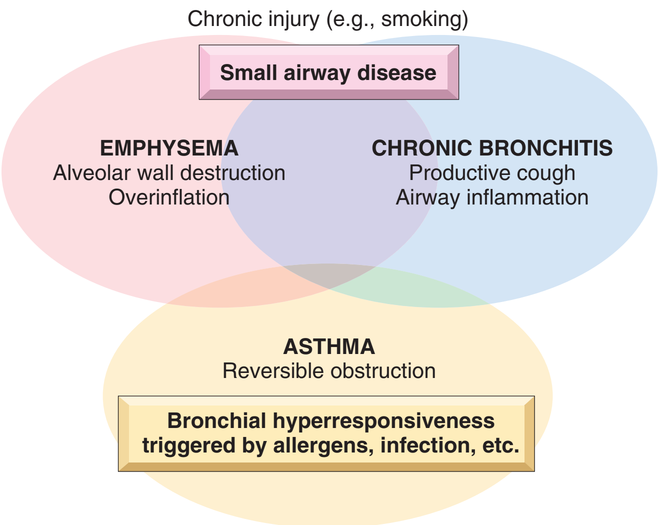

Fig. 13.4 Schematic representation of overlap between chronic obstructive lung diseases.

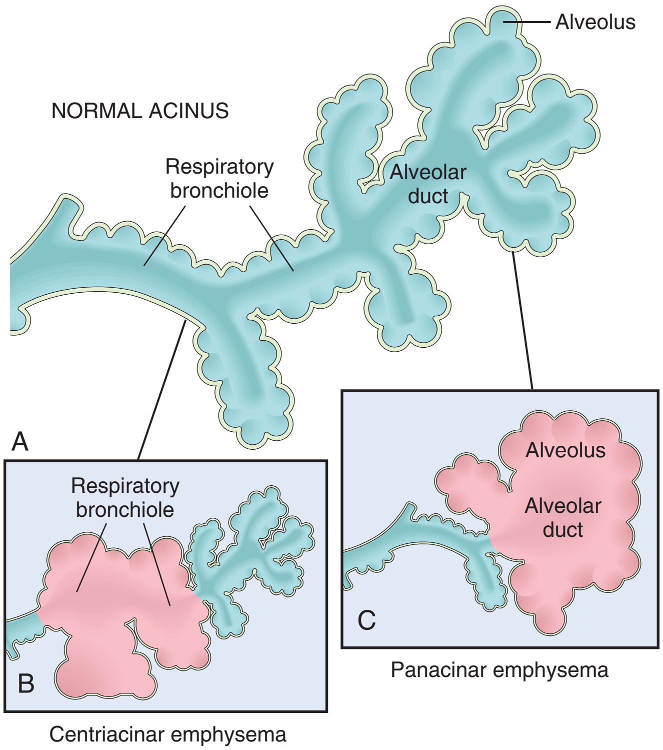

Fig. 13.5 Major patterns of emphysema. (A) Diagram of normal structure of the acinus, the fundamental unit of the lung. (B) Centriacinar emphysema with dilation that initially affects the respiratory bronchioles. (C) Panacinar emphysema with initial distention of all the peripheral structures (i.e., the alveolus and alveolar duct); the disease later extends to affect the respiratory bronchioles.

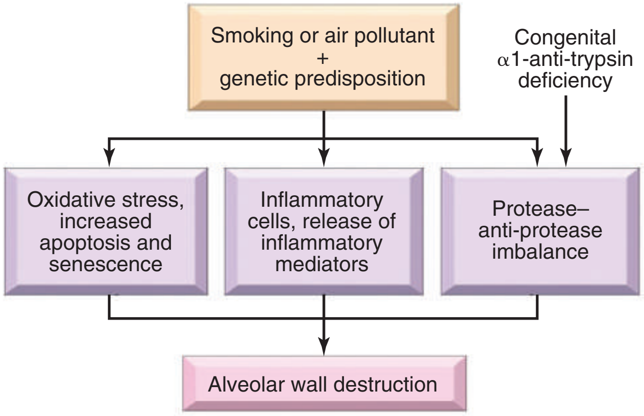

Fig. 13.6 Pathogenesis of emphysema. See text for details.

- *Irregular emphysema.* **Irregular emphysema, so named because the acinus is irregularly involved, is almost invariably associated with scarring,** such as that resulting from healed inflammatory diseases. Although clinically asymptomatic, this may be the most common form of emphysema.

Pathogenesis

Inhaled cigarette smoke and other noxious particles cause lung damage and inflammation, which, particularly in patients with a genetic predisposition, result in parenchymal destruction (emphysema) and airway disease (bronchiolitis and chronic bronchitis). Factors that influence the development of emphysema include the following (Fig. 13.6):

- *Inflammatory cells and mediators:* A wide variety of inflammatory mediators have been shown to be increased (including leukotriene B_4, IL-8, TNF, and others) that attract more inflammatory cells from the circulation (chemotactic factors), amplify the inflammatory process (proinflammatory cytokines), and induce structural changes (growth factors). The inflammatory cells present in lesions include neutrophils, macrophages, and CD4+ and CD8+ T cells. It is not known if the T cells are specific for a particular antigen or are recruited as part of inflammation.
- *Protease–anti-protease imbalance:* Several proteases are released from the inflammatory cells and epithelial cells that break down connective tissues. In patients who develop emphysema, there is a relative deficiency of protective anti-proteases (further discussed below).
- *Oxidative stress:* Reactive oxygen species are generated by cigarette smoke and other inhaled particles and released from activated inflammatory cells such as macrophages and neutrophils. These cause additional tissue damage and inflammation (Chapter 3).
- *Airway infection:* Although infection is not thought to play a role in the initiation of tissue destruction, bacterial and/or viral infections cause acute exacerbations.

The idea that proteases are important is based in part on the observation that patients with a genetic deficiency of the anti-protease α1-anti-trypsin have a predisposition to develop pulmonary emphysema, which is compounded by smoking. About 1% of all patients with emphysema have this defect. α1-anti-trypsin, normally present in serum, tissue fluids, and macrophages, is a major inhibitor of proteases (particularly elastase) secreted by neutrophils during inflammation. α1-anti-trypsin is encoded by a gene in the proteinase inhibitor *(Pi)* locus on chromosome 14. The *Pi* locus is polymorphic, and approximately 0.012% of the U.S. population is homozygous for the *Z* allele, a genotype that is associated with markedly decreased serum levels of α1-anti-trypsin. More than 80% of these individuals develop symptomatic panacinar emphysema, which occurs at an earlier age and is of greater severity if the individual smokes.

Protease-mediated damage of extracellular matrix has a central role in the airway obstruction seen in emphysema. Small airways are normally held open by the elastic recoil of the lung parenchyma, and the loss of elastic tissue in the walls of alveoli that surround respiratory bronchioles reduces radial traction and thus causes the respiratory bronchioles to collapse during expiration. This leads to functional airflow obstruction despite the absence of mechanical obstruction.

MORPHOLOGY

The diagnosis and classification of emphysema depend largely on the macroscopic appearance of the lung. Typical **panacinar emphysema** produces pale, voluminous lungs that often obscure the heart when the anterior chest wall is removed at autopsy. The macroscopic features of **centriacinar emphysema** are less impressive. Until late stages, the lungs are a deeper pink than in panacinar emphysema and less voluminous, and the upper two-thirds of the lungs are more severely affected than the lower lungs. Histologic examination reveals **destruction of alveolar walls without fibrosis, leading to enlarged air spaces** (Fig. 13.7). In addition to alveolar loss, the number of alveolar capillaries is diminished. Terminal and respiratory bronchioles may be deformed because of the loss of septa that help

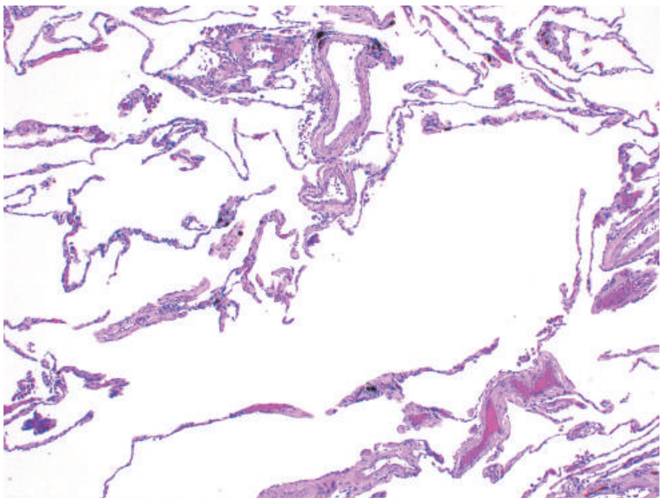

Fig. 13.7 Pulmonary emphysema. There is marked enlargement of the air spaces, with destruction of alveolar septa but without fibrosis. Note the presence of black anthracotic pigment.

tether these structures in the parenchyma. With the **loss of elastic tissue** in the surrounding alveolar septa, radial traction on the small airways is reduced. As a result, they tend to collapse during expiration—an important cause of chronic airflow obstruction in severe emphysema. Bronchiolar inflammation and submucosal fibrosis are consistently present in advanced disease.

Clinical Features

Dyspnea usually is the first symptom; it begins insidiously but is steadily progressive. In patients with underlying chronic bronchitis or chronic asthmatic bronchitis, cough and wheezing may be the initial complaints. Weight loss is common and may be severe enough to suggest an occult malignant tumor. Pulmonary function tests reveal reduced FEV_1 with normal or near-normal FVC. Hence, the FEV_1 to FVC ratio is reduced.

The classic presentation of emphysema with no "bronchitic" component is one in which the patient is barrel-chested and dyspneic, with obviously prolonged expiration, sitting forward in a hunched-over position. In these patients, air space enlargement is severe and diffusing capacity is low. Dyspnea and hyperventilation are prominent, so that until very late in the disease, gas exchange is adequate and blood gas values are relatively normal. Because of prominent dyspnea and adequate oxygenation of hemoglobin, these patients sometimes are sometimes called "pink puffers."

At the other end of the clinical spectrum is a patient with emphysema who also has pronounced chronic bronchitis and a history of recurrent infections. Dyspnea usually is less prominent, and in the absence of increased respiratory drive the patient retains carbon dioxide, becoming hypoxic and often cyanotic. For unclear reasons, such patients tend to be obese—hence the designation "blue bloaters."

In most patients with COPD the symptoms fall in between these two extremes. Hypoxia-induced pulmonary vascular spasm and loss of pulmonary capillary surface area from alveolar destruction causes the gradual development of *secondary pulmonary hypertension,* which in 20% to 30% of patients leads to right-sided congestive heart failure (cor pulmonale, Chapter 11). Death from emphysema is related to either respiratory failure or right-sided heart failure.

Conditions Related to Emphysema

Several conditions involving abnormal airspaces or accumulations of air within the lungs or other tissues also are recognized:

- *Compensatory emphysema* describes the dilation of residual alveoli in response to loss of lung substance elsewhere, such as occurs after surgical removal of a diseased lung or lobe.
- *Obstructive overinflation* refers to expansion of the lung due to air trapping. A common cause is subtotal obstruction of an airway by a tumor or foreign object. Obstructive overinflation can be life-threatening if expansion of the affected portion produces compression of the remaining normal lung.
- *Bullous emphysema* refers to any form of emphysema that produces large subpleural blebs or bullae (spaces >1 cm in diameter in the distended state) (Fig. 13.8). Such blebs represent localized accentuations of one of the four forms of emphysema; most often the blebs are subpleural, and on occasion they may rupture, leading to pneumothorax.
- *Mediastinal (interstitial) emphysema* is caused by entry of air into the interstitium of the lung, from where it may track to the mediastinum and sometimes the subcutaneous tissue. It may occur spontaneously if a sudden increase in intraalveolar pressure (as with vomiting or violent coughing) produces alveolar rupture, which allows air to dissect into the interstitium. Sometimes it develops in children with whooping cough. It may also occur in patients on respirators who have partial bronchiolar obstruction or in individuals with a perforating injury (e.g., a fractured rib). When the interstitial air gets into the subcutaneous tissue, the patient may literally blow up like a balloon, with marked swelling of the head and neck and crackling crepitation over the chest (subcutaneous emphysema). In most instances the air is resorbed spontaneously after the site of entry seals.

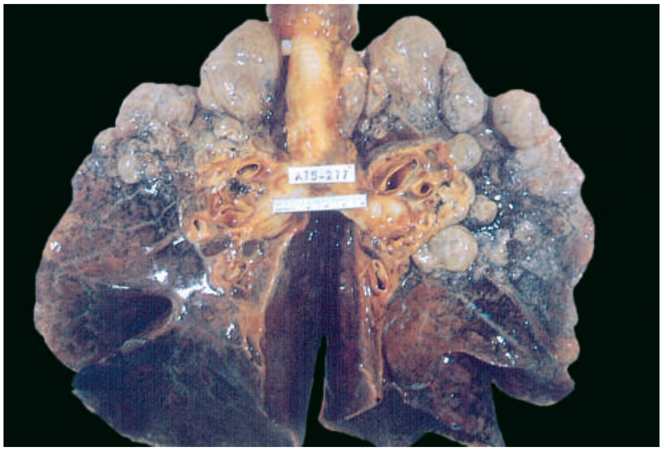

Fig. 13.8 Bullous emphysema with large apical and subpleural bullae. *(From the Teaching Collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

SUMMARY

EMPHYSEMA

- Emphysema is a chronic obstructive airway disease characterized by enlargement of air spaces distal to terminal bronchioles.
- Subtypes include centriacinar (most common: smoking-related), panacinar (seen in α_1-anti-trypsin deficiency), distal acinar, and irregular.
- Smoking and inhaled pollutants cause ongoing accumulation of inflammatory cells, which are the source of proteases such as elastases that irreversibly damage alveolar walls.
- Patients with uncomplicated emphysema present with increased chest volumes, dyspnea, and relatively normal blood oxygenation at rest ("pink puffers").
- Most patients with emphysema also have signs and symptoms of concurrent chronic bronchitis, since cigarette smoking is a risk factor for both.

Chronic Bronchitis

Chronic bronchitis is diagnosed on clinical grounds: it is defined by the presence of a persistent productive cough for at least 3 consecutive months in at least 2 consecutive years. It is common among cigarette smokers and urban dwellers in smog-ridden cities; some studies indicate that 20% to 25% of men in the 40- to 65-year-old age group have the disease. In early stages of the disease, the cough raises mucoid sputum, but airflow is not obstructed. Some patients with chronic bronchitis have evidence of hyperresponsive airways, with intermittent bronchospasm and wheezing (asthmatic bronchitis), while other bronchitic patients, especially heavy smokers, develop chronic outflow obstruction, usually with associated emphysema (COPD).

Pathogenesis

The distinctive feature of chronic bronchitis is hypersecretion of mucus, beginning in the large airways. Although the most important cause is cigarette smoking, other air pollutants, such as sulfur dioxide and nitrogen dioxide, may contribute. These environmental irritants induce hypertrophy of mucous glands in the trachea and bronchi as well as an increase in mucin-secreting goblet cells in the epithelial surfaces of smaller bronchi and bronchioles. These irritants also cause inflammation marked by the infiltration of macrophages, neutrophils, and lymphocytes. In contrast with asthma, eosinophils are not seen in chronic bronchitis. Whereas the defining mucus hypersecretion is primarily a reflection of involvement of large bronchi, the airflow obstruction in chronic bronchitis results from (1) small airway disease, induced by mucous plugging of the bronchiolar lumen, inflammation, and bronchiolar wall fibrosis, and (2) coexistent emphysema. In general, while small airway disease *(chronic bronchiolitis)* is an important component of early, mild airflow obstruction, chronic bronchitis with significant airflow obstruction almost always is complicated by emphysema.

It is postulated that many of the effects of environmental irritants on respiratory epithelium are mediated by local release of cytokines such as IL-13 from T cells and innate lymphoid cells. The transcription of the mucin gene in bronchial epithelium and the production of neutrophil elastase are increased as a consequence of exposure to tobacco smoke. Microbial infection often is present but has a secondary role, chiefly by maintaining inflammation and exacerbating symptoms.

MORPHOLOGY

As seen in gross specimens, the mucosal lining of the larger airways usually is **hyperemic and swollen** by edema fluid and is covered by a layer of mucinous or mucopurulent **secretions.** The smaller bronchi and bronchioles also may be filled with secretions. The diagnostic feature of chronic bronchitis in the trachea and larger bronchi is **enlargement of the mucus-secreting glands** (Fig. 13.9). The magnitude of the increase in size is assessed by the ratio of the thickness of the submucosal gland layer to that of the bronchial wall (the Reid index—normally 0.4). Variable numbers of inflammatory cells, largely lymphocytes and macrophages but sometimes also admixed neutrophils, are frequently seen in the bronchial mucosa. **Chronic bronchiolitis** (small airway disease), characterized by goblet cell metaplasia, mucous plugging, inflammation, and fibrosis, also is seen. In severe cases, there may be complete obliteration of the lumen as a consequence of fibrosis **(bronchiolitis obliterans).** It is the submucosal fibrosis that leads to luminal narrowing and airway obstruction. Emphysematous changes often coexist.

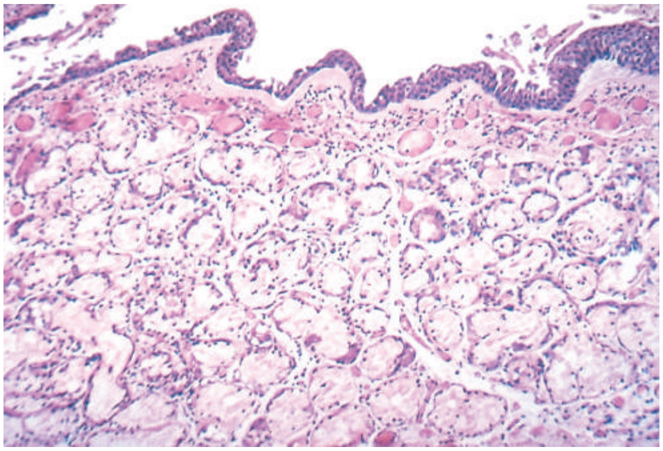

Fig. 13.9 Chronic bronchitis. The lumen of the bronchus is above. Note the marked thickening of the mucous gland layer (approximately twice-normal) and squamous metaplasia of lung epithelium. *(From the Teaching Collection of the Department of Pathology, University of Texas, Southwestern Medical School, Dallas, Texas.)*

Clinical Features

The course of chronic bronchitis is quite variable. In some patients, cough and sputum production persist indefinitely without ventilatory dysfunction, while others develop COPD with significant outflow obstruction marked by hypercapnia, hypoxemia, and cyanosis. Patients with chronic bronchitis and COPD have frequent exacerbations, more rapid disease progression, and poorer outcomes than those with emphysema alone. Progressive disease is marked by the development of pulmonary hypertension, sometimes leading to cardiac failure (Chapter 11); recurrent infections; and ultimately respiratory failure.

SUMMARY
CHRONIC BRONCHITIS

- Chronic bronchitis is defined as persistent productive cough for at least 3 consecutive months in at least 2 consecutive years.
- Cigarette smoking is the most important underlying risk factor; air pollutants also contribute.
- Chronic airway obstruction largely results from small airway disease (chronic bronchiolitis) and coexistent emphysema.
- Histologic examination demonstrates enlargement of mucus-secreting glands, goblet cell metaplasia, and bronchiolar wall fibrosis.

Asthma

Asthma is a chronic inflammatory disorder of the airways that causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or early in the morning. The hallmarks of asthma are intermittent, reversible airway obstruction; chronic bronchial inflammation with eosinophils; bronchial smooth muscle cell hypertrophy and hyperreactivity; and increased mucus secretion. Sometimes trivial stimuli are sufficient to trigger attacks in patients, because of airway hyperreactivity. Many cells play a role in the inflammatory response, in particular eosinophils, mast cells, macrophages, lymphocytes, neutrophils, and epithelial cells. Of note, asthma has increased in incidence significantly in the Western world over the past 4 decades. One explanation for this troubling trend is the *hygiene hypothesis*, according to which a lack of exposure to infectious organisms (and possibly nonpathogenic microorganisms as well) in early childhood results in defects in immune tolerance and subsequent hyperreactivity to immune stimuli later in life.

Pathogenesis

Major factors contributing to the development of asthma include genetic predisposition to type I hypersensitivity (atopy), acute and chronic airway inflammation, and bronchial hyperresponsiveness to a variety of stimuli. Asthma may be subclassified as *atopic* (evidence of allergen sensitization) or *nonatopic*. In both types, episodes of bronchospasm may be triggered by diverse exposures, such as respiratory infections (especially viral), airborne irritants (e.g., smoke, fumes), cold air, stress, and exercise. There also are varying patterns of inflammation—eosinophilic (most common), neutrophilic, mixed inflammatory, and pauci-granulocytic—that are associated with differing etiologies, immunopathologies, and responses to treatment.

The classic atopic form is associated with excessive type 2 helper T (T_H2) cell activation. Cytokines produced by T_H2 cells account for most of the features of atopic asthma—IL-4 and IL-13 stimulate IgE production, IL-5 activates eosinophils, and IL-13 also stimulates mucus production. IgE coats submucosal mast cells, which on exposure to allergen release their granule contents and secrete cytokines and other mediators. Mast cell–derived mediators produce two waves of reaction: an early (immediate) phase and a late phase (Fig. 13.10):

- The *early-phase reaction* is dominated by bronchoconstriction, increased mucus production, and vasodilation. Bronchoconstriction is triggered by mediators released from mast cells, including histamine, prostaglandin D2, and leukotrienes LTC4, D4, and E4, and also by reflex neural pathways.
- The *late-phase reaction* is inflammatory in nature. Inflammatory mediators stimulate epithelial cells to produce chemokines (including eotaxin, a potent chemoattractant and activator of eosinophils) that promote the recruitment of T_H2 cells, eosinophils, and other leukocytes, thus amplifying an inflammatory reaction that is initiated by resident immune cells.
- Repeated bouts of inflammation lead to structural changes in the bronchial wall that are collectively referred to as *airway remodeling*. These changes include hypertrophy of bronchial smooth muscle and mucus glands and increased vascularity and deposition of subepithelial collagen, which may occur as early as several years before initiation of symptoms.

Asthma tends to "run" in families, but the role of genetics in asthma is complex. Genome-wide association studies have identified a number of genetic variants associated with asthma risk, some in genes enocding factors like the IL-4 receptor that are clearly involved in asthma pathogenesis. However, the precise contribution of asthma-associated genetic variants to the development of disease remains to be determined.

Atopic Asthma

This is the most common type of asthma and is a classic example of type I IgE–mediated hypersensitivity reaction (Chapter 5). It usually begins in childhood. A positive family history of atopy and/or asthma is common, and the onset of asthmatic attacks is often preceded by allergic rhinitis, urticaria, or eczema. Attacks may be triggered by allergens in dust, pollen, animal dander, or food, or by infections. A skin test with the offending antigen results in an immediate wheal-and-flare reaction. Atopic asthma also can be diagnosed based on serum radioallergosorbent tests (RASTs) that identify the presence of IgEs that recognize specific allergens.

Non-Atopic Asthma

Patients with nonatopic forms of asthma do not have evidence of allergen sensitization, and skin test results usually are negative. A positive family history of asthma is less common. Respiratory infections due to viruses (e.g., rhinovirus, parainfluenza virus) and inhaled air pollutants (e.g., sulfur dioxide, ozone, nitrogen dioxide) are common triggers. It is thought that virus-induced inflammation of the respiratory mucosa lowers the threshold of the subepithelial vagal receptors to irritants. Although the connections are not well understood, the ultimate humoral and cellular mediators of airway obstruction (e.g., eosinophils) are common to both atopic and nonatopic variants of asthma, so they are treated in a similar way.

Drug-Induced Asthma

Several pharmacologic agents provoke asthma, aspirin being the most striking example. Patients with aspirin sensitivity present with recurrent rhinitis, nasal polyps, urticaria, and bronchospasm. The precise pathogenesis is unknown but is likely to involve some abnormality in prostaglandin metabolism stemming from inhibition of cyclooxygenase by aspirin.

Occupational Asthma

Occupational asthma may be triggered by fumes (epoxy resins, plastics), organic and chemical dusts (wood, cotton, platinum), gases (toluene), and other chemicals. Asthma attacks usually develop after repeated exposure to the inciting antigen(s).

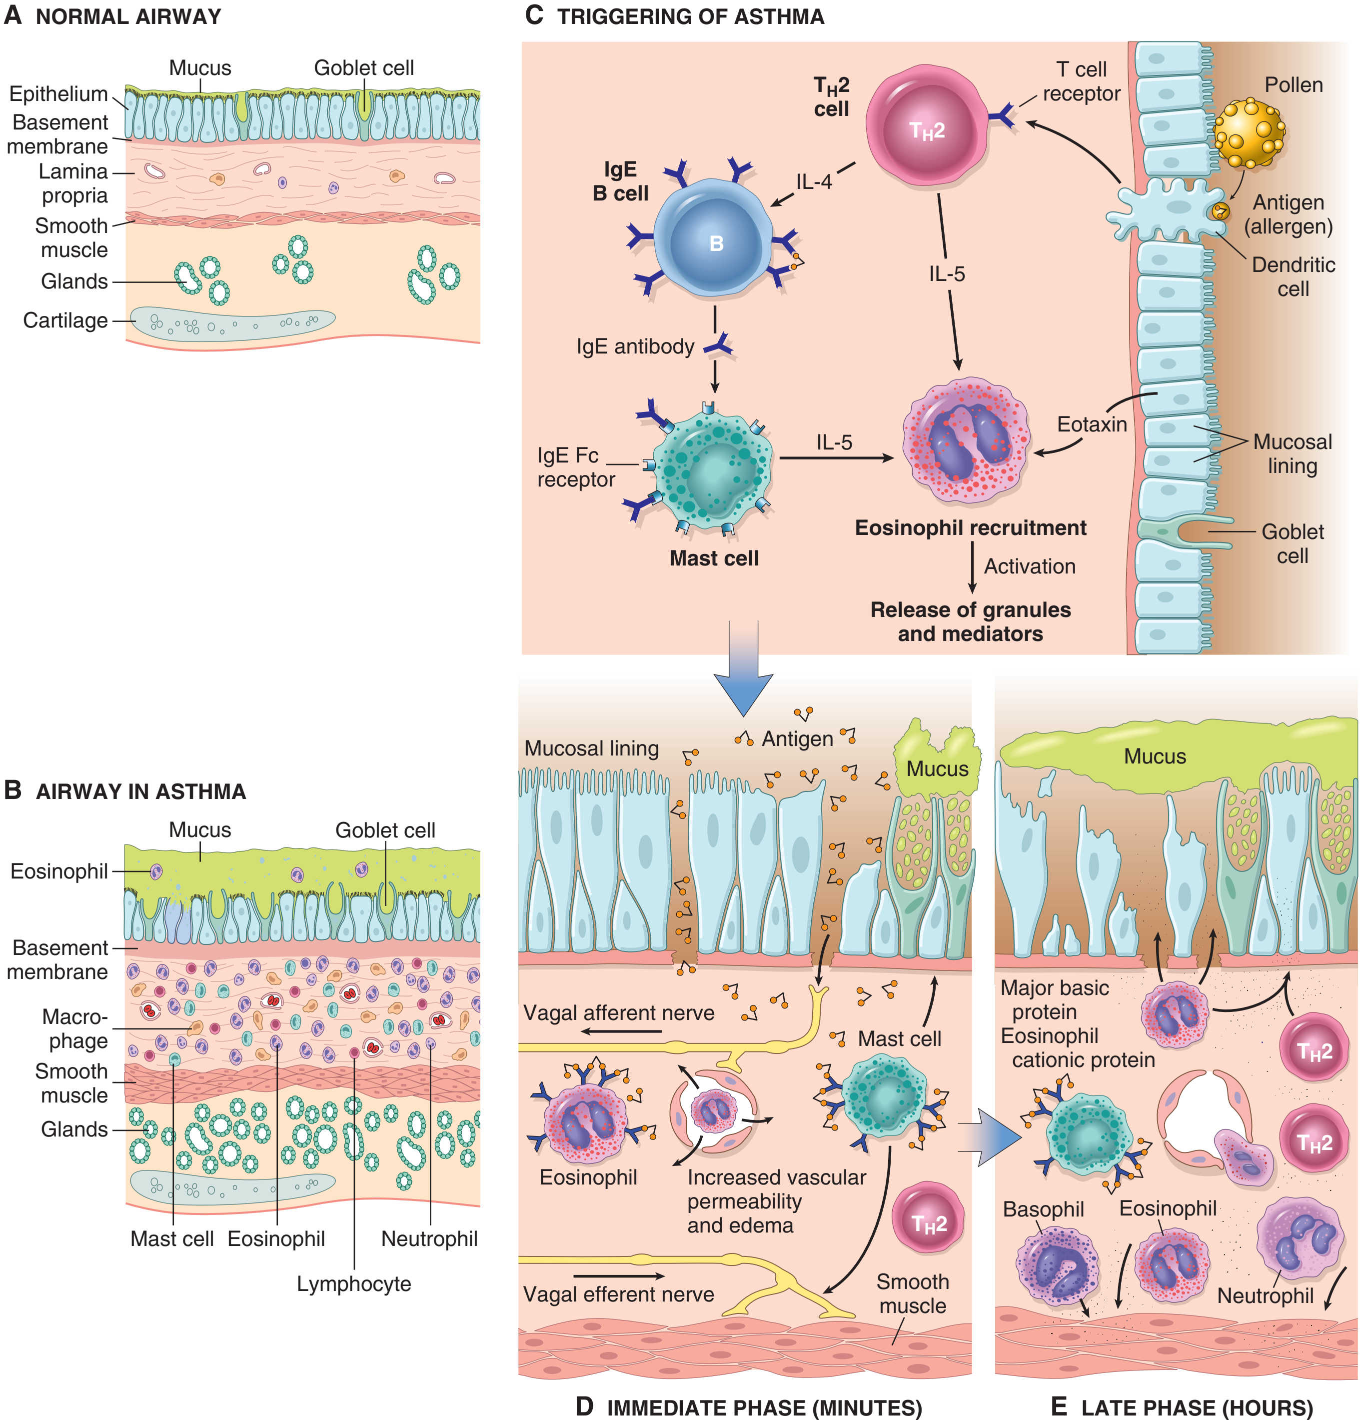

Fig. 13.10 (A and B) Comparison of a normal airway and an airway involved by asthma. The asthmatic airway is marked by accumulation of mucus in the bronchial lumen secondary to an increase in the number of mucus-secreting goblet cells in the mucosa and hypertrophy of submucosal glands; intense chronic inflammation due to recruitment of eosinophils, macrophages, and other inflammatory cells; thickened basement membrane; and hypertrophy and hyperplasia of smooth muscle cells. (C) Inhaled allergens (antigen) elicit a T_H2-dominated response favoring IgE production and eosinophil recruitment. (D) On reexposure to antigen (Ag), the immediate reaction is triggered by Ag-induced cross-linking of IgE bound to Fc receptors on mast cells. These cells release preformed mediators that directly and via neuronal reflexes induce bronchospasm, increased vascular permeability, mucus production, and recruitment of leukocytes. (E) Leukocytes recruited to the site of reaction (neutrophils, eosinophils, and basophils; lymphocytes and monocytes) release additional mediators that initiate the late phase of asthma. Several factors released from eosinophils (e.g., major basic protein, eosinophil cationic protein) also cause damage to the epithelium.

MORPHOLOGY

The morphologic changes in asthma have been described in individuals who die of prolonged severe attacks (status asthmaticus) and in mucosal biopsy specimens of individuals challenged with allergens. In fatal cases, the lungs are distended due to air trapping (overinflation), and there may be small areas of atelectasis. The most striking finding is occlusion of bronchi and bronchioles by thick, tenacious **mucous plugs** containing whorls of shed epithelium **(Curschmann spirals).** Numerous eosinophils and **Charcot-Leyden crystals** (crystalloids made up of the eosinophil protein galectin-10) also are present. Other characteristic morphologic changes in asthma (Fig. 13.10B), collectively called airway remodeling, include

- Thickening of airway wall
- Sub-basement membrane fibrosis (Fig. 13.11)
- Increased submucosal vascularity
- An increase in size of the submucosal glands and goblet cell metaplasia of the airway epithelium
- Hypertrophy and/or hyperplasia of the bronchial muscle

Clinical Features

An attack of asthma is characterized by severe dyspnea and wheezing due to bronchoconstriction and mucus plugging, which leads to trapping of air in distal airspaces and progressive hyperinflation of the lungs. In the usual case, attacks last from 1 to several hours and subside either spontaneously or with therapy. Intervals between attacks are characteristically free from overt respiratory difficulties, but persistent, subtle deficits can be detected by pulmonary function tests. Occasionally a severe paroxysm occurs that does not respond to therapy and persists for days and even weeks *(status asthmaticus)*. The associated hypercapnia, acidosis, and severe hypoxia may be fatal, although in most cases the condition is more disabling than lethal. Standard therapies include anti-inflammatory drugs, particularly glucocorticoids, and bronchodilators such as beta-adrenergic drugs and leukotriene inhibitors (recall that leukotrienes are potent bronchoconstrictors). Agents that block specific immune mediators, such as IL-4 and IL-5, are of modest benefit in some patients but are not broadly efficacious, perhaps because of disease heterogeneity. Another approach called *bronchial thermoplasty,* which involves controlled delivery of thermal energy during bronchoscopy to reduce the mass of smooth muscle and airway responsiveness, is being evaluated in patients with severe, poorly controlled asthma.

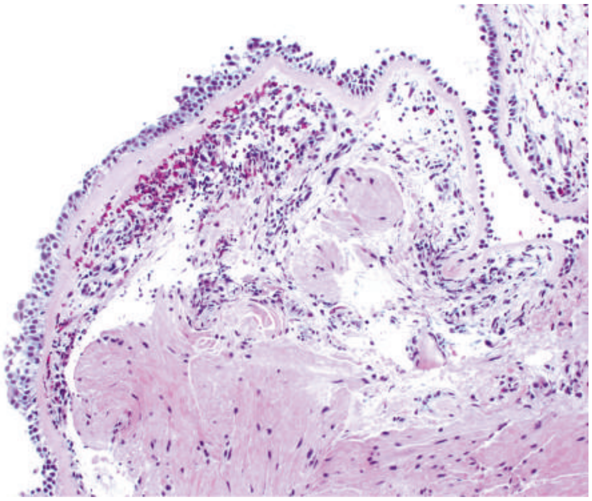

Fig. 13.11 Bronchial biopsy specimen from an asthmatic patient showing sub–basement membrane fibrosis, eosinophilic inflammation, and smooth muscle hyperplasia.

SUMMARY

ASTHMA

- Asthma is characterized by reversible bronchoconstriction caused by airway hyperresponsiveness to a variety of stimuli.
- Atopic asthma most often is caused by a T_H2 and IgE-mediated immunologic reaction to environmental allergens and is characterized by early-phase (immediate) and late-phase reactions. The T_H2 cytokines IL-4, IL-5, and IL-13 are important mediators. Non-T_H2 inflammation also has roles in atopic asthma that are being defined.
- Triggers for nonatopic asthma are less clear but include viral infections and inhaled air pollutants, which also can trigger atopic asthma.
- Eosinophils are key inflammatory cells found in almost all subtypes of asthma; eosinophil products (such as major basic protein) are responsible for airway damage.
- Airway remodeling (sub-basement membrane thickening and hypertrophy of bronchial glands and smooth muscle) adds an irreversible component to the obstructive disease.

Bronchiectasis

Bronchiectasis is the permanent dilation of bronchi and bronchioles caused by destruction of smooth muscle and the supporting elastic tissue; it typically results from or is associated with chronic necrotizing infections. It is not a primary disorder, as it always occurs secondary to persistent infection or obstruction caused by a variety of conditions. Bronchiectasis gives rise to a characteristic symptom complex dominated by cough and expectoration of copious amounts of purulent sputum. Diagnosis depends on an appropriate history and radiographic demonstration of bronchial dilation. The conditions that most commonly predispose to bronchiectasis include:

- *Bronchial obstruction.* Common causes are tumors, foreign bodies, and impaction of mucus. In these conditions, bronchiectasis is localized to the obstructed lung segment. Bronchiectasis also may complicate atopic asthma and chronic bronchitis.
- *Congenital or hereditary conditions*—for example:
  - *Cystic fibrosis,* in which widespread severe bronchiectasis results from obstruction caused by abnormally viscid mucus and secondary infections (Chapter 7).
  - *Immunodeficiency states,* particularly immunoglobulin deficiencies, in which localized or diffuse bronchiectasis often develops because of recurrent bacterial infections.

- *Primary ciliary dyskinesia* (also called the immotile cilia syndrome). This is a rare autosomal recessive disorder that is frequently associated with bronchiectasis and with sterility in males. It is caused by inherited abnormalities of cilia that impair mucociliary clearance of the airways, leading to persistent infections.
- *Necrotizing, or suppurative, pneumonia,* particularly with virulent organisms such as *Staphylococcus aureus or Klebsiella spp.,* predispose affected patients to development of bronchiectasis. Posttuberculosis bronchiectasis continues to be a significant cause of morbidity in endemic areas.

Pathogenesis

Two intertwined processes contribute to bronchiectasis: obstruction and chronic infection. Either may be the initiator. For example, obstruction caused by a foreign body impairs clearance of secretions, providing a favorable substrate for superimposed infection. The resultant inflammatory damage to the bronchial wall and the accumulating exudate further distend the airways, leading to irreversible dilation. Conversely, a persistent necrotizing infection in the bronchi or bronchioles may lead to poor clearance of secretions, obstruction, and inflammation with peribronchial fibrosis and traction on the bronchi, culminating again in full-blown bronchiectasis.

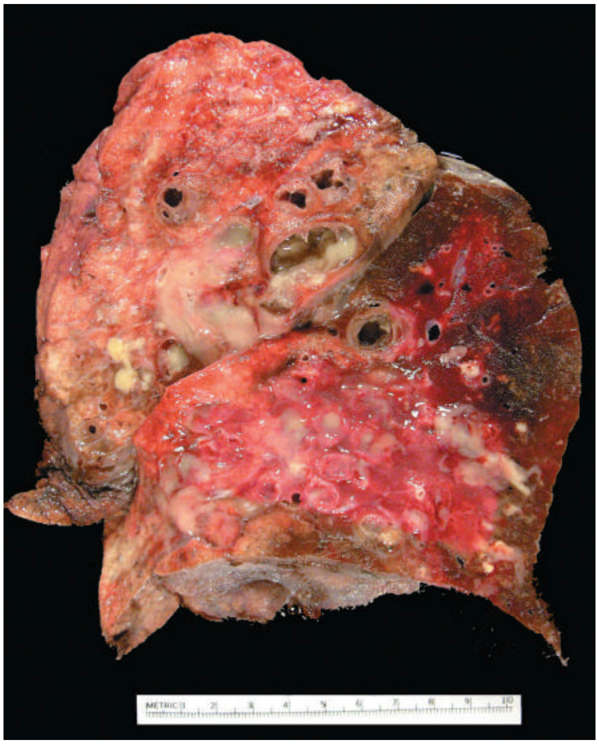

Fig. 13.12 Bronchiectasis in a patient with cystic fibrosis who underwent lung resection for transplantation. Cut surface of lung shows markedly dilated bronchi filled with purulent mucus that extend to subpleural regions.

MORPHOLOGY

Bronchiectasis usually affects the lower lobes bilaterally, particularly those air passages that are most vertical. When caused by tumors or aspiration of foreign bodies, the involvement may be sharply localized to a single segment of the lungs. Usually, the most severe involvement is found in the more distal bronchi and bronchioles. **The airways may be dilated to as much as four times their usual diameter** and can be seen on gross examination almost out to the pleural surface (Fig. 13.12). By contrast, in normal lungs, the bronchioles cannot be followed by eye beyond a point 2 to 3 cm from the pleura.

The histologic findings vary with the activity and chronicity of the disease. In full-blown active cases, an intense acute and chronic inflammatory exudate within the walls of the bronchi and bronchioles leads to desquamation of lining epithelium and extensive areas of ulceration. Typically, mixed flora are cultured from the sputum. The usual organisms include staphylococci, streptococci, pneumococci, enteric organisms, anaerobic and microaerophilic bacteria, and (particularly in children) *Haemophilus influenzae* and *Pseudomonas aeruginosa.*

When healing occurs, the lining epithelium may regenerate completely; however, the injury usually cannot be repaired and abnormal dilation and scarring persist. Fibrosis of the bronchial and bronchiolar walls and peribronchiolar fibrosis develop in more chronic cases. In some instances the necrosis destroys the bronchial or bronchiolar walls, producing an abscess cavity.

Clinical Features

Bronchiectasis is characterized by severe, persistent cough associated with expectoration of mucopurulent, sometimes fetid, sputum. Other common symptoms include dyspnea, rhinosinusitis, and hemoptysis. Symptoms often are episodic and are precipitated by upper-respiratory tract infections or the introduction of new pathogenic agents. Severe, widespread bronchiectasis may lead to significant obstructive ventilatory defects, with hypoxemia, hypercapnia, pulmonary hypertension, and cor pulmonale. However, with current treatment outcomes have improved and severe complications of bronchiectasis, such as brain abscess, amyloidosis (Chapter 5), and cor pulmonale, occur less frequently now than in the past.

CHRONIC INTERSTITIAL (RESTRICTIVE, INFILTRATIVE) LUNG DISEASES

Chronic interstitial diseases are a heterogeneous group of disorders characterized by bilateral, often patchy, pulmonary fibrosis mainly affecting the walls of the alveoli (see Fig. 13.1). Many of the entities in this group are of unknown cause and pathogenesis; some have an intraalveolar and an interstitial component. Chronic interstitial lung diseases are categorized based on clinicopathologic features and characteristic histology (Table 13.2). However, it must be acknowledged that there is frequent overlap in histologic features among the different conditions. The shared histologic features and the similarity in clinical signs, symptoms, radiographic alterations, and pathophysiologic changes justify their consideration as a

Respiratory bronchiolitis

group. The hallmark of these disorders is reduced compliance (stiff lungs), which in turn necessitates increased effort to breathe (dyspnea). Furthermore, damage to the alveolar epithelium and interstitial vasculature produces abnormalities in the ventilation–perfusion ratio, leading to hypoxia. Chest radiographs show small nodules, irregular lines, or "ground-glass shadows." With progression, patients may develop respiratory failure, pulmonary hypertension, and cor pulmonale (Chapter 11). When advanced, the etiology of the underlying diseases may be difficult to determine because they all result in diffuse scarring and gross destruction of the lung, referred to as *end-stage* or *"honeycomb" lung.*

Fibrosing Diseases

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) refers to a pulmonary disorder of unknown etiology that is characterized by patchy, progressive bilateral interstitial fibrosis. Because its etiology is unknown, it is also known as *cryptogenic fibrosing alveolitis.* Males are affected more often than females, and it is a disease of aging, virtually never occurring before 50 years of age. The radiologic and histologic pattern of fibrosis is referred to as *usual interstitial pneumonia (UIP),* which is required for the diagnosis of IPF. Of note, similar pathologic changes in the lung may be present in entities such as asbestosis, collagen vascular diseases, and other conditions. Therefore, IPF is a diagnosis of exclusion.

Pathogenesis

The interstitial fibrosis that characterizes IPF is believed to result from repeated injury and defective repair of alveolar epithelium, often in a genetically predisposed individual (Fig. 13.13). The cause of the injury is obscure, and a variety of sources have been proposed, including chronic gastroesophageal reflux. However, only a small fraction of individuals suffering from reflux or exposed to other proposed environmental triggers develop IPF; thus, other factors must have a predominant role. The clearest etiologic clues come from genetic studies. Germ line mutations leading to loss of telomerase are associated with increased risk, suggesting that cellular senescence contributes to a profibrotic phenotype. The link to cellular aging also is in line with the observation that IPF is a disorder of older adults, rarely occurring before the age of 55 years. Other genetic associations also point to the primary defect residing in epithelial cells. Specifically, approximately 35% of affected individuals have a genetic variant in the *MUC5B* gene that alters the production of mucin, while a smaller number of affected patients have germ line mutations in surfactant genes. These genes are only expressed in lung epithelial cells, indicating that epithelial cell abnormalities can be the primary initiators of IPF. It is hypothesized that abnormal epithelial repair at the sites of chronic injury and inflammation gives rise to exuberant fibroblastic or myofibroblastic proliferation, leading to the characteristic fibroblastic foci. Although the mechanisms of fibrosis are incompletely understood, recent data point to excessive activation of profibrotic factors such as TGF-β.

MORPHOLOGY

Grossly, the pleural surfaces of the lung are cobblestoned due to retraction of scars along the interlobular septa. The cut surface shows firm, rubbery white areas of fibrosis, which occurs preferentially within the lower lobe, the subpleural regions, and along the interlobular septa. Histologically, the hallmark is **patchy interstitial fibrosis,** which varies in intensity (Fig. 13.14) and

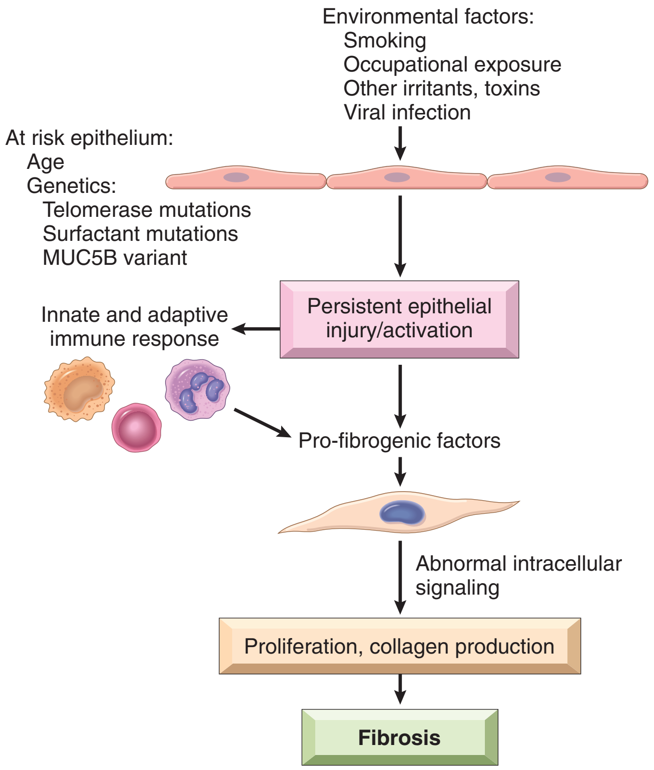

Fig. 13.13 Proposed pathogenic mechanisms in idiopathic pulmonary fibrosis. See text for details.

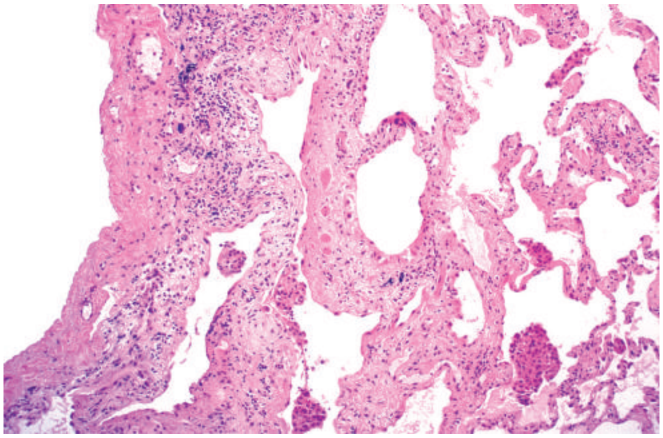

Fig. 13.14 Usual interstitial pneumonia. The fibrosis, which varies in intensity, is more pronounced in the subpleural region.

worsens with time. The earliest lesions demonstrate exuberant fibroblastic proliferation (**fibroblastic foci**) (Fig. 13.15). Over time these areas become more collagenous and less cellular. Quite typical is the existence of both early and late lesions**.** The dense fibrosis causes collapse of alveolar walls and formation of cystic spaces lined by hyperplastic type II pneumocytes or bronchiolar epithelium **(honeycomb fibrosis).** The interstitial inflammation usually is patchy and consists of an alveolar septal infiltrate of mostly lymphocytes and occasional plasma cells, mast cells, and eosinophils. Secondary pulmonary hypertensive changes (intimal fibrosis and medial thickening of pulmonary arteries) are often present.

Clinical Features

IPF usually presents with the gradual onset of a nonproductive cough and progressive dyspnea. On physical examination, most patients have characteristic "dry" or "Velcrolike" crackles during inspiration. Cyanosis, cor pulmonale, and peripheral edema may develop in later stages of the disease. The characteristic clinical and radiologic findings (subpleural and basilar fibrosis, reticular abnormalities, and "honeycombing") often are diagnostic. Anti-inflammatory therapies have proven to be of little use, in line with the idea that inflammation is of secondary pathogenic importance. By contrast, anti-fibrotic therapies such as nintedanib, a tyrosine kinase inhibitor, and pirfenidone, an inhibitor of TGF-β, have produced positive outcomes in clinical trials and are now approved for use in patients with IPF. The overall prognosis remains poor, however; survival is only 3 to 5 years, and lung transplantation is the only definitive treatment.

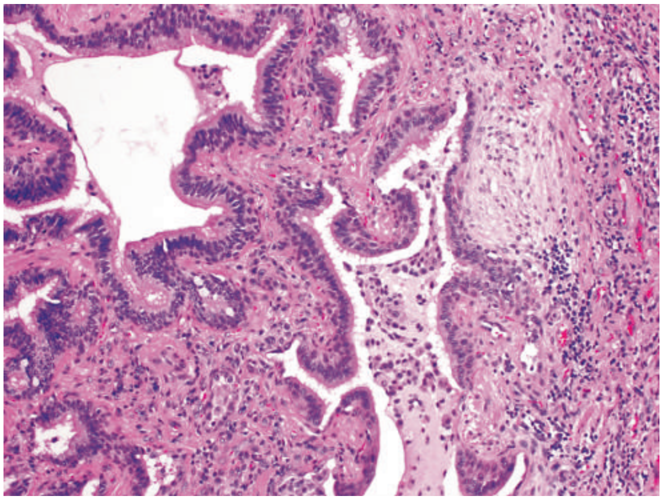

Fig. 13.15 Usual interstitial pneumonia. Fibroblastic focus with fibers running parallel to surface and bluish myxoid extracellular matrix. Honeycombing is present to the left.

Other Fibrosing Diseases

Other rare pulmonary diseases associated with fibrosis need to be considered in the differential diagnosis of IPF, several of which are worthy of brief mention. One is *nonspecific interstitial pneumonia* (NSIP). NSIP is a chronic bilateral interstitial lung disease of unknown etiology, which (despite its name) has distinct radiologic, histologic, and clinical features, including a frequent association with collagen vascular disorders such as rheumatoid arthritis. It is important to recognize NSIP because it has a much better prognosis than IPF. It is characterized by mild to moderate interstitial chronic inflammation and/or fibrosis that is patchy but uniform in the areas involved. A second uncommon entity associated with fibrosis is *cryptogenic organizing pneumonia*. It presents with cough and dyspnea, and chest radiographs demonstrate subpleural or peribronchial patchy areas of airspace consolidation which are due to intraalveolar plugs of loose organizing connective tissue. Some patients recover spontaneously while most require treatment, usually with oral steroids. Also in the differential diagnosis of fibrosing pulmonary disorders are several rheumatologic entitiies, such as systemic sclerosis, rheumatoid arthritis and systemic lupus erythematosus, which may be complicated by diffuse pulmonary fibrosis.

SUMMARY

CHRONIC INTERSTITIAL LUNG DISEASES

- Diffuse interstitial fibrosis of the lung gives rise to restrictive lung diseases characterized by reduced lung compliance and reduced forced vital capacity (FVC). The ratio of FEV to FVC is normal.
- Diseases that cause diffuse interstitial fibrosis are heterogeneous. The unifying pathogenic factor is injury to the alveoli leading to activation of macrophages and release of fibrogenic cytokines such as TGF-β.
- Idiopathic pulmonary fibrosis is prototypic of restrictive lung diseases. It is characterized by patchy interstitial fibrosis, fibroblastic foci, and formation of cystic spaces (honeycomb lung). This histologic pattern is known as usual interstitial pneumonia (UIP).

Pneumoconioses

Pneumoconiosis is a term originally coined to describe lung disorders caused by inhalation of mineral dusts. The term has been broadened to include diseases induced by organic and inorganic particulates, and some experts also regard

Table 13.3 Mineral Dust–Induced Lung Disease

Agent	Disease	Exposure
Coal dust	Simple coal worker's pneumoconiosis: macules and nodules Complicated coal worker's pneumoconiosis: PMF	Coal mining
Silica	Silicosis	Sandblasting, quarrying, mining, stone cutting, foundry work, ceramics
Asbestos	Asbestosis, pleural effusions, pleural plaques, or diffuse fibrosis; mesothelioma; carcinoma of the lung and larynx	Mining, milling, and fabrication of ores and materials; installation and removal of insulation

PMF, Progressive massive fibrosis.

chemical fume- and vapor-induced lung diseases as pneumoconioses. The mineral dust pneumoconioses—the three most common of which are caused by inhalation of coal dust, silica, and asbestos—usually stem from exposure in the workplace. Asbestos is the exception, as with this mineral the increased risk for cancer extends to family members of asbestos workers and to individuals exposed outside of the workplace. Table 13.3 indicates the pathologic conditions associated with each mineral dust and the major industries in which the dust exposure may produce disease.

Pathogenesis

The reaction of the lung to mineral dusts depends on many variables, including the size, shape, solubility, and reactivity of the particles. For example, particles greater than 5 to 10 μm are unlikely to reach distal airways, whereas particles smaller than 0.5 μm move into and out of alveoli, often without substantial deposition and injury. Particles that are 1 to 5 μm in diameter are the most dangerous, because they get lodged at the bifurcation of the distal airways. Coal dust is relatively inert, and large amounts must be deposited in the lungs before lung disease is clinically detectable. Silica, asbestos, and beryllium are more reactive than coal dust, resulting in fibrotic reactions at lower concentrations. Most inhaled dust is entrapped in the mucus blanket and rapidly removed from the lung by ciliary movement. However, some of the particles become impacted at alveolar duct bifurcations, where macrophages accumulate and engulf the trapped particulates.

The pulmonary alveolar macrophage is a key cellular element in the initiation and perpetuation of inflammation, lung injury and fibrosis. Following phagocytosis by macrophages, many particles activate the inflammasome and induce production of the pro-inflammatory cytokine IL-1 as well as the release of other factors, which initiates an inflammatory response that leads to fibroblast proliferation and collagen deposition. Some of the inhaled particles may reach the lymphatics either by direct drainage or within migrating macrophages and thereby initiate an immune response to components of the particulates and/or to self-proteins that are modified by the particles. This then leads to an amplification and extension of the local reaction. Tobacco smoking worsens the effects of all inhaled mineral dusts, more so with asbestos than other particles.

Coal Worker's Pneumoconiosis

Worldwide dust reduction in coal mines has greatly reduced the incidence of coal dust–induced disease. The spectrum of lung findings in coal workers is wide, ranging from *asymptomatic anthracosis,* in which pigment deposits without a perceptible cellular reaction; to *simple coal worker's pneumoconiosis (CWP),* in which macrophages accumulate with little to no pulmonary dysfunction; to *complicated CWP* or *progressive massive fibrosis (PMF),* in which fibrosis is extensive and lung function is compromised (see Table 13.3). Although statistics vary, it seems that less than 10% of cases of simple CWP progress to PMF. Of note, PMF is a generic term that applies to a confluent fibrosing reaction in the lung; this can be a complication of any of the pneumoconioses discussed here.

Although coal is mainly carbon, coal mine dust contains a variety of trace metals, inorganic minerals, and crystalline silica. The ratio of carbon to contaminating chemicals and minerals ("coal rank") increases from bituminous to anthracite coal; in general, anthracite mining has been associated with a higher risk for CWP.

MORPHOLOGY

Pulmonary anthracosis is the most innocuous coal-induced pulmonary lesion in coal miners and also is commonly seen in urban dwellers and tobacco smokers. Inhaled carbon pigment is engulfed by alveolar or interstitial macrophages, which then accumulate in the connective tissue along the pulmonary and pleural lymphatics and in draining lymph nodes.

Simple CWP is characterized by the presence of **coal macules** and larger **coal nodules.** The coal macule consists of dust-laden macrophages and small amounts of collagen fibers arrayed in a delicate network. Although these lesions are scattered throughout the lung, the upper lobes and upper zones of the lower lobes are more heavily involved. In due course, **centrilobular emphysema** may occur. Functionally significant emphysema is more common in the United Kingdom and Europe, probably because in these locales the coal rank is higher than in the United States.

Complicated CWP (PMF) occurs on a background of simple CWP by coalescence of coal nodules and generally develops over many years. It is characterized by multiple, dark black scars larger than 2 cm and sometimes up to 10 cm in greatest diameter that consist of dense collagen and pigment (Fig. 13.16).

Clinical Features

CWP usually is a benign disease that produces little decrement in lung function. In those in whom PMF develops, there is increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale. Progression from CWP to PMF has been linked to a variety of variables including

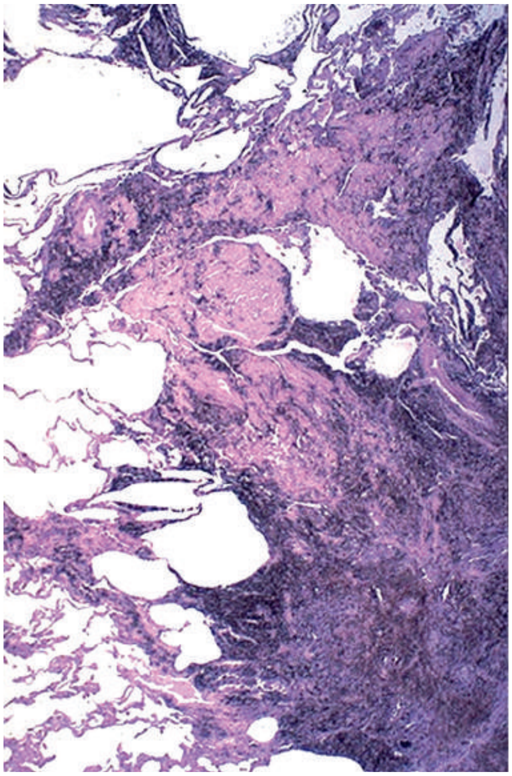

Fig. 13.16 Progressive massive fibrosis in a coal worker. A large amount of black pigment is associated with fibrosis. *(From Klatt EC:* Robbins and Cotran atlas of pathology, *ed 2, Elsevier, Philadelphia, p 121.)*

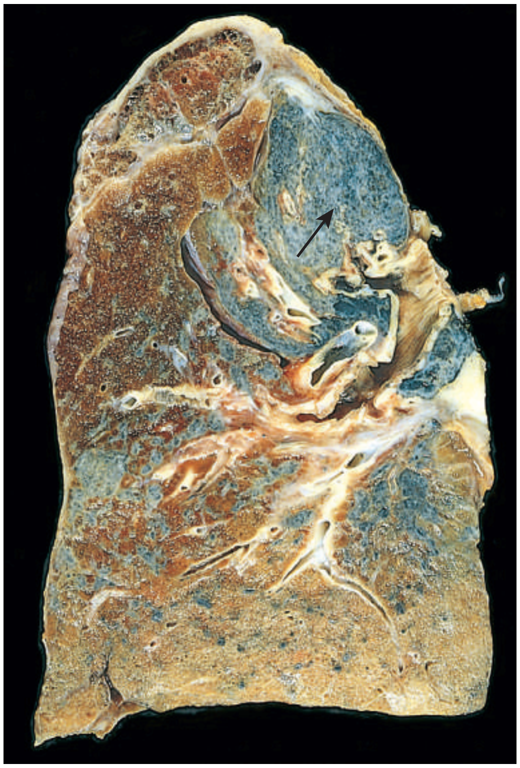

Fig. 13.17 Advanced silicosis, seen in a transected lung. Scarring has contracted the upper lobe into a small dark mass *(arrow)*. Note the dense pleural thickening. *(Courtesy of Dr. John Godleski, Brigham and Women's Hospital, Boston, Massachusetts.)*

higher coal dust exposure levels and total dust burden. Unfortunately, once established PMF has a tendency to progress even in the absence of further exposure. After taking smoking-related risk into account, there is no increased frequency of lung carcinoma in coal miners, a feature that distinguishes CWP from both silica and asbestos exposures (discussed next).

Silicosis

Silicosis is currently the most prevalent chronic occupational disease in the world. It is caused by inhalation of crystalline silica, mostly in occupational settings. Workers involved in sandblasting and hard-rock mining are at particularly high risk. Silica occurs in both crystalline and amorphous forms, but crystalline forms (including quartz, cristobalite, and tridymite) are by far the most toxic and fibrogenic. Of these, quartz is most commonly implicated in silicosis. After inhalation, the particles interact with epithelial cells and macrophages. Ingested silica particles cause activation of the inflammasome and the subsequent release of inflammatory mediators by pulmonary macrophages, including IL-1, TNF, fibronectin, lipid mediators, oxygen-derived free radicals, and fibrogenic cytokines. When mixed with other minerals, the fibrogenic effect of quartz is reduced. This fortuitous situation is commonplace, as quartz in the workplace is rarely pure. Thus, for example, miners of the iron-containing ore hematite may have abundant quartz in their lungs yet have relatively mild lung disease because of the protective effect of hematite.

MORPHOLOGY

Silicotic nodules in their early stages are tiny, barely palpable, discrete, pale-to-black (if coal dust is present) nodules in the upper zones of the lungs (Fig. 13.17). Microscopically, the silicotic nodule demonstrates **concentrically arranged hyalinized collagen fibers** surrounding an amorphous center. The "whorled" appearance of the collagen fibers is quite distinctive for silicosis (Fig. 13.18). Examination of the nodules by **polarized**

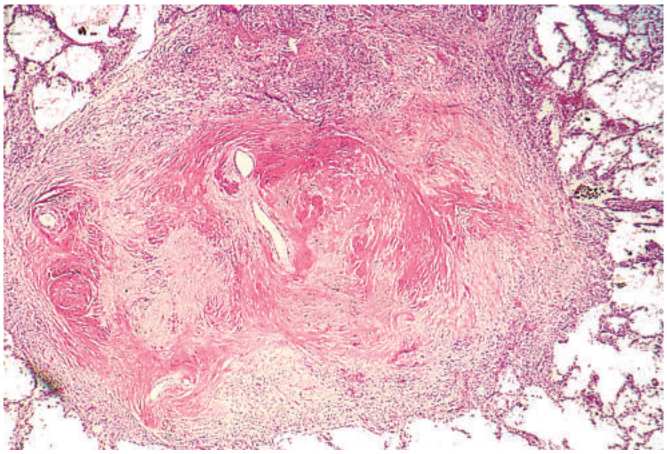

Fig. 13.18 Coalescent collagenous silicotic nodules. *(Courtesy of Dr. John Godleski, Brigham and Women's Hospital, Boston, Massachusetts.)*

microscopy reveals weakly birefringent silica particles, primarily in the center of the nodules. As the disease progresses, individual nodules may coalesce into hard, collagenous scars, with eventual progression to PMF. The intervening lung parenchyma may be compressed or overexpanded, and a honeycomb pattern may develop. Fibrotic lesions also may occur in hilar lymph nodes and the pleura.

Clinical Features

Silicosis usually is detected in asymptomatic workers on routine chest radiographs, which typically show a fine nodularity in the upper zones of the lung. Most patients do not develop shortness of breath until late in the course, after PMF is present. Many patients with PMF develop pulmonary hypertension and cor pulmonale as a result of chronic hypoxia–induced vasoconstriction and parenchymal destruction. The disease is slowly progressive, often impairing pulmonary function to such a degree that physical activity is severely limited. Silicosis is associated with an increased susceptibility to tuberculosis. It is postulated that silicosis depresses cell-mediated immunity, and crystalline silica may inhibit the ability of pulmonary macrophages to kill phagocytosed mycobacteria. Nodules of silicotuberculosis often contain a central zone of caseation. The relationship between silica and lung cancer is unsettled, but most studies suggest that silica exposure is associated with some increase in risk.

Asbestosis and Asbestos-Related Diseases

Asbestos is a family of crystalline hydrated silicates with a fibrous geometry. On the basis of epidemiologic studies, occupational exposure to asbestos is linked to (1) parenchymal interstitial fibrosis *(asbestosis);* (2) localized fibrous plaques, or, rarely, diffuse fibrosis in the pleura; (3) pleural effusions; (4) lung carcinoma; (5) malignant pleural and peritoneal mesothelioma; and (6) laryngeal carcinoma. An increased incidence of asbestos-related cancers in family members of asbestos workers has alerted the general public to the potential hazards of asbestos in the environment.

Pathogenesis

As with silica crystals, once phagocytosed by macrophages, asbestos fibers activate the inflammasome and damage phagolysosomal membranes, stimulating the release of proinflammatory factors and fibrogenic mediators. In addition to cellular and fibrotic lung reactions, asbestos probably also functions as both a tumor initiator and a promoter. Some of the oncogenic effects of asbestos on the mesothelium are mediated by reactive free radicals generated by asbestos fibers, which preferentially localize in the distal lung close to the mesothelial layer. However, potentially toxic chemicals adsorbed onto the asbestos fibers also undoubtedly contribute to the pathogenicity of the fibers. For example, the adsorption of carcinogens in tobacco smoke onto asbestos fibers may be the basis for the remarkable synergy between tobacco smoking and the development of lung carcinoma in asbestos workers.

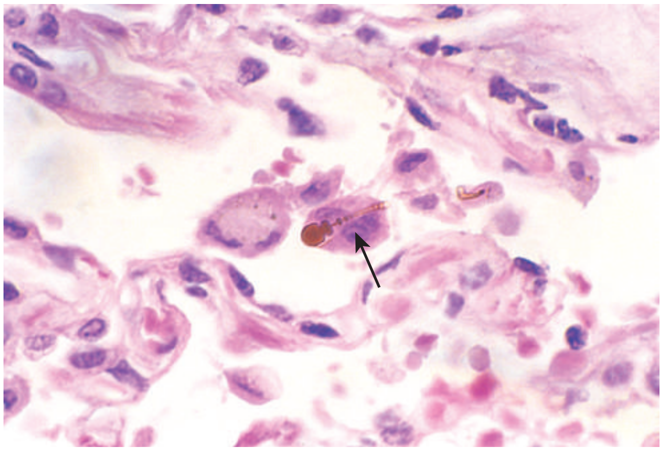

Fig. 13.19 High-power detail of an asbestos body, revealing the typical beading and knobbed ends *(arrow)*.

MORPHOLOGY

Asbestosis is marked by **diffuse pulmonary interstitial fibrosis**, characterized by the presence of **asbestos bodies,** which are seen as golden brown, fusiform or beaded rods with a translucent center. They consist of asbestos fibers coated with an iron-containing proteinaceous material (Fig. 13.19). Asbestos bodies apparently are formed when macrophages attempt to phagocytose asbestos fibers; the iron "crust" is derived from phagocyte ferritin.

In contrast with CWP and silicosis, asbestosis begins in the lower lobes and subpleurally, spreading to the middle and upper lobes of the lungs as the fibrosis progresses. Contraction of the fibrous tissue distorts the normal architecture, creating enlarged air spaces enclosed within thick fibrous walls; eventually, the affected regions become honeycombed. Simultaneously, fibrosis develops in the visceral pleura, causing adhesions between the lungs and the chest wall. The scarring may trap and narrow pulmonary arteries and arterioles, causing pulmonary hypertension and cor pulmonale.

Pleural plaques are the most common manifestation of asbestos exposure and are well-circumscribed plaques of dense collagen (Fig. 13.20), often containing calcium. They develop most frequently on the anterior and posterolateral aspects of the **parietal pleura** and over the domes of the diaphragm. Uncommonly, asbestos exposure induces pleural effusion or diffuse pleural fibrosis.

Clinical Features

The clinical findings in asbestosis are indistinguishable from those of any other chronic interstitial lung disease. Progressively worsening dyspnea appears 10 to 20 years after exposure. It is usually accompanied by a cough and production of sputum. The disease may remain static or progress to congestive heart failure, cor pulmonale, and death. Pleural plaques are usually asymptomatic and are detected on radiographs as circumscribed densities.

Both lung carcinoma and malignant mesothelioma develop in workers exposed to asbestos. The risk for developing lung carcinoma is increased about 5-fold for asbestos workers; the relative risk for mesothelioma, normally a very

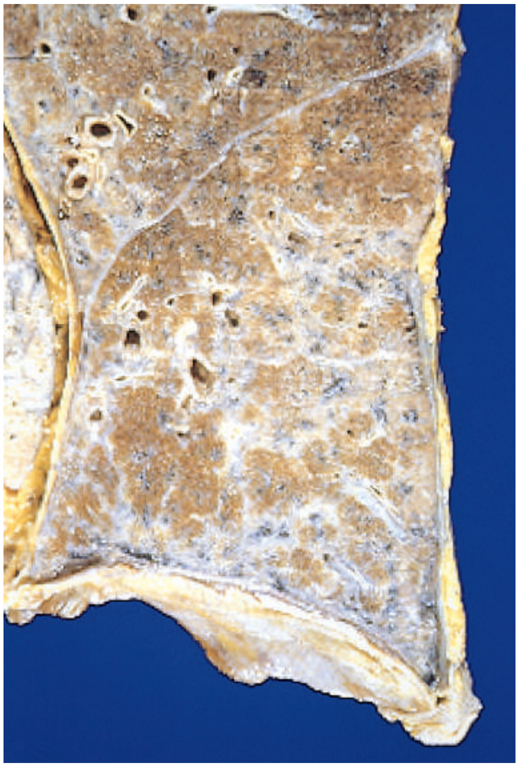

Fig. 13.20 Asbestosis. Markedly thickened visceral pleura covers the lateral and diaphragmatic surface of the lung. Note also severe interstitial fibrosis diffusely affecting the lower lobe of the lung.

rare tumor (2–17 cases per 1 million individuals), is more than 1000 times greater. Concomitant cigarette smoking greatly increases the risk for lung carcinoma but not for mesothelioma. Lung or pleural cancer associated with asbestos exposure carries a particularly poor prognosis.

SUMMARY

PNEUMOCONIOSES

- Pneumoconioses encompass a group of chronic fibrosing diseases of the lung resulting from exposure to organic and inorganic particulates, most commonly mineral dust.
- Pulmonary alveolar macrophages play a central role in the pathogenesis of lung injury by promoting inflammation and producing reactive oxygen species and fibrogenic cytokines.
- Coal dust–induced disease varies from asymptomatic anthracosis, to simple coal worker's pneumoconiosis (coal macules or nodules, and centrilobular emphysema), to progressive massive fibrosis (PMF), manifested by increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale.
- Silicosis is the most common pneumoconiosis in the world, and crystalline silica (e.g., quartz) is the usual culprit.
- The manifestations of silicosis range from asymptomatic silicotic nodules to PMF; individuals with silicosis also have an increased susceptibility to tuberculosis. The relationship between silica exposure and subsequent lung cancer is controversial.
- Asbestos exposure is linked with six disease processes: (1) parenchymal interstitial fibrosis (asbestosis); (2) localized fibrous plaques or, rarely, diffuse pleural fibrosis; (3) pleural effusions; (4) lung cancer; (5) malignant pleural and peritoneal mesothelioma; and (6) laryngeal cancer.
- Cigarette smoking increases the risk for lung cancer in the setting of asbestos exposure; moreover, even family members of workers exposed to asbestos are at increased risk for cancer.

Drug- and Radiation-Induced Pulmonary Disease

Drugs can cause a variety of acute and chronic alterations in respiratory structure and function. For example, *bleomycin,* an anti-cancer agent, causes pneumonitis and interstitial fibrosis as a result of direct toxicity of the drug and by stimulating the influx of inflammatory cells into the alveoli. *Amiodarone,* an anti-arrhythmic agent, also is associated with risk for pneumonitis and fibrosis. *Radiation pneumonitis* is a well-known complication of irradiation of pulmonary and other thoracic tumors. *Acute radiation pneumonitis,* which typically occurs 1 to 6 months after therapy in as many as 20% of the patients, is manifested by fever, dyspnea out of proportion to the volume of irradiated lung, pleural effusion, and pulmonary infiltrates in the irradiated lung bed. These signs and symptoms may resolve with corticosteroid therapy or progress to *chronic radiation pneumonitis,* associated with pulmonary fibrosis.

Granulomatous Diseases

Sarcoidosis

Sarcoidosis is a multisystem disease of unknown etiology characterized by noncaseating granulomatous inflammation in many tissues and organs. We discuss it here because one presentation of sarcoidosis is as a restrictive lung disease. Other diseases, including mycobacterial or fungal infections and berylliosis, sometimes also produce noncaseating granulomas; therefore, the histologic diagnosis of sarcoidosis is one of exclusion. Although sarcoidosis can manifest in many different ways, bilateral hilar lymphadenopathy or lung involvement (or both), visible on chest radiographs, is the major finding at presentation in most cases. Eye and skin involvement each occurs in about 25% of cases, and either may occasionally be the presenting feature of the disease.

Epidemiology

Sarcoidosis occurs throughout the world, affecting both genders and all races and age groups. There are, however, certain interesting epidemiologic trends:

- A consistent predilection for adults younger than 40 years of age.
- A high incidence in Danish and Swedish populations, and in the United States among African Americans (in whom the frequency is 10 times higher than in whites).
- A higher prevalence among nonsmokers, an association that is virtually unique to sarcoidosis among pulmonary diseases.

Etiology and Pathogenesis

Although the etiology of sarcoidosis remains unknown, several lines of evidence suggest that it is a disease of

disordered immune regulation in genetically predisposed individuals exposed to certain environmental agents. The role of each of these contributory influences is summarized in the following discussion.

Several immunologic abnormalities in sarcoidosis suggest the development of a cell-mediated response to an unidentified antigen. The process is driven by CD4+ helper T cells. These immunologic "clues" include the following:

- Intraalveolar and interstitial accumulation of CD4+ T_H1 cells, with peripheral T cell cytopenia
- Oligoclonal expansion of CD4+ T_H1 T cells within the lung as determined by analysis of T cell receptor rearrangements
- Increases in T_H1 cytokines such as IL-2 and IFN-γ, resulting in T cell proliferation and macrophage activation, respectively
- Increases in several cytokines in the local environment (IL-8, TNF, macrophage inflammatory protein-1α) that favor recruitment of additional T cells and monocytes and contribute to the formation of granulomas
- Anergy to common skin test antigens such as *Candida* or purified protein derivative (PPD)
- Polyclonal hypergammaglobulinemia
- Familial and racial clustering of cases, suggesting the involvement of genetic factors

After lung transplantation, sarcoidosis recurs in the new lungs in at least one-third of patients, but without any effect on survival. Finally, several putative "antigens" have been proposed as the inciting agent for sarcoidosis (e.g., viruses, mycobacteria, *Borrelia,* pollen), but there is no "smoking gun" linking sarcoidosis to any specific antigen or infectious agent.

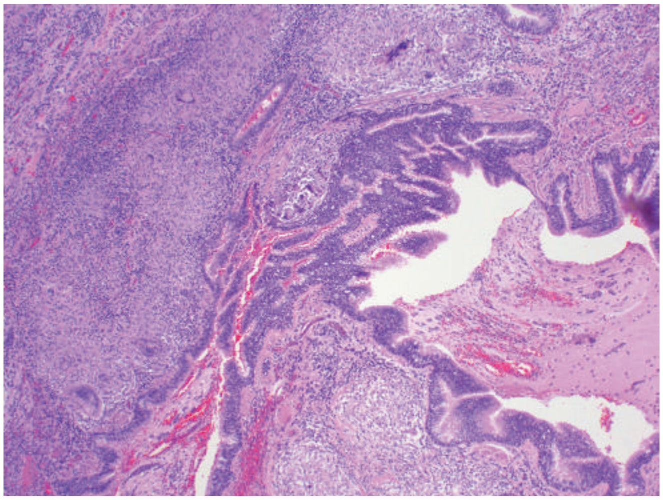

Fig. 13.21 Sarcoid. Characteristic peribronchial noncaseating granulomas with many giant cells are present.

MORPHOLOGY

The cardinal histopathologic feature of sarcoidosis, irrespective of the organ involved, is the **nonnecrotizing epithelioid granuloma** (Fig. 13.21). This is a discrete, compact collection of epithelioid cells rimmed by an outer zone rich in CD4+ T cells. It is not uncommon to see intermixed multinucleate giant cells formed by fusion of macrophages. Early on, a thin layer of laminated fibroblasts is found peripheral to the granuloma; over time, these proliferate and lay down collagen that replaces the entire granuloma with a hyalinized scar. Two other microscopic features are sometimes seen in the granulomas: (1) **Schaumann bodies,** laminated concretions composed of calcium and proteins; and (2) **asteroid bodies,** stellate inclusions enclosed within giant cells. Their presence is not required for diagnosis of sarcoidosis, and they may also occur in granulomas of other origins. Rarely, foci of central necrosis may be present in sarcoid granulomas, especially in the nodular form.

The **lungs** are involved at some stage of the disease in 90% of patients. The granulomas predominantly involve the interstitium rather than air spaces, with some tendency to localize in the connective tissue around bronchioles and pulmonary venules and in the pleura ("lymphangitic" distribution). The bronchoalveolar lavage fluid contains abundant CD4+ T cells. In 5% to 15% of patients, the granulomas eventually are replaced by **diffuse interstitial fibrosis,** resulting in a so-called "honeycomb lung".

Intrathoracic **hilar and paratracheal lymph nodes** are enlarged in 75% to 90% of patients, while one-third present with peripheral lymphadenopathy. The nodes are characteristically painless and have a firm, rubbery texture. Unlike in tuberculosis, lymph nodes in sarcoidosis are "nonmatted" (nonadherent) and do not ulcerate.

Skin lesions are encountered in approximately 25% of patients. **Erythema nodosum,** the hallmark of acute sarcoidosis, consists of raised, red, tender nodules on the anterior aspects of the legs. Sarcoidal granulomas are uncommon in these lesions. By contrast, discrete painless subcutaneous nodules can also occur in sarcoidosis, and these usually reveal abundant noncaseating granulomas.

Involvement of the eye and lacrimal glands occurs in about one-fifth to one-half of patients. The ocular involvement takes the form of **iritis** or **iridocyclitis** and may be unilateral or bilateral. As a consequence, corneal opacities, glaucoma, and (less commonly) total loss of vision may develop. The posterior uveal tract also is affected, with resultant **choroiditis, retinitis,** and **optic nerve involvement.** These ocular lesions are frequently accompanied by inflammation in the lacrimal glands, with suppression of lacrimation **(sicca syndrome). Unilateral or bilateral parotitis with painful enlargement of the parotid glands** occurs in less than 10% of patients with sarcoidosis; some go on to develop xerostomia (dry mouth). Combined uveoparotid involvement is designated **Mikulicz syndrome.**

The spleen may appear unaffected grossly, but in about three-fourths of cases, it contains granulomas. In approximately 10%, it becomes clinically enlarged. **The liver** demonstrates microscopic granulomatous lesions, usually in the portal triads, about as often as the spleen, but only about one-third of patients demonstrate hepatomegaly or abnormal liver function. Sarcoid involvement of **bone marrow** is reported in as many as 40% of patients, although it rarely causes severe manifestations. Other findings may include hypercalcemia and hypercalciuria. These changes are not related to bone destruction but rather are caused by increased calcium absorption secondary to production of active vitamin D by the macrophages that form the granulomas.

Clinical Features

In many affected individuals, the disease is entirely asymptomatic, discovered on routine chest films as bilateral hilar adenopathy or as an incidental finding at autopsy. In others, peripheral lymphadenopathy, cutaneous lesions, eye involvement, splenomegaly, or hepatomegaly may be presenting manifestations. In about two-thirds of symptomatic cases, there is gradual appearance of respiratory symptoms (shortness of breath, dry cough, or vague substernal discomfort) or constitutional signs and symptoms (fever, fatigue, weight loss, anorexia, night sweats). A definitive diagnostic test for sarcoidosis does not exist, and establishing a diagnosis requires the presence of clinical and radiologic findings that are consistent with the disease, the exclusion of other disorders with similar presentations, and the identification of noncaseating granulomas in involved tissues. In particular, tuberculosis must be excluded.

Sarcoidosis follows an unpredictable course characterized by either progressive chronicity or periods of activity interspersed with remissions. The remissions may be spontaneous or initiated by steroid therapy and often are permanent. Overall, 65% to 70% of affected individuals recover with minimal or no residual manifestations. Another 20% develop permanent lung dysfunction or visual impairment. Of the remaining 10% to 15%, most succumb to progressive pulmonary fibrosis and cor pulmonale.

SUMMARY
SARCOIDOSIS

- Sarcoidosis is a multisystem disease of unknown etiology; the diagnostic histopathologic feature is the presence of noncaseating granulomas in various tissues.
- Immunologic abnormalities include high levels of CD4+ T_H1 cells in the lung that secrete cytokines such as IFN-γ.
- Clinical manifestations include lymph node enlargement, eye involvement (sicca syndrome [dry eyes], iritis, or iridocyclitis), skin lesions (erythema nodosum, painless subcutaneous nodules), and visceral involvement (liver, skin, bone marrow). Lung involvement occurs in 90% of cases, with formation of granulomas and interstitial fibrosis.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis is an immunologically mediated inflammatory lung disease that primarily affects the alveoli and is therefore often called *allergic alveolitis.* Most often it is an occupational disease that results from heightened sensitivity to inhaled antigens such as those found in moldy hay (Table 13.4). Unlike bronchial asthma, in which bronchi are the focus of immunologically mediated injury, the damage in hypersensitivity pneumonitis occurs at the level of alveoli. Hence, it manifests predominantly as a restrictive lung disease with the typical decreases in diffusion capacity, lung compliance, and total lung volume. The responsible occupational and household exposures are diverse, but the syndromes share common clinical and pathologic findings and probably have a very similar pathophysiologic basis.

Table 13.4 Sources of Antigens Causing Hypersensitivity Pneumonitis

Source of Antigen	Types of Exposures
Mushrooms, fungi, yeasts	Contaminated wood, humidifiers, central hot air heating ducts, peat moss plants
Bacteria	Dairy barns (farmer's lung)
Mycobacteria	Metalworking fluids, sauna, hot tub
Birds	Pigeons, dove feathers, ducks, parakeets
Chemicals	Isocyanates (auto painters), zinc, dyes

From Lacasse Y, Girard M, Cormier Y: Recent advances in hypersensitivity pneumonitis, *Chest* 142:208, 2012.

Several lines of evidence suggest that hypersensitivity pneumonitis is an immunologically mediated disease:

- Bronchoalveolar lavage specimens consistently show increased numbers of CD4+ and CD8+ T lymphocytes.
- Most affected patients have specific antibodies against the offending antigen in their serum.
- Complement and immunoglobulins have been demonstrated within vessel walls by immunofluorescence.
- Noncaseating granulomas are found in the lungs of two-thirds of affected patients.

MORPHOLOGY

The histopathologic picture in both acute and chronic forms of hypersensitivity pneumonitis includes patchy mononuclear cell infiltrates in the pulmonary interstitium, with a characteristic peribronchiolar accentuation. Lymphocytes predominate, but plasma cells and epithelioid macrophages also are present. In acute forms of the disease, variable numbers of neutrophils also may be seen. **"Loose," poorly formed granulomas,** without necrosis, are present in more than two-thirds of cases, usually in a peribronchiolar location (Fig. 13.22). In advanced chronic cases, bilateral, upper-lobe–dominant interstitial fibrosis (UIP pattern) occurs.

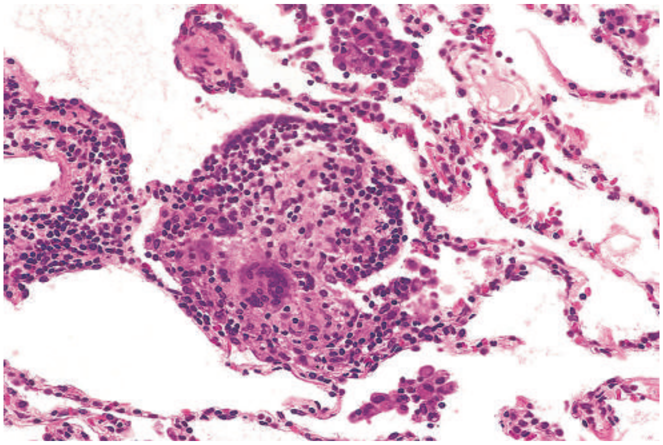

Fig. 13.22 Hypersensitivity pneumonitis, histologic appearance. Loosely formed interstitial granulomas and chronic inflammation are characteristic.

Clinical Features

Hypersensitivity pneumonitis may manifest either as an acute reaction, with fever, cough, dyspnea, and constitutional signs and symptoms arising 4 to 8 hours after exposure, or as a chronic disease characterized by insidious onset of cough, dyspnea, malaise, and weight loss. With the acute form, the diagnosis is usually obvious because of the temporal relationship of symptom onset and exposure to the incriminating antigen. If antigenic exposure is terminated after acute attacks of the disease, complete resolution of pulmonary symptoms occurs within days. Failure to remove the inciting agent from the environment eventually results in an irreversible chronic interstitial pulmonary disease.

Pulmonary Eosinophilia

A number of disorders are characterized by pulmonary infiltrates rich in eosinophils, which are recruited to the lung by local release of chemotactic factors. These diverse diseases generally are of immunologic origin, but the etiology is not understood. Pulmonary eosinophilia is divided into the following categories:

- *Acute eosinophilic pneumonia with respiratory failure,* characterized by rapid onset of fever, dyspnea, hypoxia, and diffuse pulmonary infiltrates on chest radiographs. The bronchoalveolar lavage fluid typically contains more than 25% eosinophils. There is prompt response to corticosteroids.
- *Simple pulmonary eosinophilia (Loeffler syndrome),* characterized by transient pulmonary lesions, eosinophilia in the blood, and a benign clinical course. The alveolar septa are thickened by an infiltrate containing eosinophils and occasional giant cells.
- *Tropical eosinophilia,* caused by infection with microfilariae and helminthic parasites
- *Secondary eosinophilia,* seen, for example, in association with asthma, drug allergies, and certain forms of vasculitis
- *Idiopathic chronic eosinophilic pneumonia,* characterized by aggregates of lymphocytes and eosinophils within the septal walls and the alveolar spaces, typically in the periphery of the lung fields, and accompanied by high fever, night sweats, and dyspnea. This is a disease of exclusion, once other causes of pulmonary eosinophilia have been ruled out.

Smoking-Related Interstitial Diseases

In addition to obstructive lung disease (COPD), smoking is also is associated with restrictive or interstitial lung diseases. *Desquamative interstitial pneumonia (DIP)* and *respiratory bronchiolitis* are two related examples of smoking-associated interstitial lung disease. The most striking histologic feature of DIP is the accumulation of large numbers of macrophages containing dusty-brown pigment *(smoker's macrophages)* in the air spaces (Fig. 13.23). The alveolar septa are thickened by a sparse inflammatory infiltrate (usually lymphocytes); interstitial fibrosis, when present, is mild. Pulmonary function tests usually show a mild restrictive abnormality. Overall, patients with DIP have a good prognosis and an excellent response to steroids and smoking cessation; however, some patients progress despite therapy. Respiratory bronchiolitis is a common lesion found in smokers that is characterized by the presence of pigmented intraluminal macrophages akin to those in DIP, but in a "bronchiolocentric" distribution (first- and second-order respiratory bronchioles). Mild peribronchiolar fibrosis also is seen. As with DIP, affected patients present with gradual onset of dyspnea and dry cough, and the symptoms recede with smoking cessation.

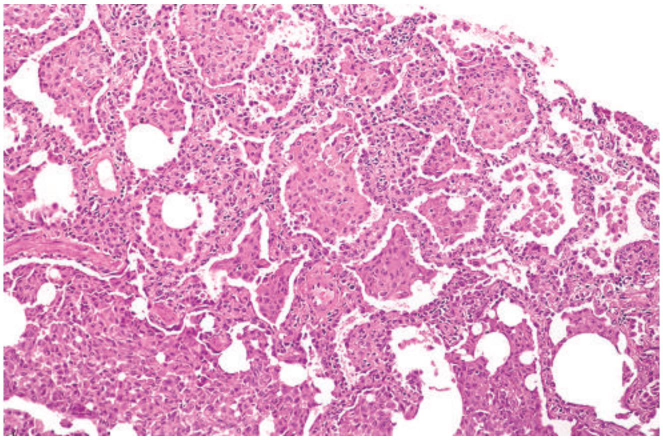

Fig. 13.23 Desquamative interstitial pneumonia. There is accumulation of large numbers of macrophages within the alveolar spaces with only slight fibrous thickening of the alveolar walls.

PULMONARY DISEASES OF VASCULAR ORIGIN

Pulmonary Embolism, Hemorrhage, and Infarction

Thromboembolism causes approximately 50,000 deaths per year in the United States and even when not directly fatal often complicates the course of other diseases. The true incidence of nonfatal pulmonary embolism is not known. Some cases undoubtedly occur outside the hospital in ambulatory patients, in whom the emboli are small and clinically silent. Even among hospitalized patients, no more than one-third are diagnosed before death. Autopsy data on the incidence of pulmonary embolism vary widely, ranging from 1% in the general hospitalized population, to 30% in individuals dying after severe burns, trauma, or fractures.

Blood clots that occlude the large pulmonary arteries are almost always embolic in origin. More than 95% of all pulmonary emboli arise from thrombi within the large deep veins of the legs, most often those that have propagated to involve the popliteal vein and larger veins above it. The influences that predispose to venous thrombosis in the legs are discussed in Chapter 4, but the following risk factors are paramount: (1) prolonged bed rest (particularly with immobilization of the legs); (2) surgery, especially orthopedic surgery on the knee or hip; (3) severe trauma (including burns or multiple fractures); (4) congestive heart failure; (5) in women, the period around parturition or the

use of oral contraception pills with high estrogen content; (6) disseminated cancer; and (7) primary disorders of hypercoagulability (e.g., factor V Leiden) (Chapter 4).

The pathophysiologic consequences of pulmonary thromboembolism depend largely on the size of the embolus, which in turn dictates the size of the occluded pulmonary artery, and the cardiopulmonary status of the patient. There are two important consequences of pulmonary arterial occlusion: (1) an increase in pulmonary artery pressure from blockage of flow and, possibly, vasospasm caused by neurogenic mechanisms and/or release of mediators (e.g., thromboxane A_2, serotonin); and (2) ischemia of the downstream pulmonary parenchyma. Thus, occlusion of a major vessel results in an abrupt increase in pulmonary artery pressure, diminished cardiac output, right-sided heart failure *(acute cor pulmonale),* and sometimes sudden death. If smaller vessels are occluded, the result is less catastrophic and may even be clinically silent. Hypoxemia develops as a result of multiple mechanisms:

- *Perfusion of atelectatic lung zones.* Alveolar collapse occurs in ischemic areas because of a reduction in surfactant production and because pain associated with embolism leads to reduced movement of the chest wall.
- The decrease in cardiac output causes a *widening of the difference in arterial-venous oxygen saturation.*
- *Right-to-left shunting* of blood may occur through a patent foramen ovale, present in 30% of normal individuals.

Recall that the lungs are oxygenated not only by the pulmonary arteries but also by bronchial arteries and directly from air in the alveoli. Thus, ischemic necrosis (infarction) is the exception rather than the rule, occurring in as few as 10% of patients with thromboemboli. It occurs only if there is compromise in cardiac function or bronchial circulation, or if the region of the lung at risk is underventilated as a result of underlying pulmonary disease.

MORPHOLOGY

The consequences of pulmonary embolism, as noted, depend on the size of the embolic mass and the general state of the circulation. A large embolus may embed in the main pulmonary artery or its major branches or lodge astride the bifurcation as a **saddle embolus** (Fig. 13.24). Death usually follows so suddenly from hypoxia or acute failure of the right side of the heart (acute cor pulmonale) that there is no time for morphologic alterations in the lung. Smaller emboli become impacted in medium-sized and small-sized pulmonary arteries. With adequate circulation and bronchial arterial flow, the vitality of the lung parenchyma is maintained, but alveolar hemorrhage may occur as a result of ischemic damage to the endothelial cells.

With compromised cardiovascular status, as may occur with congestive heart failure, **infarction** results. The more peripheral the embolic occlusion, the higher the risk for infarction. About three-fourths of all infarcts affect the lower lobes, and more than one-half are multiple. Characteristically, they are wedge-shaped, with their base at the pleural surface and the apex pointing toward the hilus of the lung. Pulmonary infarcts typically are hemorrhagic and appear as raised, red-blue areas of coagulative necrosis in the early stages (Fig. 13.25). The adjacent pleural surface often is covered by a fibrinous exudate. The occluded vessel is usually located near the apex of the infarcted area. The red cells begin to lyse within 48 hours, and the infarct gradually becomes red-brown as hemosiderin is produced. In time, fibrous replacement begins at the margins as a gray-white peripheral zone and eventually converts the infarct into a scar.

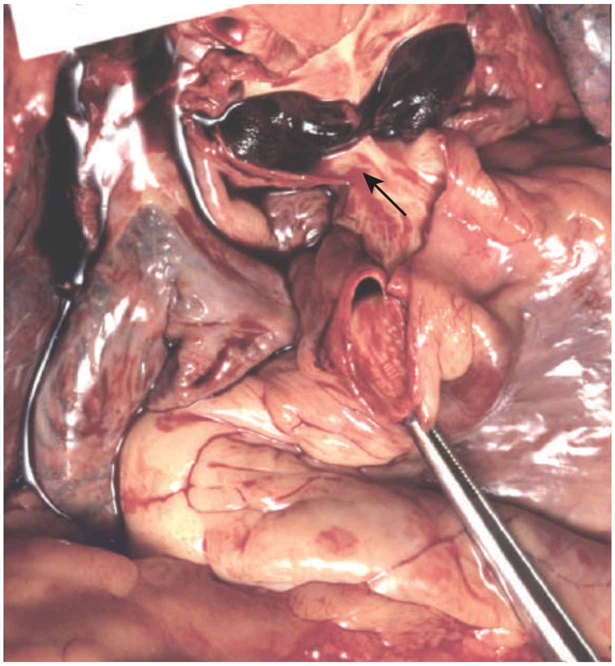

Fig. 13.24 Large saddle embolus from the femoral vein lying astride the main left and right pulmonary arteries. *(Courtesy of Dr. Linda Margraf, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Clinical Features

The clinical consequences of pulmonary thromboembolism are summarized as follows:

- Most (60% to 80%) are clinically silent because they are small; the bronchial circulation sustains the viability of

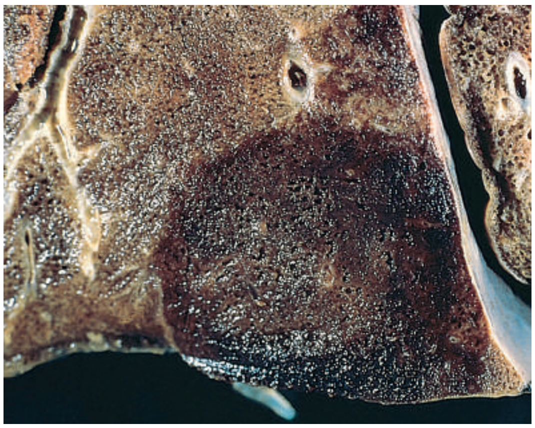

Fig. 13.25 A small, roughly wedge-shaped hemorrhagic pulmonary infarct of recent occurrence.

the affected lung parenchyma, and the embolic mass is rapidly removed by fibrinolytic activity.
- In 5% of cases, death, acute right-sided heart failure, or cardiovascular collapse (shock) occurs suddenly. Massive pulmonary embolism is one of the few causes of virtually instantaneous death. These severe consequences typically happen when more than 60% of the total pulmonary vasculature is obstructed by a large embolus or multiple simultaneous small emboli.
- Obstruction of small to medium pulmonary branches (10% to 15% of cases) causes pulmonary infarction if some element of circulatory insufficiency also is present. Typically, individuals who sustain infarctions present with dyspnea.
- In a small but significant subset of patients (accounting for <3% of cases), recurrent "showers" of emboli lead to pulmonary hypertension, chronic right-sided heart failure, and, in time, pulmonary vascular sclerosis with progressively worsening of dyspnea.

Emboli usually resolve after the initial acute event, as endogenous fibrinolytic activity often leads to their complete dissolution. However, in the presence of an underlying predisposing factor, a small, innocuous embolus may presage a larger one, and patients who have experienced one pulmonary embolism have a 30% chance of developing a second. Prophylactic therapy may include anticoagulation, early ambulation for postoperative and postparturient patients, application of elastic stockings, intermittent pneumatic calf compression, and isometric leg exercises for bedridden patients. Those who develop pulmonary embolism are given anti-coagulation therapy. Patients with massive pulmonary embolism who are hemodynamically unstable (shock, acute right heart failure) are candidates for thrombolytic therapy.

Nonthrombotic pulmonary emboli come in several uncommon but potentially lethal forms, such as air, fat, and amniotic fluid embolism (Chapter 4). Intravenous drug abuse often is associated with foreign body embolism in the pulmonary microvasculature; the presence of magnesium trisilicate (talc) in the intravenous mixture elicits a granulomatous response within the interstitium or pulmonary arteries. Involvement of the interstitium may lead to fibrosis, while vascular involvement leads to pulmonary hypertension. Residual talc crystals can be demonstrated within the granulomas using polarized light. Bone marrow embolism (denoted by the presence of hematopoietic and fat elements within a pulmonary artery) can occur after massive trauma and in patients with bone infarction secondary to sickle cell anemia.

SUMMARY

PULMONARY EMBOLISM

- Almost all large pulmonary artery thrombi are embolic in origin, usually arising from the deep veins of the lower leg.
- Risk factors include prolonged bed rest, knee or hip surgery, severe trauma, congestive heart failure, use of oral contraceptives (especially those with high estrogen content), disseminated cancer, and genetic causes of hypercoagulability.
- Most emboli (60% to 80%) are clinically silent; a minority (5%, typically large "saddle emboli") cause acute right-sided heart failure, shock, or sudden death; and the remainder cause pulmonary infarction.
- Risk for recurrence is high.

Pulmonary Hypertension

The pulmonary circulation normally is one of low resistance, and pulmonary blood pressures are only about one-eighth of systemic pressures. **Pulmonary hypertension (defined as pressures of 25 mm Hg or more at rest) may be caused by a decrease in the cross-sectional area of the pulmonary vascular bed or, less commonly, by increased pulmonary vascular blood flow.** Based on shared features, the World Health Organization has classified pulmonary hypertension into the following five groups:
- *Pulmonary arterial hypertension,* a diverse collection of disorders that includes heritable forms of pulmonary hypertension and diseases that cause pulmonary hypertension by affecting small pulmonary muscular arterioles; these include connective tissue diseases, human immunodeficiency virus, and congenital heart disease with left to right shunts
- *Pulmonary hypertension due to left-sided heart disease,* including systolic and diastolic dysfunction and valvular disease
- *Pulmonary hypertension due to lung diseases and/or hypoxia,* including COPD and interstitial lung disease
- *Chronic thromboembolic pulmonary hypertension*
- *Pulmonary hypertension with unclear or multifactorial mechanisms*

Pathogenesis

As can be gathered from this classification, pulmonary hypertension has diverse causes. Some of the more common causes are the following:
- *Chronic obstructive or interstitial lung diseases* (group 3). These diseases obliterate alveolar capillaries, increasing pulmonary resistance to blood flow and, secondarily, pulmonary blood pressure.
- *Antecedent congenital or acquired heart disease* (group 2). Mitral stenosis, for example, causes an increase in left atrial pressure and pulmonary venous pressure that is eventually transmitted to the arterial side of the pulmonary vasculature, leading to hypertension.
- *Recurrent thromboemboli* (group 4). Recurrent pulmonary emboli may cause pulmonary hypertension by reducing the functional cross-sectional area of the pulmonary vascular bed, which in turn leads to an increase in pulmonary vascular resistance.
- *Autoimmune diseases* (group 1). Several of these diseases (most notably systemic sclerosis) involve the pulmonary vasculature and/or the interstitium, leading to increased vascular resistance and pulmonary hypertension.
- *Obstructive sleep apnea* (also group 3) is a common disorder that is associated with obesity and hypoxemia. It is now recognized to be a significant contributor to the development of pulmonary hypertension and cor pulmonale.

Uncommonly, pulmonary hypertension is encountered in patients in whom all known causes are excluded; this is referred to as *idiopathic pulmonary arterial hypertension*. This name is a misnomer, however, as up to 80% of "idiopathic" pulmonary hypertension (sometimes referred to as *primary pulmonary hypertension*) has a genetic basis, sometimes being inherited in families as an autosomal dominant trait. Within these families, there is incomplete penetrance, and only 10% to 20% of the family members develop overt disease. As is often the case, investigating the molecular basis of an uncommon familial form of the disease has provided new pathogenic insights, in this instance by shining a spotlight on the role of the bone morphogenetic protein (BMP)–signaling pathway. Inactivating germ line mutations in the gene encoding bone morphogenetic protein receptor 2 (BMPR2) are found in 75% of the familial cases of pulmonary hypertension and 25% of sporadic cases. More recently, mutations in other genes that are involved in the BMPR2 pathway also have been identified in affected patients. Details remain to be worked out, but it appears that defects in BMPR2 signaling leads to dysfunction of endothelium and proliferation of vascular smooth muscle cells in the pulmonary vasculature. Because only 10% to 20% of individuals with *BMPR2* mutations develop disease, it is likely that modifier genes and/or environmental triggers also contribute to the pathogenesis of the disorder.

MORPHOLOGY

Regardless of their etiology, all forms of pulmonary hypertension are associated with **medial hypertrophy of the pulmonary muscular and elastic arteries, pulmonary arterial atherosclerosis, and right ventricular hypertrophy.** The presence of organizing or recanalized thrombi favors recurrent pulmonary emboli as the cause, and the coexistence of diffuse pulmonary fibrosis, or severe emphysema and chronic bronchitis, points to chronic hypoxia as the initiating event. The vessel changes can involve the entire arterial tree, from the main pulmonary arteries down to the arterioles (Fig. 13.26). In severe cases, atheromatous deposits form in the pulmonary artery and its major branches. The arterioles and small arteries are most prominently affected by medial hypertrophy and intimal fibrosis, sometimes narrowing the lumens to pinpoint channels. An uncommon but characteristic pathologic change is the **plexiform lesion,** so called because a tuft of capillary formations is present, producing a network, or web, that spans the lumens of dilated thin-walled, small arteries and may extend outside the vessel.

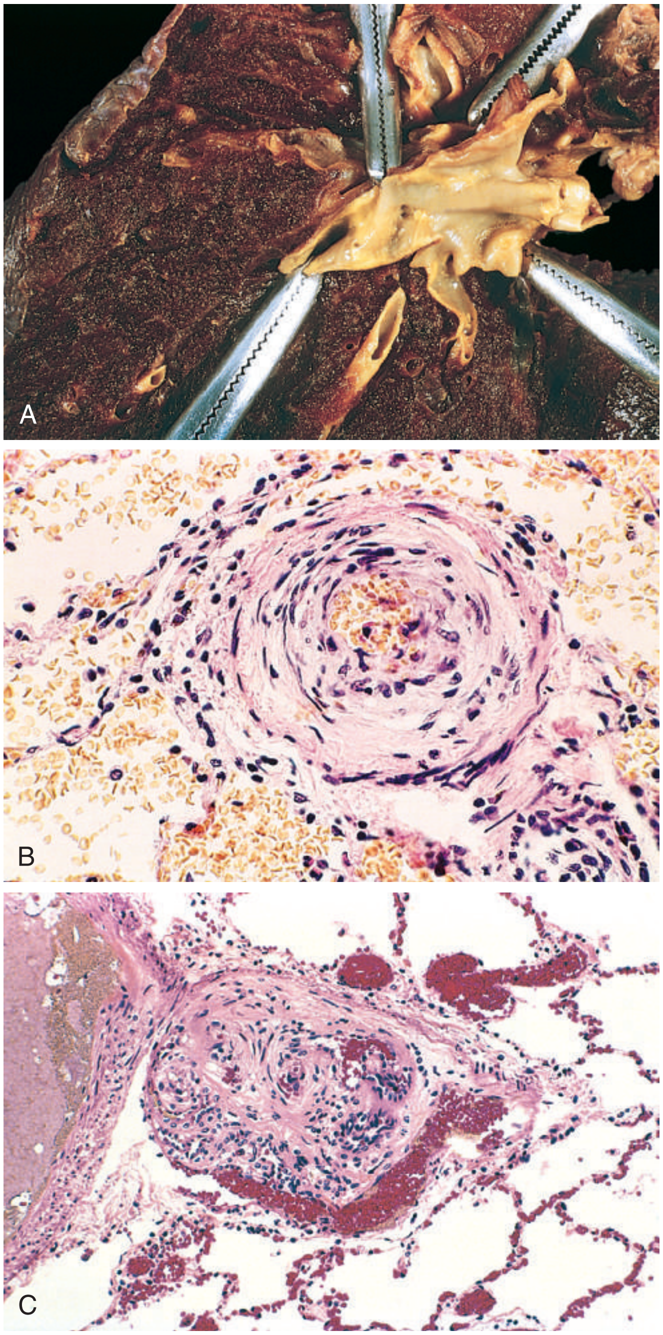

Fig. 13.26 Vascular changes in pulmonary hypertension. (A) Atheroma formation, a change usually limited to large pulmonary arteries. (B) Marked medial hypertrophy. (C) Plexiform lesion characteristic of advanced pulmonary hypertension seen in small arteries.

Clinical Features

Pulmonary hypertension produces symptoms when the disease is advanced. Idiopathic pulmonary hypertension is most common in women 20 to 40 years of age and occurs occasionally in young children. The presenting features are usually dyspnea and fatigue, but some patients have anginal chest pain. Over time, respiratory distress, cyanosis, and right ventricular hypertrophy appear, and death from decompensated cor pulmonale, often with superimposed thromboembolism and pneumonia, ensues within 2 to 5 years in 80% of patients.

Treatment choices depend on the underlying cause. For those with secondary disease, therapy is directed at the trigger (e.g., thromboembolic disease or hypoxemia). A variety of vasodilators have been used with varying success in those with group 1 disease or refractory disease belonging to other groups. Lung transplantation is the definitive treatment for selected patients.

Diffuse Alveolar Hemorrhage Syndromes

Pulmonary hemorrhage is a dramatic complication of some interstitial lung disorders. Among these so-called "pulmonary hemorrhage syndromes" are (1) Goodpasture syndrome, (2) idiopathic pulmonary hemosiderosis, and (3) granulomatosis with polyangiitis.

Goodpasture Syndrome

Goodpasture syndrome is an uncommon autoimmune disease in which lung and kidney injury are caused by circulating autoantibodies against certain domains of type IV collagen that are intrinsic to the basement membranes of renal glomeruli and pulmonary alveoli. The antibodies trigger destruction and inflammation of the basement membranes in pulmonary alveoli and renal glomeruli, giving rise to *necrotizing hemorrhagic interstitial pneumonitis* and *rapidly progressive glomerulonephritis.*

MORPHOLOGY

The lungs are heavy and have areas of red-brown consolidation due to **diffuse alveolar hemorrhage.** Microscopic examination shows focal necrosis of alveolar walls associated with intra-alveolar hemorrhage, fibrous thickening of septa, and hypertrophic type II pneumocytes. There is abundant **hemosiderin** due to earlier episodes of hemorrhage (Fig. 13.27). The characteristic **linear pattern of immunoglobulin deposition** (usually IgG, sometimes IgA or IgM) that is the hallmark diagnostic finding in renal biopsy specimens (Chapter 14) also may be seen along the alveolar septa.

Most cases of Goodpasture syndrome occur in patients in their teens or twenties. In contrast to many other autoimmune diseases, there is a male preponderance. The majority of patients are active smokers. Plasmapheresis and immunosuppressive therapy have markedly improved a once-dismal prognosis. Plasma exchange removes offending antibodies, and immunosuppressive drugs inhibit antibody production. With severe renal disease, renal transplantation is eventually required.

Granulomatosis and Polyangiitis

More than 80% of patients with granulomatosis and polyangiitis (GPA; formerly *Wegener granulomatosis*) develop upper-respiratory or pulmonary manifestations at some time in their course. This is discussed in Chapter 10. Here we list the salient pulmonary features. The lung lesions are characterized by a combination of necrotizing vasculitis ("angiitis") and parenchymal necrotizing granulomatous inflammation. The signs and symptoms stem from involvement of the upper-respiratory tract (chronic sinusitis, epistaxis, nasal perforation) and the lungs (cough, hemoptysis, chest pain). Anti-neutrophil cytoplasmic antibodies (PR3-ANCAs) are present in close to 95% of cases (Chapter 10).

PULMONARY INFECTIONS

Pulmonary infections in the form of pneumonia are responsible for one sixth of all deaths in the United States. Pneumonia can be broadly defined as any infection in the lung. Normally, the lung parenchyma remains sterile because of a number of highly effective immune and nonimmune defense mechanisms that extend throughout the respiratory system from the nasopharynx to the alveolar air spaces (Fig. 13.28). The vulnerability of the lung to infection dsepite these defenses is not surprising because (1) many microbes are airborne and readily inhaled into the lungs; (2) nasopharyngeal flora are regularly aspirated during sleep, even by healthy individuals; and (3) lung diseases often lower local immune defenses.

The importance of immune defenses in preventing pulmonary infections is emphasized by patients with inherited or acquired defects in innate immunity (including neutrophil and complement defects) or adaptive immunity (e.g., humoral immunodeficiency), all of which lead to an

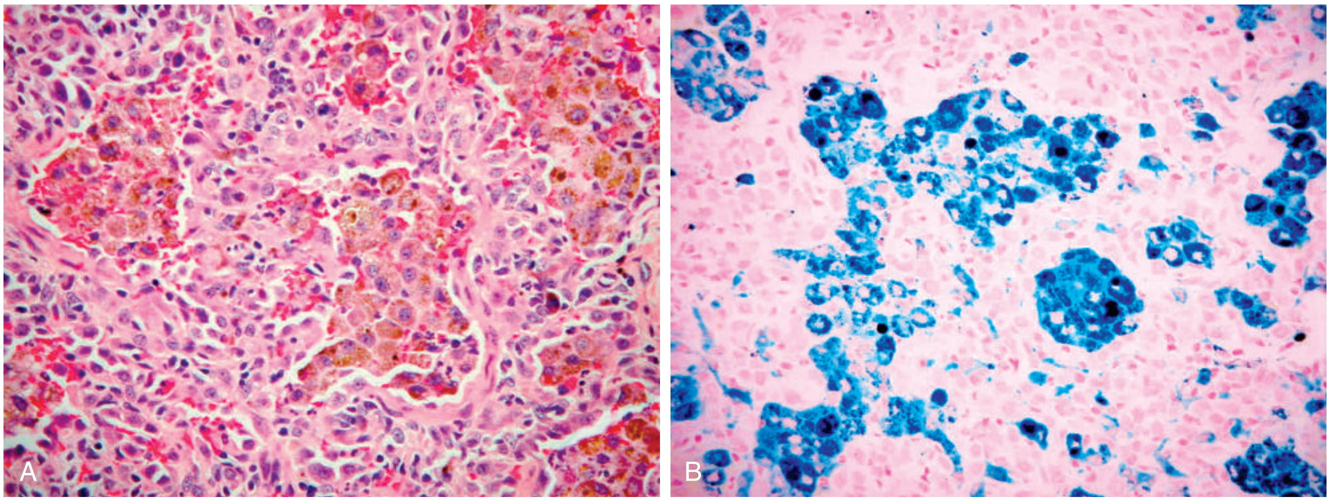

Fig. 13.27 Diffuse alveolar hemorrhage syndrome. (A) Lung biopsy specimen demonstrates large numbers of intraalveolar hemosiderin-laden macrophages on a background of thickened fibrous septa. (B) The tissue has been stained with Prussian blue, an iron stain that highlights the abundant intracellular hemosiderin. *(From the Teaching Collection of the Department of Pathology, Children's Medical Center, Dallas, Texas.)*

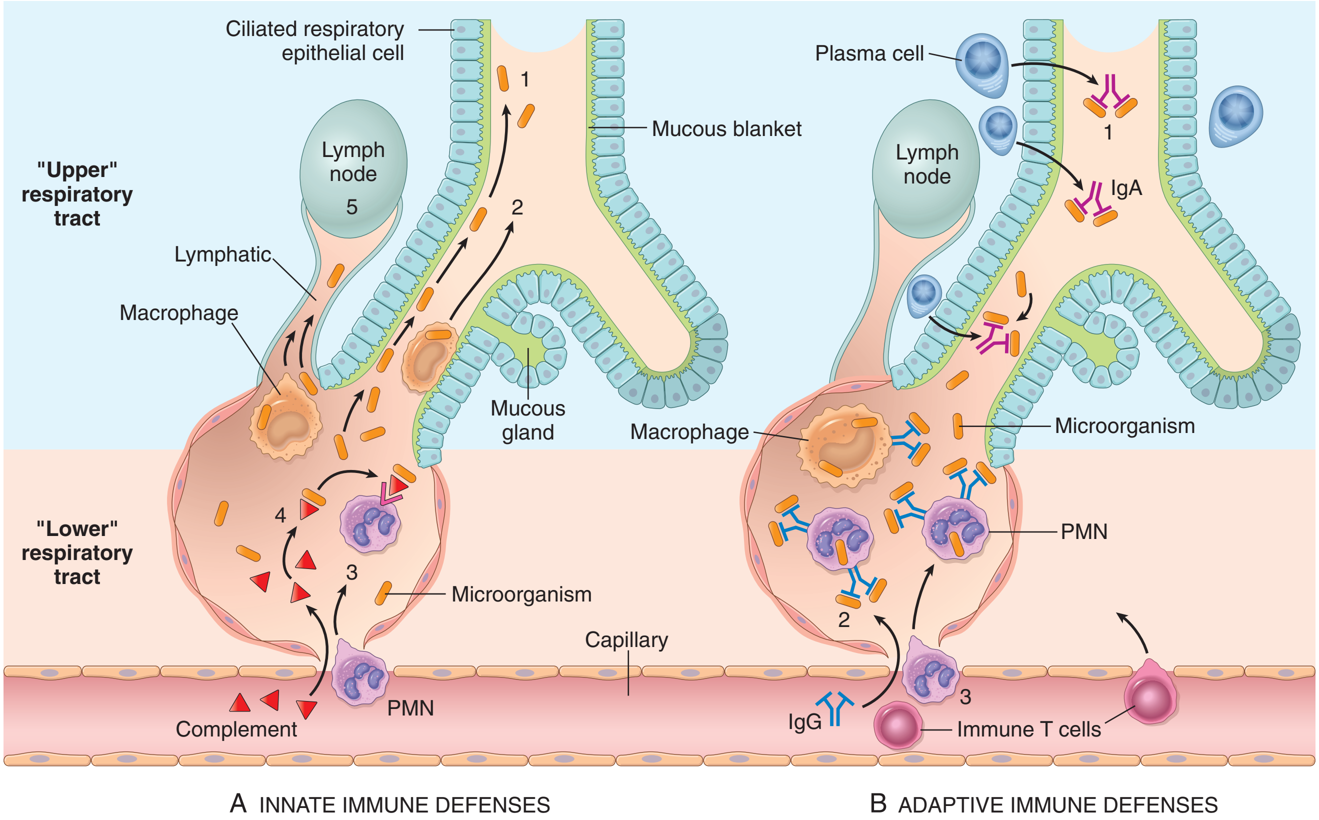

Fig. 13.28 Lung defense mechanisms. (A) Innate defenses against infection: *1*, In the normal lung, removal of microbial organisms depends on entrapment in the mucous blanket and removal by means of the mucociliary elevator; *2*, Phagocytosis by alveolar macrophages can kill and degrade organisms and remove them from the air spaces by migrating onto the mucociliary elevator; or *3*, phagocytosis and killing by neutrophils recruited by macrophage factors; *4*, Complement may enter the alveoli and be activated by the alternative pathway to produce the opsonin C3b, which enhances phagocytosis; *5*, Organisms, including those ingested by phagocytes, may reach the draining lymph nodes to initiate immune responses. (B) Additional mechanisms operate after development of adaptive immunity: *1*, Secreted IgA can block attachment of the microorganism to epithelium in the upper-respiratory tract; *2*, In the lower-respiratory tract, serum antibodies (IgM, IgG) are present in the alveolar lining fluid and activate complement more efficiently by the classic pathway, yielding C3b *(not shown)*; In addition, IgG is an opsonin; *3*, The accumulation of immune T cells is important for controlling infections by viruses and other intracellular microorganisms. *PMN*, neutrophil.

increased incidence of infections with pyogenic bacteria. For example, patients with mutations in MYD88, an adaptor protein required for signaling by Toll-like receptors, are extremely susceptible to severe necrotizing pneumococcal infections, while patients with congenital defects in IgA production (the major immunoglobulin in airways secretions) are at increased risk for pneumonias caused by encapsulated organisms such as pneumococcus and *H. influenzae*. On the other hand, defects in T_H1 cell–mediated immunity lead mainly to increased infections with intracellular microbes such as atypical mycobacteria. Much more commonly, lifestyle choices interfere with host immune defense mechanisms and facilitate infections. For example, cigarette smoke compromises mucociliary clearance and pulmonary macrophage activity, and alcohol impairs neutrophile function as well as cough and epiglottic reflexes (thereby increasing the risk for aspiration).

Bacterial pneumonias are classified according to the specific etiologic agent or, if no pathogen can be isolated, by the clinical setting in which the infection occurs. Altogether, seven distinct clinical settings are recognized, each associated with a fairly distinct group of pathogens (summarized in Table 13.5). Thus, consideration of the clinical setting can be a helpful guide when anti-microbial therapy has to be given empirically.

Community-Acquired Bacterial Pneumonias

Bacterial pneumonias often follow a viral upper-respiratory tract infection. *S. pneumoniae* (i.e., the pneumococcus) is the most common cause of community-acquired acute pneumonia and is discussed first, followed by other relative common pathogens.

Streptococcus pneumoniae

Pneumococcal infections occur with increased frequency in two clinical settings: (1) chronic diseases such as CHF, COPD, or diabetes; and (2) congenital or acquired defects in immunoglobulin production (e.g., acquired immune deficiency syndrome [AIDS]). In addition, decreased or absent splenic function (e.g., sickle cell disease or after splenectomy) greatly increases the risk for overwhelming pneumococcal sepsis. You will recall that the spleen contains the largest collection of phagocytes in the body and is the major organ responsible for removing pneumococci from the blood. The spleen also is an important site for

Table 13.5 The Pneumonia Syndromes and Implicated Pathogens

Community-Acquired Bacterial Pneumonia
Streptococcus pneumoniae *Haemophilus influenzae* *Moraxella catarrhalis* *Staphylococcus aureus* *Legionella pneumophila* Enterobacteriaceae *(Klebsiella pneumoniae)* and *Pseudomonas spp.* *Mycoplasma pneumoniae* *Chlamydia pneumoniae* *Coxiella burnetii* (Q fever)
Community-Acquired Viral Pneumonia
Respiratory syncytial virus, human metapneumovirus, parainfluenza virus (children); influenza A and B (adults); adenovirus (military recruits)
Nosocomial Pneumonia
Gram-negative rods belonging to *Enterobacteriaceae* (*Klebsiella* spp., *Serratia marcescens, Escherichia coli*) and *Pseudomonas* spp. *S. aureus* (usually methicillin-resistant)
Aspiration Pneumonia
Anaerobic oral flora (*Bacteroides, Prevotella, Fusobacterium, Peptostreptococcus*), admixed with aerobic bacteria (*S. pneumoniae, S. aureus, H. influenzae,* and *Pseudomonas aeruginosa*)
Chronic Pneumonia
Nocardia Actinomyces Granulomatous: Mycobacterium tuberculosis and atypical mycobacteria, *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis*
Necrotizing Pneumonia and Lung Abscess
Anaerobic bacteria (extremely common), with or without mixed aerobic infection *S. aureus, K. pneumoniae, Streptococcus pyogenes,* and type 3 pneumococcus (uncommon)
Pneumonia in the Immunocompromised Host
Cytomegalovirus *Pneumocystis jiroveci* Mycobacterium avium complex (MAC) Invasive aspergillosis Invasive candidiasis "Usual" bacterial, viral, and fungal organisms (listed above)

production of antibodies against polysaccharides, which are the dominant protective antibodies against encapsulated bacteria.

The presence of numerous neutrophils in sputum containing the typical gram-positive, lancet-shaped diplococci supports the diagnosis of pneumococcal pneumonia, but it must be remembered that *S. pneumoniae* is a part of the endogenous flora in 20% of adults, and therefore false-positive results may be obtained. Isolation of pneumococci from blood cultures is more specific but less sensitive (in the early phase of illness, only 20% to 30% of patients have positive blood cultures). Pneumococcal vaccines containing capsular polysaccharides from the common serotypes are used in individuals at high risk for pneumococcal sepsis.

Haemophilus influenzae

Both encapsulated and unencapsulated forms of *H. influenzae* are important causes of community-acquired pneumonias. The former can cause a particularly life-threatening form of pneumonia in children, often after a respiratory viral infection. Adults at risk for developing infections include those with chronic pulmonary diseases such as chronic bronchitis, cystic fibrosis, and bronchiectasis. *H. influenzae* is the most common bacterial cause of acute exacerbations of COPD. Encapsulated *H. influenzae* type b was formerly an important cause of epiglottitis and suppurative meningitis in children, but vaccination against this organism in infancy has significantly reduced the risk.

Moraxella catarrhalis

M. catarrhalis is being increasingly recognized as a cause of bacterial pneumonia, especially in older adults. It is the second most common bacterial cause of acute exacerbation of COPD in adults. Along with *S. pneumoniae* and *H. influenzae, M. catarrhalis* is one of the three most frequent causes of otitis media (infection of the middle ear) in children.

Staphylococcus aureus

S. aureus is an important cause of secondary bacterial pneumonia in children and healthy adults after viral respiratory illnesses (e.g., measles in children and influenza in both children and adults). Staphylococcal pneumonia is associated with a high incidence of complications, such as lung abscess and empyema. Staphylococcal pneumonia occurring in association with right-sided staphylococcal endocarditis is a serious complication of intravenous drug abuse. It is also an important cause of nosocomial pneumonia (discussed later).

Klebsiella pneumoniae

K. pneumoniae is the most frequent cause of gram-negative bacterial pneumonia. *Klebsiella*-related pneumonia frequently afflicts debilitated and malnourished individuals, particularly *chronic alcoholics*. Thick and gelatinous sputum is characteristic, because the organism produces an abundant viscid capsular polysaccharide, which the patient may have difficulty coughing up.

Pseudomonas aeruginosa

Although discussed here with community-acquired pathogens because of its association with infections in cystic fibrosis, *P. aeruginosa* infection is most commonly is seen in nosocomial settings (discussed later). *Pseudomonas* pneumonia also is common in individuals who are neutropenic, usually secondary to chemotherapy; in victims of extensive burns; and in patients requiring mechanical ventilation. *P. aeruginosa* has a propensity to invade blood vessels at the site of infection, with consequent extrapulmonary spread. *Pseudomonas* bacteremia is a fulminant disease, with death often occurring within a matter of days. Histologic examination reveals organisms invading the walls of necrotic blood vessels (*Pseudomonas vasculitis*), leading to secondary coagulative necrosis of the pulmonary parenchyma.

Legionella pneumophila

L. pneumophila is the agent of Legionnaire disease, an eponym for the epidemic and sporadic forms of pneumonia caused by this organism. Pontiac fever is a related self-limited upper-respiratory tract infection caused by *L. pneumophila,* without pneumonic symptoms. *L. pneumophila*

flourishes in artificial aquatic environments, such as water-cooling towers and within the tubing system of domestic (potable) water supplies. The mode of transmission is thought to be either inhalation of aerosolized organisms or aspiration of contaminated drinking water. *Legionella* pneumonia is common in individuals with some predisposing condition such as cardiac, renal, immunologic, or hematologic disease. Organ transplant recipients are particularly susceptible. *Legionella* pneumonia may be quite severe, frequently requiring hospitalization and producing a fatality rate of 30% to 50% in immunosuppressed individuals. Rapid diagnosis is facilitated by demonstration of *Legionella* antigens in the urine or by a positive fluorescent antibody test on sputum samples; culture remains the standard diagnostic modality. PCR-based tests can be used on bronchial secretions in atypical cases.

Mycoplasma pneumoniae

Mycoplasma infections are particularly common among children and young adults. They occur sporadically or as local epidemics in closed communities (schools, military camps, prisons). Tests for *Mycoplasma* antigens and polymerase chain reaction (PCR) testing for *Mycoplasma* DNA are available.

Fig. 13.30 Lobar pneumonia with gray hepatization. The lower lobe is uniformly consolidated.

MORPHOLOGY

Bacterial pneumonia has two patterns of anatomic distribution: lobular bronchopneumonia and lobar pneumonia (Fig. 13.29). In the context of pneumonias, the term "consolidation," used frequently, refers to "solidification" of the lung due to replacement of the air by exudate in the alveoli. Patchy consolidation of the lung is the dominant characteristic of **bronchopneumonia**, while consolidation of a large portion of a lobe or of an entire lobe defines **lobar pneumonia** (Fig. 13.30). These anatomic categorizations may be difficult to apply in individual cases because patterns overlap, and patchy involvement may evolve to become confluent over time, producing complete lobar consolidation. Moreover, the same organisms may produce either pattern depending on patient susceptibility. Most important from the clinical standpoint are identification of the causative agent and determination of the extent of disease.

In **lobar pneumonia**, four stages of the inflammatory response have classically been described. In the first stage of **congestion,** the lung is heavy, boggy, and red. It is characterized by vascular engorgement, intraalveolar fluid with few neutrophils, and often the presence of numerous bacteria. The stage of **red hepatization** that follows is characterized by massive confluent exudation, as neutrophils, red cells, and fibrin fill the alveolar spaces (Fig. 13.31A). On gross examination, the lobe is red, firm, and airless, with a liver-like consistency, hence the term hepatization. The stage of **gray hepatization** that follows is marked by progressive disintegration of red cells and the persistence of a fibrinosuppurative exudate (see Fig. 13.31B), resulting in a color change to grayish-brown. In the final stage of **resolution,** the exudate within the alveolar spaces is broken down by enzymatic digestion to produce granular, semifluid debris that is resorbed, ingested by macrophages, expectorated, or organized by fibroblasts growing into it (Fig. 13.31C). Pleural fibrinous reaction to the underlying inflammation is often present in the early stages if the consolidation extends to the surface **(pleuritis).** It may resolve or undergo organization, leaving fibrous thickening or permanent adhesions.

Foci of **bronchopneumonia** are consolidated areas of acute suppurative inflammation. The consolidation may be confined to one lobe but is more often multilobar and frequently bilateral and basal because of the tendency of secretions to gravitate to the lower lobes. Well-developed lesions are slightly elevated, dry, granular, gray-red to yellow, and poorly delimited at their margins. Histologically, a neutrophil-rich exudate fills the bronchi, bronchioles, and adjacent alveolar spaces (see Fig. 13.31A).

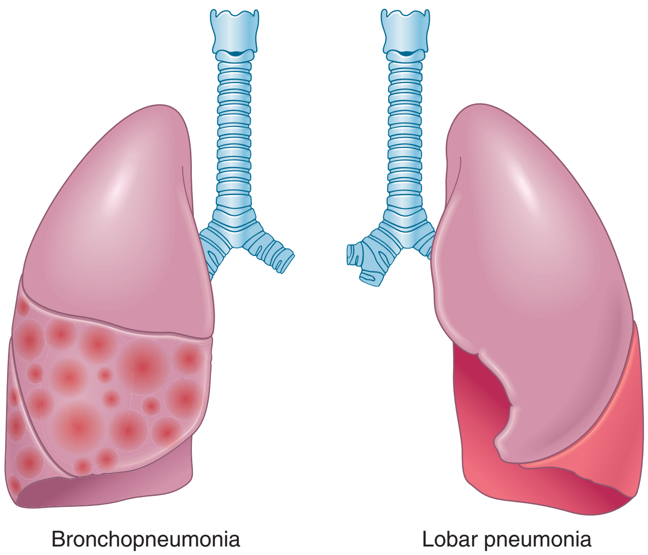

Fig. 13.29 The anatomic distribution of bronchopneumonia and lobar pneumonia affecting the lower lobes of the lung.

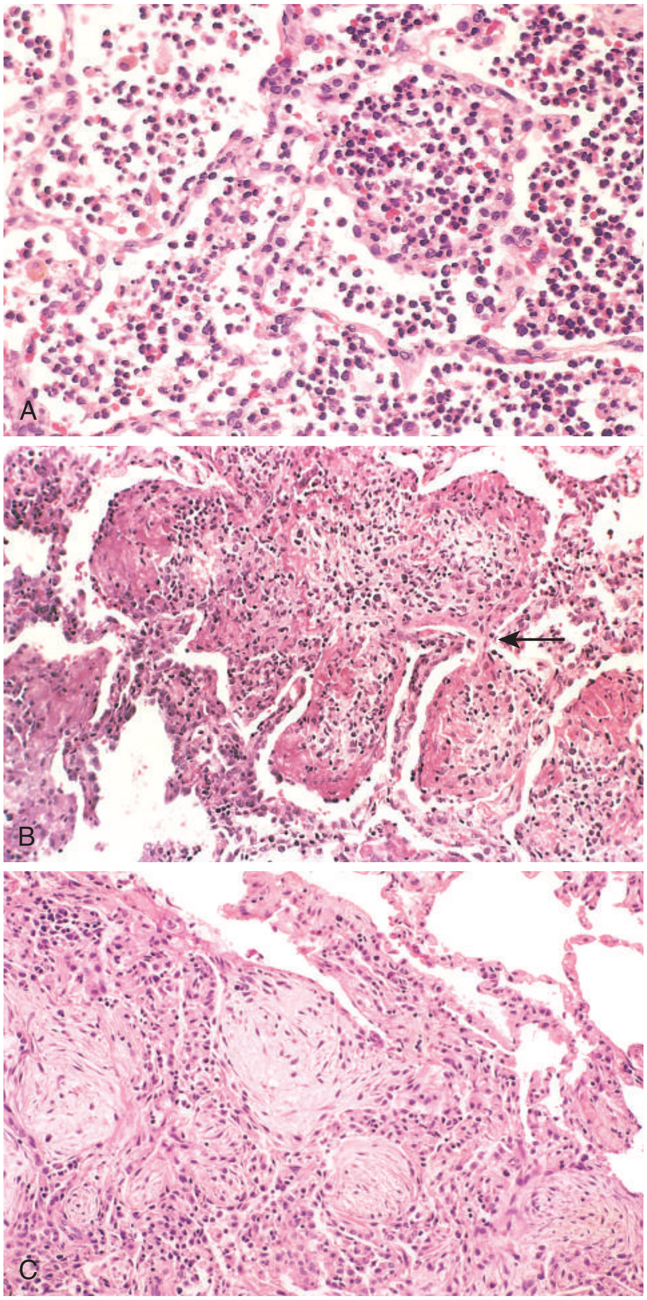

Fig. 13.31 (A) Acute pneumonia. The congested septal capillaries and extensive neutrophil exudation into alveoli correspond to early red hepatization. Fibrin nets have not yet formed. (B) Early organization of intraalveolar exudates, seen in areas to be streaming through the pores of Kohn *(arrow)*. (C) Advanced organizing pneumonia, featuring transformation of exudates to fibromyxoid masses richly infiltrated by macrophages and fibroblasts.

Complications of pneumonia include (1) tissue destruction and necrosis, causing **abscess formation**; (2) spread of infection to the pleural cavity, causing the intrapleural fibrinosuppurative reaction known as **empyema**; and (3) **bacteremic dissemination** to the heart valves, pericardium, brain, kidneys, spleen, or joints, causing metastatic abscesses, endocarditis, meningitis, or suppurative arthritis.

Clinical Features

The major symptoms of typical community-acquired acute bacterial pneumonia are abrupt onset of high fever, shaking chills, and cough producing mucopurulent sputum; occasional patients have hemoptysis. When pleuritis is present, it is accompanied by pleuritic pain and pleural friction rub. The whole lobe is radiopaque in lobar pneumonia, whereas there are focal opacities in bronchopneumonia.

The clinical picture is markedly modified by the administration of effective antibiotics. Treated patients may be relatively afebrile with few clinical signs 48 to 72 hours after the initiation of antibiotics. The identification of the organism and the determination of its antibiotic sensitivity are the keystones of therapy. Less than 10% of patients with pneumonia severe enough to merit hospitalization now succumb, and in most such instances death results from a complication, such as empyema, meningitis, endocarditis, or pericarditis, or to some predisposing influence, such as debility or chronic alcoholism.

Community-Acquired Viral Pneumonias

The most common causes of community-acquired viral pneumonias are influenza types A and B, the respiratory syncytial viruses, human metapneumovirus, adenovirus, rhinoviruses, rubeola virus, and varicella virus (see Table 13.5). Nearly all of these agents also cause upper-respiratory tract infections ("common cold").

These pathologic viruses share a propensity to infect and damage resspiratory epithelium, producing an inflammatory response. When the process extends to alveoli, there is usually interstitial inflammation, but some outpouring of fluid into alveolar spaces may also occur, so that on chest films the changes may mimic those of bacterial pneumonia. As a result, it is not possible to distinguish bacterial and viral pneumonia based on radiologic appearance alone. Moreover, damage leading to necrosis of the respiratory epithelium inhibits mucociliary clearance and predisposes to secondary bacterial infections. Such serious complications of viral infection are more likely in infants, older adults, malnourished patients, alcoholics, and immunosuppressed individuals.

MORPHOLOGY

The morphologic patterns in viral pneumonias are similar. The process may be patchy, or it may involve whole lobes bilaterally or unilaterally. Macroscopically, the affected areas are red-blue, congested, and subcrepitant. On histologic examination, the **inflammatory reaction is largely confined to the walls of the alveoli** (Fig. 13.32). The septa are widened and edematous; they usually contain a mononuclear inflammatory infiltrate of lymphocytes, macrophages and, occasionally, plasma cells. In the classic case, alveolar spaces in viral pneumonias are free of cellular exudate. In severe cases, however, full-blown diffuse alveolar damage with hyaline membranes may develop. In less severe, uncomplicated cases, subsidence of the disease is followed by reconstitution of the normal architecture. Superimposed bacterial infection, as expected, results in a mixed histologic picture.

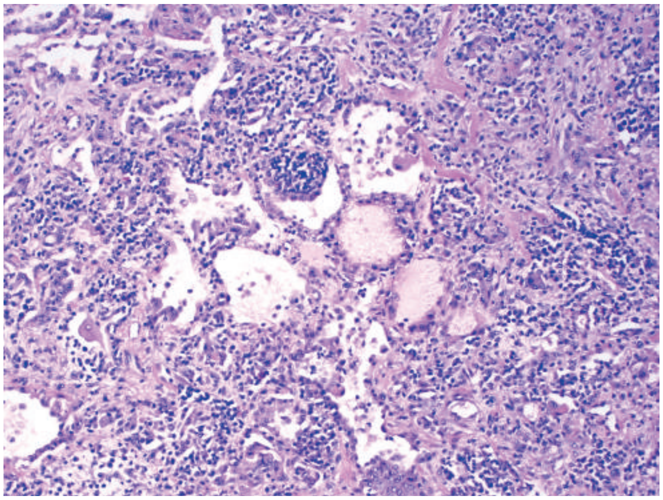

Fig. 13.32 Viral pneumonia. The thickened alveolar walls are infiltrated with lymphocytes and some plasma cells, which are spilling over into alveolar spaces. Note the focal alveolar edema *(center)* and early fibrosis *(upper right)*.

Clinical Features

The clinical course of viral pneumonia is extremely varied. It may masquerade as a severe upper-respiratory tract infection or "chest cold" that goes undiagnosed, or manifest as a fulminant, life-threatening infection in immunocompromised patients. The initial presentation usually is that of an acute, nonspecific febrile illness characterized by fever, headache, and malaise and, later, cough with minimal sputum. The localization of the inflammatory exudate to the alveolar walls, prevents oxygenation of blood flowing through the affected air spaces which in turn causes mismatch of ventilation and perfusion. As a result, the degree of respiratory distress often seems out of proportion to the physical and radiographic findings. Identifying the causative agent can be difficult.

Influenza Infections

Perhaps no other communicable disorder causes as much public concern in the developed world as the threat of an influenza epidemic. The influenza virus is a single-stranded RNA virus, bound by a nucleoprotein that determines the virus type—A, B, or C. The viral surface has a lipid bilayer containing the viral hemagglutinin and neuraminidase, which determine the subtype (e.g., H1N1, H3N2). Host antibodies to the hemagglutinin and neuraminidase prevent and ameliorate, respectively, future infection with the influenza virus. The type A viruses infect humans, pigs, horses, and birds and are the major cause of *pandemic* and *epidemic* influenza infections. Epidemics of influenza occur through mutations of the hemagglutinin and neuraminidase antigens that allow the virus to escape most host antibodies *(antigenic drift)*. Pandemics, which last longer and are more widespread than epidemics, may occur when both the hemagglutinin and neuraminidase are replaced through recombination of RNA segments with those of animal viruses, making all animals susceptible to the new influenza virus *(antigenic shift)*. Commercially available influenza vaccines provide reasonable protection against the disease, especially in vulnerable infants and in older adults.

Insight into future pandemics has come from studying those past. DNA analysis of viral genomes retrieved from the lungs of a soldier who died in the great 1918 influenza pandemic that killed 20 million to 40 million individuals worldwide identified swine influenza sequences, consistent with this virus having its origin in an antigenic shift. The first flu pandemic of this century, in 2009, also resulted from an antigenic shift involving a virus of swine origin. It caused particularly severe infections in young adults, apparently because older adults had antibodies against past influenza strains that conveyed partial protection. Comorbidities such as diabetes, heart disease, lung disease, and immunosuppression also were associated with a higher risk for severe infection.

What then might be the source of the next great pandemic? One concern is centered on avian influenza, which normally infects birds. One avian strain, type H5N1, has spread throughout the world in wild and domestic birds. As of September 2015, approximately 700 H5N1 influenza virus infections and 400 deaths in humans (from 15 countries) have been reported to the World Health Organization (WHO). Nearly all cases have been acquired by close contact with domestic birds; most deaths resulted from pneumonia. Fortunately, the transmission of the current H5N1 avian virus is inefficient. However, if H5N1 influenza recombines with an influenza that is highly infectious for humans, a strain might emerge that is capable of sustained human-to-human transmission (and, thus, of causing the next great pandemic).

SUMMARY

ACUTE PNEUMONIAS

- *S. pneumoniae* (the pneumococcus) is the most common cause of community-acquired bacterial pneumonia and usually has a lobar pattern of involvement.
- Morphologically, lobar pneumonias evolve through four stages: congestion, red hepatization, gray hepatization, and resolution.
- Other common causes of bacterial pneumonias in the community include *H. influenzae* and *M. catarrhalis* (both associated with acute exacerbations of COPD), *S. aureus* (usually secondary to viral respiratory infections), *K. pneumoniae* (observed in chronic alcoholics), *P. aeruginosa* (seen in individuals with cystic fibrosis, in burn victims, and in patients with neutropenia), and *L. pneumophila*, seen particularly in organ transplant recipients.
- *Viral pneumonias* are characterized by respiratory distress out of proportion to the clinical and radiologic signs, and by inflammation that is predominantly confined to alveolar septa, with generally clear alveoli.
- Common causes of viral pneumonia include influenza A and B, respiratory syncytial virus, human metapneumovirus, parainfluenza virus, and adenovirus.

Hospital-Acquired Pneumonias

Nosocomial, or hospital-acquired, pneumonias are defined as pulmonary infections acquired in the course of a hospital stay. These infections not only have an adverse impact on the clinical course of ill patients, but

also add considerably to the burgeoning costs of health care. Nosocomial infections are common in hospitalized individuals with severe underlying disease, those who are immunosuppressed, or those on prolonged antibiotic regimens. Patients on mechanical ventilation are a particularly high-risk group, and infections acquired in this setting are given the designation *ventilator-associated pneumonia.* Gram-negative rods (members of *Enterobacteriaceae* and *Pseudomonas* spp.) and *S. aureus* are the most common isolates; unlike community-acquired pneumonias, *S. pneumoniae* is not a common pathogen in the hospital setting.

Aspiration Pneumonia

Aspiration pneumonia occurs in debilitated patients or those who aspirate gastric contents while unconscious (e.g., after a stroke) or during repeated vomiting. Those affected have abnormal gag and swallowing reflexes that facilitate aspiration. The resultant pneumonia is partly chemical, due to the extremely irritating effects of the gastric acid, and partly bacterial. Typically, more than one organism is recovered on culture, aerobes being more common than anaerobes (see Table 13.5). Aspiration pneumonia is often necrotizing, pursues a fulminant clinical course, and is a frequent cause of death in individuals predisposed to aspiration. In those who survive, abscess formation is a common complication. Microaspiration, by contrast, occurs in many individuals, especially those with gastroesophageal reflux, and may exacerbate other lung diseases but does not lead to pneumonia.

Lung Abscess

***Lung abscess* refers to a localized area of suppurative necrosis within the pulmonary parenchyma, resulting in the formation of one or more large cavities.** The causative organism may be introduced into the lung by any of the following mechanisms:

- *Aspiration of infective material* from carious teeth or infected sinuses or tonsils. This may occur during oral surgery, anesthesia, coma, or alcoholic intoxication, and in debilitated patients with depressed cough reflexes.
- *Aspiration of gastric contents,* usually accompanied by infectious organisms originating in the oropharynx.
- *As a complication of necrotizing bacterial pneumonias,* particularly those caused by *S. aureus, Streptococcus pyogenes, K. pneumoniae, Pseudomonas* spp., and, rarely, type 3 pneumococci. Mycotic infections and bronchiectasis also may lead to lung abscesses.
- *Bronchial obstruction,* particularly with bronchogenic carcinoma obstructing a bronchus or bronchiole. Impaired drainage, distal atelectasis, and aspiration of blood and tumor fragments all contribute to the development of abscesses. An abscess also may form within an excavated necrotic portion of a tumor.
- *Septic embolism,* from infective endocarditis of the right side of the heart.
- In addition, lung abscesses may result from *hematogenous spread of bacteria* in disseminated pyogenic infection. This occurs most characteristically in staphylococcal bacteremia and often results in multiple lung abscesses.

Anaerobic bacteria are present in almost all lung abscesses, and they are the exclusive isolates in one-third to two-thirds of cases. The most frequently encountered anaerobes are commensals normally found in the oral cavity, principally species of *Prevotella, Fusobacterium, Bacteroides, Peptostreptococcus,* and microaerophilic streptococci.

MORPHOLOGY

Abscesses range in diameter from a few millimeters to large cavities 5 to 6 cm across. The localization and number of abscesses depend on their mode of development. Pulmonary abscesses resulting from aspiration of infective material are **more common on the right side** (with its more vertical airways) than on the left, and most are single. On the right side, they tend to occur in the posterior segment of the upper lobe and in the apical segments of the lower lobe, because these locations reflect the probable course of aspirated material when the patient is recumbent. Abscesses that develop in the course of pneumonia or bronchiectasis commonly are multiple, basal, and diffusely scattered. Septic emboli and abscesses arising from hematogenous seeding are commonly multiple and may affect any region of the lungs.

As the focus of suppuration enlarges, it almost inevitably ruptures into airways. Thus, the contained exudate may be partially drained, producing an air-fluid level on radiographic examination. Occasionally, abscesses rupture into the pleural cavity and produce bronchopleural fistulas, the consequence of which is **pneumothorax** or **empyema.** Other complications arise from embolization of septic material to the brain, giving rise to meningitis or brain abscess. On histologic examination, as expected with any abscess, the suppurative focus is surrounded by variable amounts of fibrous scarring and mononuclear infiltration (lymphocytes, plasma cells, macrophages), depending on the chronicity of the lesion.

Clinical Features

The manifestations of a lung abscess are much like those of bronchiectasis and include a prominent cough that usually yields copious amounts of foul-smelling, purulent, or sanguineous sputum; occasionally, hemoptysis occurs. Spiking fever and malaise are common. Clubbing of the fingers, weight loss, and anemia may all occur. Abscesses occur in 10% to 15% of patients with bronchogenic carcinoma; thus, when a lung abscess is suspected in an older adult, underlying carcinoma must be considered. Secondary amyloidosis (Chapter 5) may develop in chronic cases. Treatment includes antibiotic therapy and, if needed, surgical drainage. Overall, the mortality rate is in the range of 10%.

Chronic Pneumonias

Chronic pneumonia most often is a localized lesion in an immunocompetent individual, with or without regional lymph node involvement. There is typically granulomatous inflammation, which may be due to bacteria (e.g., *M. tuberculosis*) or fungi. In immunocompromised patients, such as those with debilitating illness, on immunosuppressive regimens, or with human immunodeficiency

virus (HIV) infection (see later), the usual presentation is widespread disease due to systemic dissemination of the causative organism. Tuberculosis is by far the most important entity within the spectrum of chronic pneumonias.

Tuberculosis

Tuberculosis is a communicable chronic granulomatous disease caused by *Mycobacterium tuberculosis.* It usually involves the lungs but may affect any organ or tissue in the body.

Epidemiology

The World Health Organization (WHO) considers tuberculosis to be the most common cause of death resulting from a single infectious agent. It is estimated that 1.7 billion individuals are infected worldwide, with 8 to 10 million new cases and 1.5 million deaths per year. In the Western world, deaths from tuberculosis peaked in 1800 and steadily declined throughout the 1800s and 1900s. However, in 1984 the decline in new cases stopped abruptly, a change that resulted from the increased incidence of tuberculosis in HIV-infected individuals. As a consequence of intensive public health surveillance and tuberculosis prophylaxis among immunosuppressed individuals, the incidence of tuberculosis in U.S.-born individuals has declined since 1992. In 2014, there were approximately 9400 new cases of active tuberculosis in the United States, with nearly 60% of these occurring in immigrants from countries where tuberculosis is endemic.

Tuberculosis flourishes under conditions of poverty, crowding, and chronic debilitating illness. In the United States, tuberculosis is a disease of older adults, the urban poor, patients with AIDS, and members of minority communities. African Americans, Native Americans, the Inuit (from Alaska), Hispanics, and immigrants from Southeast Asia have higher rates of disease than other segments of the population. Certain disease states also increase the risk, such as diabetes mellitus, Hodgkin lymphoma, chronic lung disease (particularly silicosis), chronic renal failure, malnutrition, alcoholism, and immunosuppression. In areas of the world where HIV infection is prevalent, HIV infection is the dominant risk factor for the development of tuberculosis.

It is important that *infection* be differentiated from *disease.* Infection implies seeding of a focus with organisms, which may or may not cause clinically significant tissue damage (i.e., disease). Although other routes may be involved, most infections are acquired by direct person-to-person transmission of airborne droplets of organisms from an active case to a susceptible host. In most individuals, an asymptomatic focus of pulmonary infection appears that is self-limited, although uncommonly, primary tuberculosis may result in the development of fever and pleural effusions. Generally, the only evidence of infection, if any remains, is a tiny, telltale fibrocalcific nodule at the site of the infection. Viable organisms may remain dormant in such loci for decades, and possibly for the life of the host. Such individuals are infected but do not have active disease and therefore cannot transmit organisms to others. Yet, if their immune defenses are lowered, the infection may reactivate to produce communicable and potentially life-threatening disease.

Infection with *M. tuberculosis* typically leads to the development of delayed hypersensitivity, which can be detected by the tuberculin (Mantoux) test. About 2 to 4 weeks after the infection has begun, intracutaneous injection of 0.1 mL of sterile purified protein derivative (PPD) induces a visible and palpable induration (at least 5 mm in diameter) that peaks in 48 to 72 hours. Sometimes, more PPD is required to elicit the reaction, and unfortunately, in some responders, the standard dose may produce a large, necrotizing lesion. A positive tuberculin skin test result signifies cell-mediated hypersensitivity to tubercular antigens, but does not differentiate between infection and disease. A well-recognized limitation of this test is that false-negative reactions (or skin test anergy) may be produced by certain viral infections, sarcoidosis, malnutrition, Hodgkin lymphoma, immunosuppression, and (notably) overwhelming active tuberculous disease. False-positive reactions may result from infection by atypical mycobacteria.

About 80% of the population in certain Asian and African countries is tuberculin-positive. In contrast, in 2012, approximately, 5% to 10% of the U.S. population was positive, indicating the marked difference in rates of exposure to the tubercle bacillus. In general, 3% to 4% of previously unexposed individuals acquire active tuberculosis during the first year after "tuberculin conversion," and no more than 15% do so thereafter. Thus, only a small fraction of those who contract an infection develop active disease.

Etiology and Pathogenesis

Mycobacteria are slender rods that are acid-fast (i.e., they have a high content of complex lipids that readily bind the Ziehl-Neelsen [carbol fuchsin] stain and subsequently stubbornly resist decolorization). *M. tuberculosis hominis* is responsible for most cases of tuberculosis; the reservoir of infection typically is found in individuals with active pulmonary disease. Transmission usually is direct, by inhalation of airborne organisms in aerosols generated by expectoration or by exposure to contaminated secretions of infected individuals. Oropharyngeal and intestinal tuberculosis contracted by drinking milk contaminated with *Mycobacterium bovis* infection is now rare except in those countries with tuberculous dairy cows and sales of unpasteurized milk. Other mycobacteria, particularly *Mycobacterium avium complex,* are much less virulent than *M. tuberculosis* and rarely cause disease in immunocompetent individuals. However, they cause disease in 10% to 30% of patients with AIDS.

Pathogenesis

The pathogenesis of tuberculosis in the previously unexposed immunocompetent individual is centered on the development of cell-mediated immunity, which confers resistance to the organism and results in development of tissue hypersensitivity to tubercular antigens. The pathologic features of tuberculosis, such as caseating granulomas and cavitation, are the result of the destructive tissue hypersensitivity that is part and parcel of the host immune response. Because the effector cells for both protective

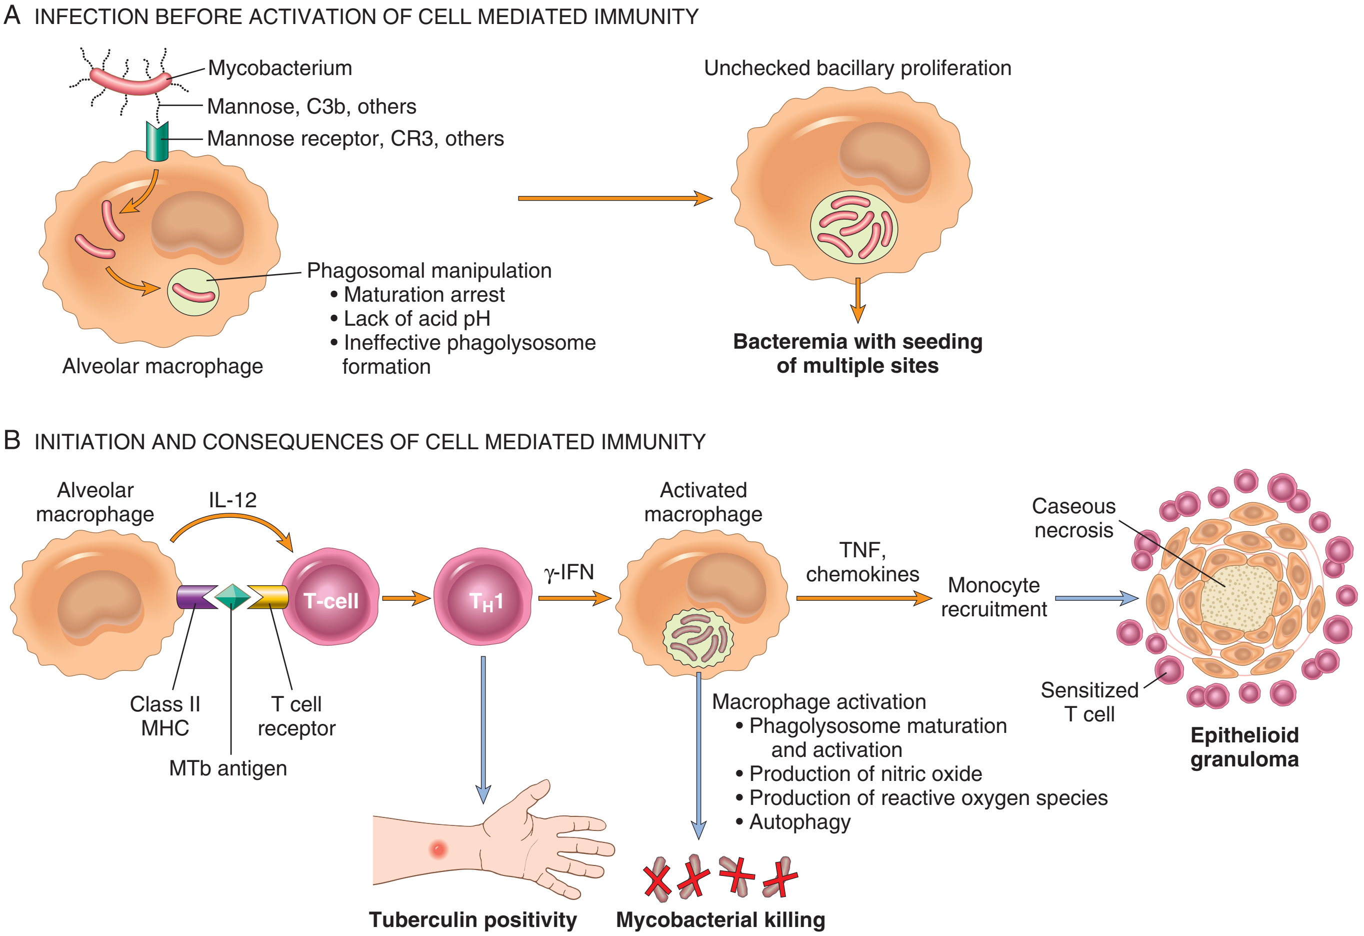

Fig. 13.33 Sequence of events in the natural history of primary pulmonary tuberculosis. This sequence commences with inhalation of virulent strains of *Mycobacterium* and culminates in the development of immunity and delayed hypersensitivity to the organism. (A) Events occurring in the first 3 weeks after exposure. (B) Events thereafter. The development of resistance to the organism is accompanied by conversion to a positive result on tuberculin skin testing. Cells and bacteria are not drawn to scale. *IFN-γ,* Interferon γ; *iNOS,* inducible nitric oxide synthase; *MHC,* major histocompatibility complex; *MTb, Mycobacterium* tuberculosis; *TNF,* tumor necrosis factor.

immunity and damaging hypersensitivity are the same, the appearance of tissue hypersensitivity also signals the acquisition of immunity to the organism. The sequence of events from inhalation of the infectious inoculum to containment of the primary focus is illustrated in Fig. 13.33 and can be outlined as follows:

- *Entry into macrophages.* A virulent strain of mycobacteria gains entry to macrophage endosomes, a process mediated by several macrophage receptors, including the macrophage mannose receptor and complement receptors that recognize several components of the mycobacterial cell walls.
- *Replication in macrophages.* Once internalized, the organisms inhibit normal microbicidal responses by preventing the fusion of the lysosomes with the phagocytic vacuole, allowing the mycobacterium to persist and proliferate. Thus, the earliest phase of primary tuberculosis (the first 3 weeks) in the nonsensitized patient is characterized by bacillary proliferation within the pulmonary alveolar macrophages and air spaces, eventually resulting in bacteremia and seeding of the organisms to multiple sites. Despite the bacteremia, most individuals at this stage are asymptomatic or have a mild flulike illness.
- *Development of cell-mediated immunity.* This occurs approximately 3 weeks after exposure. Processed mycobacterial antigens reach the draining lymph nodes and are presented to CD4 T cells by dendritic cells and macrophages. Under the influence of macrophage-secreted IL-12, CD4+ T cells of the T_H1 subset are generated that are capable of secreting IFN-γ.
- *T cell–mediated macrophage activation and killing of bacteria.* IFN-γ released by the CD4+ T cells of the T_H1 subset is crucial in activating macrophages. Activated macrophages, in turn, release a variety of mediators and upregulate expression of genes with important downstream effects, including: (1) TNF, which is responsible for recruitment of monocytes, which in turn undergo activation and differentiation into the "epithelioid histiocytes" that characterize the granulomatous response; (2) inducible nitric oxide synthase (iNOS), which raises nitric oxide (NO) levels, helping to create reactive nitrogen intermediates that appear to be particularly important in killing of mycobacteria; and (3) anti-microbial peptides (defensins) that are also toxic to mycobacterial organisms.
- *Granulomatous inflammation and tissue damage.* **In addition to stimulating macrophages to kill mycobacteria,**

the T_H1 response orchestrates the formation of granulomas and caseous necrosis. Macrophages activated by IFN-γ differentiate into the "epithelioid histiocytes" that aggregate to form granulomas; some epithelioid cells may fuse to form giant cells. In many individuals, this response halts the infection before significant tissue destruction or illness occur. In other individuals with immune deficits due to age or immunosuppression, the infection progresses and the ongoing immune response results in caseation necrosis. Activated macrophages also secrete TNF and chemokines, which promote recruitment of more monocytes. The importance of TNF is underscored by the fact that patients with rheumatoid arthritis who are treated with a TNF antagonist have an increased risk for tuberculosis reactivation.

In summary, immunity to a tubercular infection is primarily mediated by T_H1 cells, which stimulate macrophages to kill mycobacteria. This immune response, while largely effective, comes at the cost of hypersensitivity and the accompanying tissue destruction. Defects in any of the steps of a T_H1 T cell response (including IL-12, IFN-γ, TNF, or nitric oxide production) result in poorly formed granulomas, absence of resistance, and disease progression. Individuals with inherited mutations in any component of the T_H1 pathway are extremely susceptible to infections with mycobacteria. Reactivation of the infection or reexposure to the bacilli in a previously sensitized host results in rapid mobilization of a defensive reaction but also increased tissue necrosis. Just as hypersensitivity and resistance appear in parallel, so, too, the loss of hypersensitivity (indicated by tuberculin negativity in a *M. tuberculosis*-infected patient) is an ominous sign of fading resistance to the organism.

Primary Tuberculosis

Primary tuberculosis is the form of disease that develops in a previously unexposed and therefore unsensitized patient. About 5% of those newly infected acquire significant disease.

In the large majority of otherwise healthy individuals, the only consequence of primary tuberculosis are the foci of scarring discussed earlier. However, these foci may harbor viable bacilli and thus serve as a nidus for disease reactivation at a later time if host defenses wane. Uncommonly, new infection leads to *progressive primary tuberculosis.* This complication occurs in patients who are overtly immunocompromised or who have more subtle defects in host defenses, as is characteristic of malnourished individuals. Certain racial groups, such as the Inuit, also are more prone to the development of progressive primary tuberculosis. The incidence of progressive primary tuberculosis is particularly high in HIV-positive patients with significant immunosuppression (i.e., CD4+ T cell counts below 200 cells/μL). Immunosuppression results in an inability to mount a CD4+ T cell–mediated response that would contain the primary focus; because hypersensitivity and resistance are most often concomitant factors, the lack of a tissue hypersensitivity reaction results in the absence of the characteristic caseating granulomas *(nonreactive tuberculosis)* (see Fig. 13.35D).

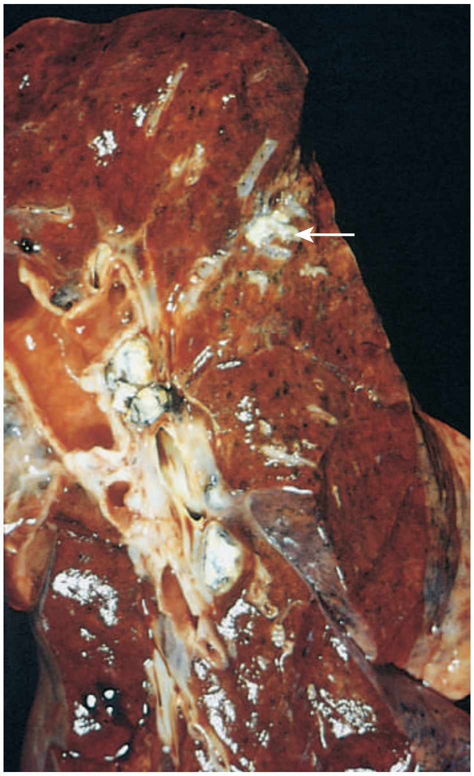

Fig. 13.34 Primary pulmonary tuberculosis, Ghon complex. The gray-white parenchymal focus *(arrow)* is under the pleura in the lower part of the upper lobe. Hilar lymph nodes with caseation are seen *(left).*

MORPHOLOGY

In countries in which bovine tuberculosis and infected milk have largely disappeared, primary tuberculosis almost always begins in the lungs. The inhaled bacilli usually implant in the distal air spaces of the lower part of the upper lobe or in the upper part of the lower lobe. They are typically close to the pleura. During the development of sensitization, a 1-cm to 1.5-cm area of gray-white inflammatory consolidation emerges. This is called the **Ghon focus.** In the majority of cases, the center of this focus undergoes caseous necrosis. Tubercle bacilli, either free or within phagocytes, travel via the lymphatic vessels to the regional lymph nodes, which also often caseate. This combination of parenchymal and nodal lesions is called the **Ghon complex** (Fig. 13.34). Lymphatic and hematogenous dissemination to other parts of the body also occurs during the first few weeks. Development of cell-mediated immunity controls the infection in approximately 95% of cases. Therefore, the Ghon complex undergoes progressive fibrosis, and calcification often follows (detectable as a **Ranke complex** on radiograph). Despite seeding of other organs, no lesions develop. Histologically, sites of infection are involved by a characteristic inflammatory reaction marked by the presence of caseating and noncaseating granulomas, which consist of epithelioid histiocytes and multinucleate giant cells (Fig. 13.35A to C).

Secondary Tuberculosis (Reactivation Tuberculosis)

Secondary tuberculosis is the pattern of disease that arises in a previously sensitized host. It may appear shortly after primary tuberculosis, but more commonly arises from reactivation of dormant primary lesions many decades

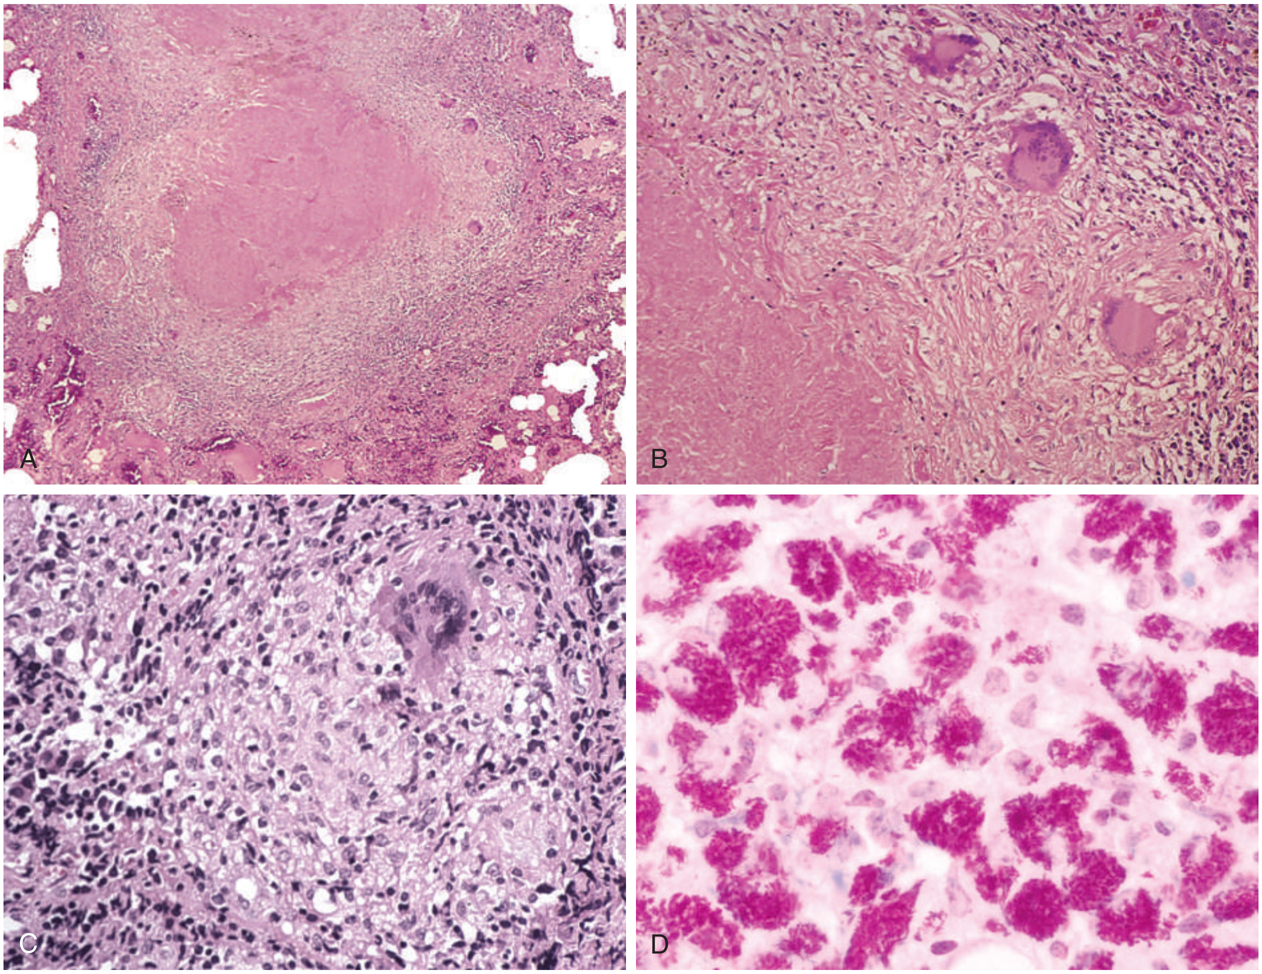

Fig. 13.35 The morphologic spectrum of tuberculosis. A characteristic tubercle at low magnification (A) and at higher power (B) shows central granular caseation surrounded by epithelioid and multinucleate giant cells. This is the usual response in individuals who develop cell-mediated immunity to the organism. (C) Occasionally, even in immunocompetent patients, tubercular granulomas may not show central caseation; hence, irrespective of the presence or absence of caseous necrosis, use of special stains for acid-fast organisms is indicated when granulomas are present. (D) In this specimen from an immunosuppressed patient, sheets of macrophages packed with mycobacteria are seen (acid-fast stain).

after initial infection, particularly when host resistance is weakened. It also may result from reinfection, which may occur either because the protection afforded by the primary disease has waned or because of exposure to a large inoculum of virulent bacilli. Whatever the source of the organism, only a few patients (<5%) with primary disease subsequently develop secondary tuberculosis.

Secondary pulmonary tuberculosis is classically localized to the apex of one or both upper lobes. The reason is obscure but may relate to high oxygen tension in the apices. Because of the preexistence of hypersensitivity, the bacilli excite a prompt and marked tissue response that tends to wall off the focus. As a result of this localization, the regional lymph nodes are less prominently involved early in the disease than they are in primary tuberculosis. On the other hand, cavitation occurs readily in the secondary form, leading to erosion into and dissemination along airways. Such changes become an important source of infectivity, because the patient now produces sputum containing bacilli.

Secondary tuberculosis should always be an important consideration in HIV-positive patients who present with pulmonary disease. Of note, although an increased risk for tuberculosis exists at all stages of HIV disease, the manifestations differ depending on the degree of immunosuppression. For example, patients with less severe immunosuppression (CD4+ T cell counts >300 cells/μL) present with "usual" secondary tuberculosis (apical disease with cavitation) while those with more advanced immunosuppression (CD4+ T cell counts below 200 cells/μL) present with a clinical picture that resembles progressive primary tuberculosis (lower and middle lobe consolidation, hilar lymphadenopathy, and noncavitary disease). The extent of immunosuppression also determines the frequency of extrapulmonary involvement, rising from 10% to 15% in mildly immunosuppressed patients to greater than 50% in those with severe immune deficiency.

MORPHOLOGY

The initial lesion usually is a small focus of consolidation, less than 2 cm in diameter, within 1 to 2 cm of the **apical pleura.** Such foci are sharply circumscribed, firm, gray-white to yellow areas that have a variable amount of central caseation and peripheral

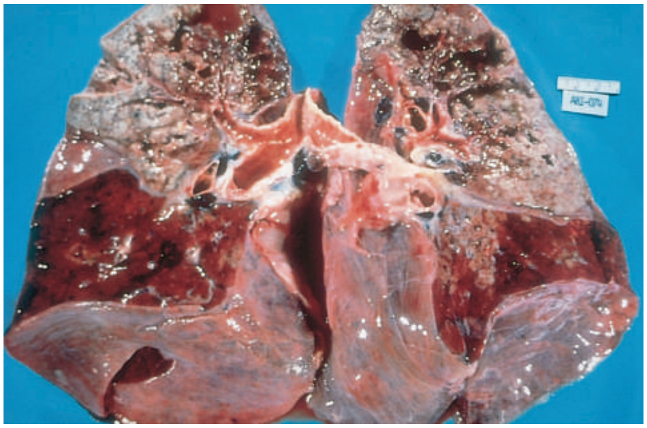

Fig. 13.36 Secondary pulmonary tuberculosis. The upper parts of both lungs are riddled with gray-white areas of caseation and multiple areas of softening and cavitation.

fibrosis. In favorable cases, the initial parenchymal focus undergoes progressive fibrous encapsulation, leaving only fibrocalcific scars. Histologically, the active lesions show characteristic coalescent tubercles with central caseation. Although tubercle bacilli can be demonstrated by appropriate methods in early exudative and caseous phases of granuloma formation, it is usually impossible to find them in the late, fibrocalcific stages.

Localized, apical, secondary pulmonary tuberculosis may heal with fibrosis either spontaneously or after therapy, or the disease may progress and extend along several different pathways. In **progressive pulmonary tuberculosis,** the apical lesion enlarges and the area of caseation expands. Erosion into a bronchus evacuates the caseous center, creating a ragged, **irregular cavity lined by caseous material** that is poorly walled off by fibrous tissue (Fig. 13.36). Erosion of blood vessels results in hemoptysis. With adequate treatment, the process may be arrested, although healing by fibrosis often distorts the pulmonary architecture. Irregular cavities, now free of caseous necrosis, may remain intact or collapse and become fibrotic. If the treatment is inadequate or host defenses are impaired, the infection may spread by direct extension and by dissemination through airways, lymphatic channels, and the vascular system. **Miliary pulmonary disease** occurs when organisms reach the bloodstream through lymphatic vessels and then recirculate to the lung via the pulmonary arteries. The lesions appear as small (2-mm) foci of yellow-white consolidation scattered through the lung parenchyma (the word *miliary* is derived from the resemblance of these foci to millet seeds). With progressive pulmonary tuberculosis, the pleural cavity is invariably involved and serous **pleural effusions, tuberculous empyema,** or **obliterative fibrous pleuritis** may develop.

Endobronchial, endotracheal, and **laryngeal tuberculosis** may develop when infective material is spread either through lymphatic channels or from expectorated infectious material. The mucosal lining may be studded with minute granulomatous lesions, sometimes apparent only on microscopic examination.

Systemic miliary tuberculosis ensues when the organisms disseminate hematogenously throughout the body. Systemic miliary tuberculosis is most prominent in the liver, bone marrow, spleen, adrenal glands, meninges, kidneys, fallopian tubes, and epididymis (Fig. 13.37).

Isolated-organ tuberculosis may appear in any one of the organs or tissues seeded hematogenously and may be the presenting manifestation of tuberculosis. Organs typically involved include the meninges (tuberculous meningitis), kidneys (renal tuberculosis), adrenal glands, bones (osteomyelitis), and fallopian tubes (salpingitis). When the vertebrae are affected, the condition is referred to as **Pott disease.** Paraspinal "cold" abscesses containing necrotic tissues may track along the tissue planes to present as an abdominal or pelvic mass.

Lymphadenitis is the most frequent form of extrapulmonary tuberculosis, usually occurring in the cervical region ("scrofula"). Lymphadenopathy tends to be unifocal, and most patients do not have concurrent extranodal disease. HIV-positive patients, on the other hand, almost always have multifocal disease, systemic symptoms, and either pulmonary or other organ involvement by active tuberculosis.

In years past, **intestinal tuberculosis** contracted by the drinking of contaminated milk was fairly common as a primary focus of tuberculosis. In developed countries today, intestinal tuberculosis is more often a complication of protracted advanced secondary tuberculosis, secondary to the swallowing of coughed-up infective material. Typically, the organisms are trapped in mucosal lymphoid aggregates of the small and large bowel, which then undergo inflammatory enlargement with ulceration of the overlying mucosa, particularly in the ileum.

The many patterns of tuberculosis are depicted in Fig. 13.38.

Clinical Features

Localized secondary tuberculosis may be asymptomatic. When manifestations appear, they are usually insidious in onset, with gradual development of both systemic and localizing symptoms and signs. Systemic manifestations, probably related to the release of cytokines by activated macrophages (e.g., TNF and IL-1), often appear early in the disease course and include malaise, anorexia, weight loss, and fever. Commonly, the fever is low grade and remittent (appearing late each afternoon and then subsiding), and night sweats occur. With progressive pulmonary involvement, increasing amounts of sputum, at first mucoid and later purulent, appear. When cavitation is present, the sputum contains tubercle bacilli. Some degree of hemoptysis

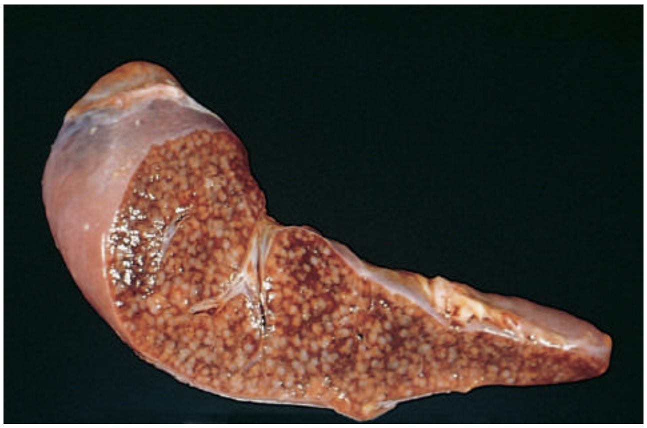

Fig. 13.37 Miliary tuberculosis of the spleen. The cut surface shows numerous gray-white granulomas.

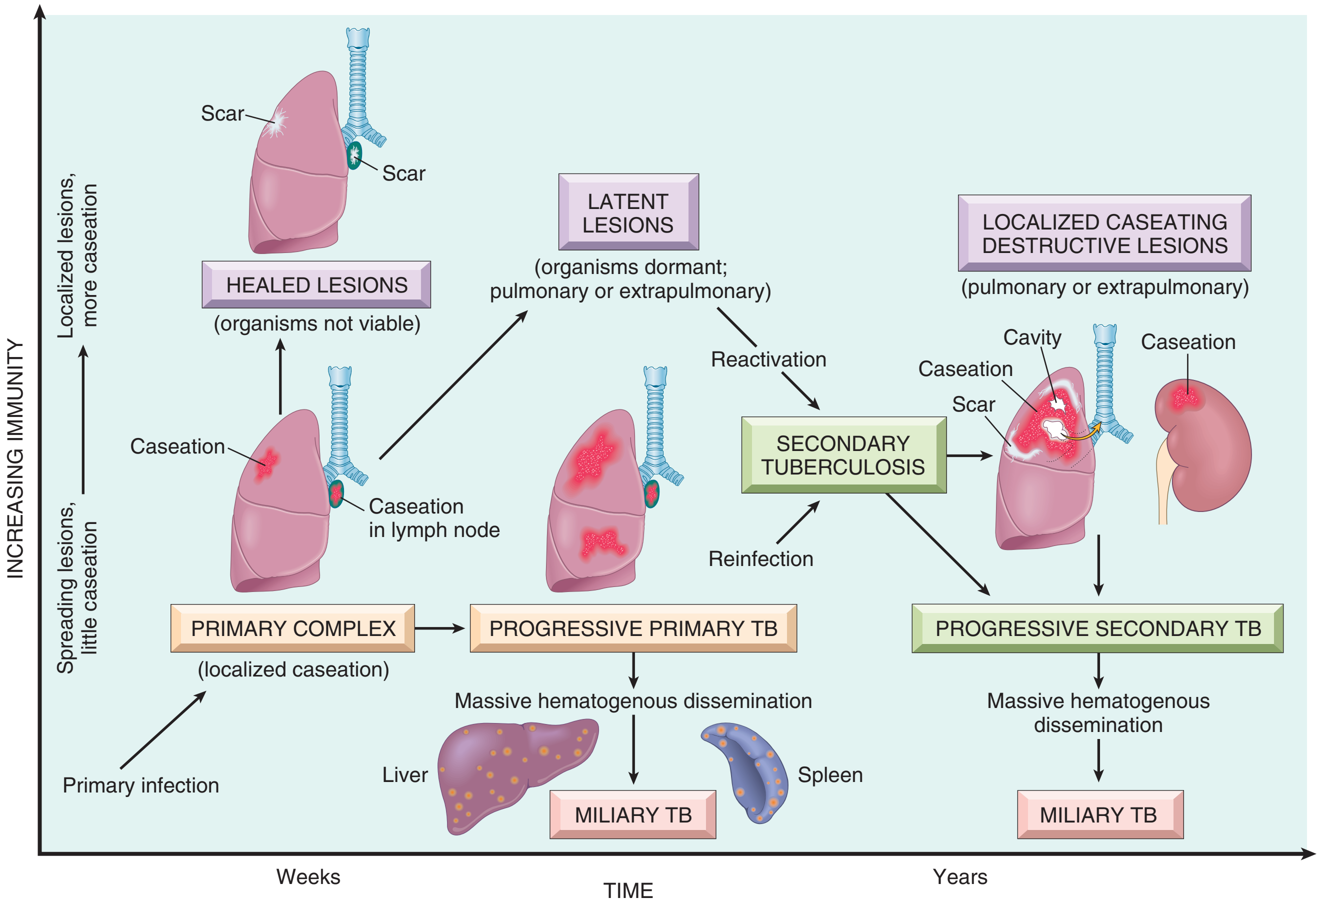

Fig. 13.38 The natural history and spectrum of tuberculosis. *(Adapted from a sketch provided by Dr. R.K. Kumar, The University of New South Wales, School of Pathology, Sydney, Australia.)*

is present in about half of all cases of pulmonary tuberculosis. Pleuritic pain may result from extension of the infection to the pleural surfaces. Extrapulmonary manifestations of tuberculosis are legion and depend on the organ system involved (e.g., tuberculous salpingitis may present as infertility, tuberculous meningitis with headache and neurologic deficits, Pott disease with back pain and paraplegia). The diagnosis of pulmonary disease is based in part on the history and on physical and radiographic findings of consolidation or cavitation in the apices of the lungs. Ultimately, however, tubercle bacilli must be identified.

The most common methodology for diagnosis of tuberculosis remains demonstration of acid-fast organisms in sputum by staining or by use of fluorescent auramine rhodamine. Conventional cultures for mycobacteria require up to 10 weeks, but liquid media–based radiometric assays that detect mycobacterial metabolism are able to provide an answer within 2 weeks. PCR amplification can be performed on liquid media with growth, as well as on tissue sections, to identify the mycobacterium. However, culture remains the standard diagnostic modality because it can identify the occasional PCR-negative case and also allows testing of drug susceptibility. Of concern, multidrug resistance (MDR), defined as resistance of mycobacteria to two or more of the primary drugs used for treatment of tuberculosis, is becoming more common, and the WHO estimated that 500,000 individuals were newly infected with multidrug-resistant tuberculosis in 2014. This represents approximately 3% of new cases and 20% of previously treated cases. The epicenter of this troubling epidemic lies in Eastern Europe and Russia, where in some locales up to 20% of new infections are with multidrug-resistant strains. Of even greater concern, approximately 5% to 10% of such cases exhibit extensive multidrug resistance, defined by resistance to a broad spectrum of antibiotics in current use against tuberculosis.

The prognosis is determined by the extent of the infection (localized versus widespread), the immune status of the host, and the antibiotic sensitivity of the organism. Understandably, the prognosis is guarded in those with multidrug-resistant tuberculosis. Amyloidosis may develop in persistent cases.

SUMMARY

TUBERCULOSIS

- Tuberculosis is a chronic granulomatous disease caused by *M. tuberculosis*, usually affecting the lungs, but virtually any extrapulmonary organ can be involved.
- Initial exposure to mycobacteria results in development of a cellular immune response that confers resistance and leads to hypersensitivity (as determined by a positive result on the tuberculin skin test).

- The T_H1 subset of CD4+ T cells has a crucial role in cell-mediated immunity against mycobacteria; mediators of inflammation and bacterial containment include IFN-γ, TNF, and nitric oxide.
- The histopathologic hallmark of host reaction to tuberculosis in immunocompetent individuals is the presence of granulomas, usually with caseous necrosis.
- Primary pulmonary tuberculosis in immunocompetent individuals is asymptomatic and results only in healed lesions, typically in a sub-pleural focus and a draining lymph node.
- Secondary (reactivation) tuberculosis arises in previously exposed individuals when host immune defenses are compromised, and usually manifests as cavitary lesions in the lung apices.
- Both progressive primary tuberculosis and secondary tuberculosis can result in systemic seeding, causing life-threatening forms of disease such as miliary tuberculosis and tuberculous meningitis.
- HIV-seropositive status is an important risk factor for development or recrudescence of active tuberculosis.

Nontuberculous Mycobacterial Disease

Nontuberculous mycobacteria most commonly cause chronic, localized pulmonary disease in immunocompetent individuals. In the United States, strains implicated most frequently include *Mycobacterium avium-intracellulare* (also called *M. avium* complex), *Mycobacterium kansasii,* and *Mycobacterium abscessus.* It is not uncommon for nontuberculous mycobacterial infection to manifest as upper-lobe cavitary disease, mimicking tuberculosis, especially in patients with a long history of smoking or alcohol abuse. Concomitant chronic pulmonary disease (COPD, cystic fibrosis, pneumoconiosis) is often present.

In immunosuppressed individuals (primarily HIV-seropositive patients), *M. avium* complex infection manifests as a disseminated disease associated with systemic signs and symptoms (fever, night sweats, weight loss). Hepatosplenomegaly and lymphadenopathy, signifying involvement of the mononuclear phagocyte system by the opportunistic pathogen, is common, as are gastrointestinal symptoms such as diarrhea and malabsorption. Pulmonary involvement is often indistinguishable from tuberculosis in patients with AIDS. Disseminated *M. avium* complex infection in patients with AIDS tends to occur late in the clinical course, when CD4+ T cell counts have fallen below 100 cells/μL. Hence, tissue examination usually does not reveal granulomas; instead, foamy macrophages "stuffed" with atypical mycobacteria typically are seen.

Histoplasmosis, Coccidioidomycosis, and Blastomycosis

Infections caused by dimorphic fungi, which include *Histoplasma capsulatum, Coccidioides immitis,* and *Blastomyces dermatitidis,* manifest either with isolated pulmonary involvement, as commonly seen in infected immunocompetent individuals, or with disseminated disease in immunocompromised individuals. T cell–mediated immune responses are critical for containing the infection, so individuals with compromised cell-mediated immunity, such as those with HIV, are prone to systemic disease. In part because of the overlap in clinical presentations, infectious diseases due to all three dimorphic fungi are considered together in this section.

Epidemiology

Each of the dimorphic fungi has a typical geographic distribution, as follows:

- *H. capsulatum* is endemic in the Ohio and central Mississippi River valleys and along the Appalachian Mountains in the southeastern United States. Warm, moist soil containing droppings from bats and birds provides an ideal medium for the growth of the mycelial form, which produces infectious spores.
- *C. immitis* is endemic in the southwestern and far western regions of the United States, particularly in California's San Joaquin Valley, where coccidial infection is known as "valley fever."
- *B. dermatitidis* has a distribution in the United States that overlaps with those in which histoplasmosis is found.

MORPHOLOGY

The yeast forms are fairly distinctive, which helps in the identification of individual fungi in tissue sections:

- *H. capsulatum:* round to oval, small yeast forms measuring 2 to 5 μm in diameter (Fig. 13.39A)
- *C. immitis:* thick-walled, nonbudding spherules, 20 to 60 μm in diameter, often filled with small endospores (see Fig. 13.39B)
- *B. dermatitidis:* round to oval and larger yeast forms than *Histoplasma* (5 to 25 μm in diameter) that reproduce by characteristic broad-based budding (see Fig. 13.39C and D)

Clinical Features

Clinical manifestations may take the form of (1) *acute (primary) pulmonary infection,* (2) *chronic (granulomatous) pulmonary disease,* or (3) *disseminated miliary disease.* The primary pulmonary nodules, composed of aggregates of macrophages filled with organisms, are associated with similar lesions in the regional lymph nodes. These lesions evolve into small granulomas complete with giant cells and may develop central necrosis and later fibrosis and calcification. The similarity to primary tuberculosis is striking, and differentiation requires identification of the yeast forms (best seen with silver stains). The clinical symptoms and signs resemble those of a "flulike" syndrome and are most often self-limited. In the vulnerable host, chronic cavitary pulmonary disease develops, with a predilection for the upper lobe, resembling the secondary form of tuberculosis. It is not uncommon for these fungi to give rise to perihilar mass lesions that resemble bronchogenic carcinoma radiologically. At this stage, manifestations may include cough, hemoptysis, and even dyspnea and chest pain.

In infants or immunocompromised adults, particularly those with HIV infection, disseminated disease (analogous to miliary tuberculosis) may develop. Under these circumstances, there are no well-formed granulomas. Instead, focal collections of phagocytes containing yeast forms are seen within the liver, spleen, lymph nodes, lymphoid tissue of the gastrointestinal tract, and bone marrow. The adrenal glands and meninges also may be involved, and in

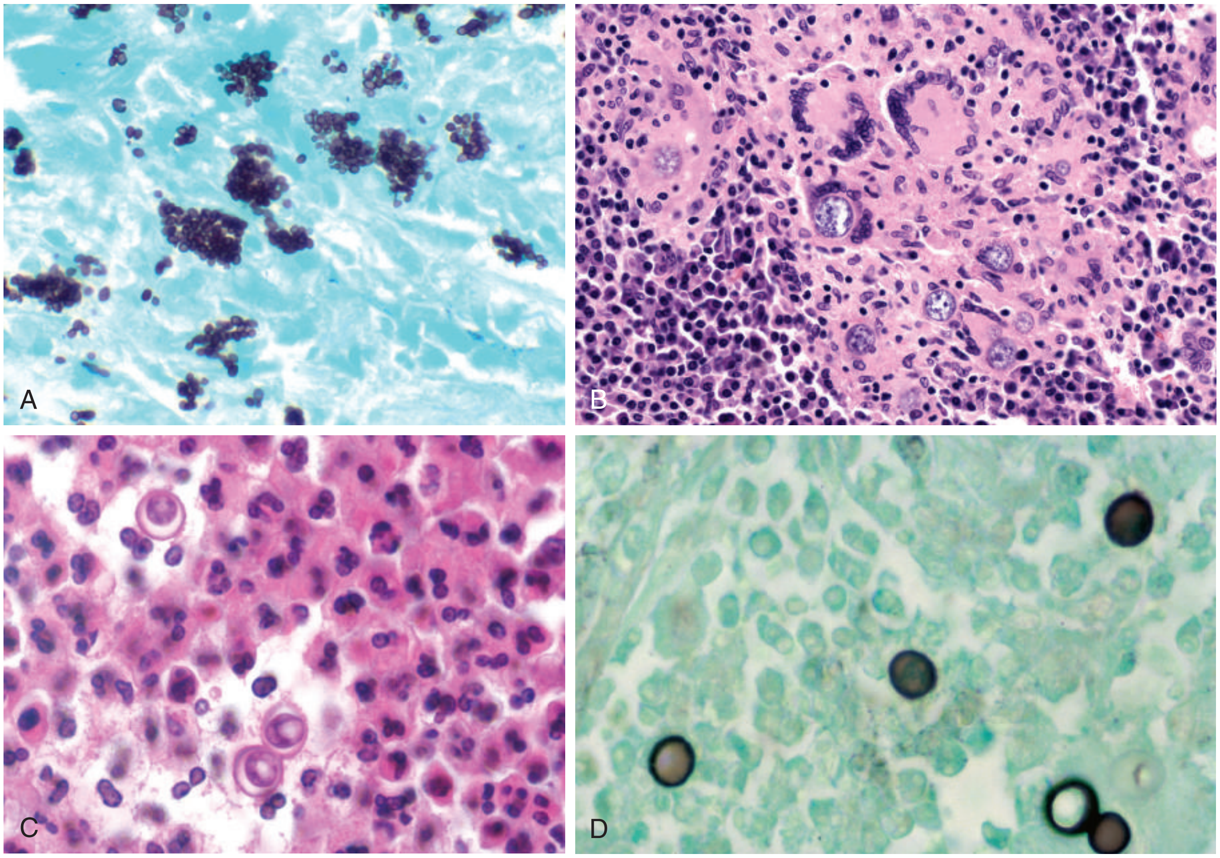

Fig. 13.39 (A) *Histoplasma capsulatum* yeast forms fill phagocytes in a lymph node of a patient with disseminated histoplasmosis (silver stain). (B) Coccidioidomycosis with intact spherules within multinucleated giant cells. (C) Blastomycosis, with rounded budding yeasts, larger than neutrophils. Note the characteristic thick wall and nuclei (not seen in other fungi). (D) Silver stain highlights the broad-based budding seen in *Blastomyces immitis* organisms.

a minority of cases, ulcers form in the nose and mouth, on the tongue, or in the larynx. Disseminated disease produces a febrile illness marked by hepatosplenomegaly, anemia, leukopenia, and thrombocytopenia. Cutaneous infections with disseminated *Blastomyces* organisms frequently induce striking epithelial hyperplasia, which may be mistaken for squamous cell carcinoma.

Pneumonia in the Immunocompromised Host

The appearance of a pulmonary infiltrate and signs of infection (e.g., fever) are some of the most common and serious complications in individuals with immune systems that are suppressed by disease, immunosuppressive drugs, or therapeutic irradiation. A wide variety of "opportunistic" pathogens, many of which rarely cause infection in normal individuals, can cause infections in these settings, and often more than one agent is involved. The more common pulmonary pathogens include (1) bacteria *(P. aeruginosa*, *Mycobacterium* spp., *L. pneumophila,* and *Listeria monocytogenes);* (2) viruses (cytomegalovirus and herpesvirus); and (3) fungi *(P. jiroveci, Candida* spp., *Aspergillus* spp., and *Cryptococcus neoformans).*

Cytomegalovirus Infection

Infection by cytomegalovirus (CMV), a member of the herpesvirus family, may manifest in various forms, depending partly on the age and the immune status of the host. Cells infected by the virus exhibit gigantism of both the cytoplasm and the nucleus. The nucleus typically contains a large inclusion surrounded by a clear halo ("owl's eye"), which gives the name to the classic form of symptomatic disease that occurs in neonates—*cytomegalic inclusion disease.* Although classic cytomegalic inclusion disease involves many organs, CMV infections are discussed here because in immunosuppressed adults, particularly patients with AIDS and recipients of allogeneic hematopoietic stem cell transplants, CMV pneumonitis is a serious problem.

Transmission of CMV can occur by several mechanisms, depending on the age group:

- A fetus can be infected transplacentally from a newly acquired or reactivated infection in the mother (*congenital* CMV infection).
- The virus can be transmitted to the infant through cervical or vaginal secretions at birth, or later through the breast milk of a mother with an active infection (*perinatal* CMV infection).
- Preschool children, especially in day care centers, can acquire it through saliva. Toddlers so infected readily transmit the virus to their parents.
- In patients older than 15 years of age, the venereal route is the dominant mode of transmission, but spread also may occur through contact with respiratory secretions and by the fecal-oral route.
- Iatrogenic transmission can occur at any age through organ transplantation or blood transfusion.

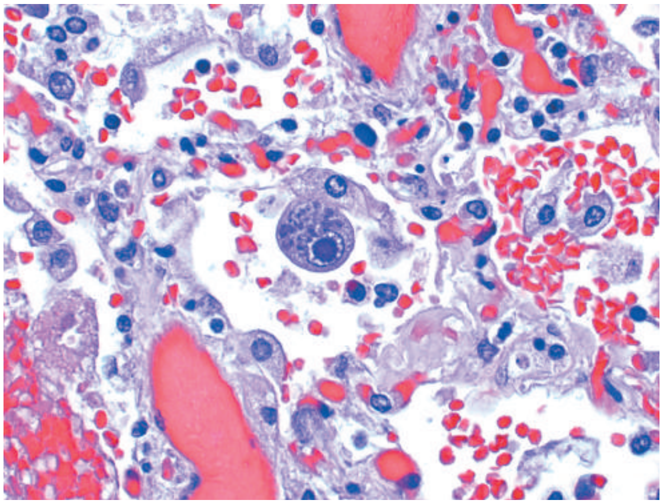

Fig. 13.40 Cytomegalovirus infection of the lung. A distinct nuclear inclusion and multiple cytoplasmic inclusions are seen in an enlarged cell.

MORPHOLOGY

Histologically, the characteristic enlargement of CMV-infected cells is readily appreciated. In the glandular organs, the parenchymal epithelial cells are affected; in the brain, the neurons; in the lungs, the alveolar macrophages and epithelial and endothelial cells; and in the kidneys, the tubular epithelial and glomerular endothelial cells. **Infected cells are strikingly enlarged, often to a diameter of 40 μm, and exhibit cellular and nuclear pleiomorphism.** Prominent intranuclear basophilic inclusions spanning half the nuclear diameter are usually set off from the nuclear membrane by a clear halo (Fig. 13.40). Within the cytoplasm of these cells, smaller basophilic inclusions also may be seen.

Cytomegalovirus Mononucleosis

In healthy young children and adults, the disease is nearly always asymptomatic. In surveys around the world, 50% to 100% of adults demonstrate anti-CMV antibodies in the serum, indicating previous exposure. The most common clinical manifestation of CMV infection in immunocompetent hosts beyond the neonatal period is an infectious mononucleosis–like illness marked by fever, atypical lymphocytosis, lymphadenopathy, and hepatomegaly accompanied by abnormal liver function test results, suggesting mild hepatitis. Most patients recover from CMV mononucleosis without any sequelae, although excretion of the virus may occur in body fluids for months to years. Irrespective of the presence or absence of symptoms after infection, an individual who is once infected becomes seropositive for life. The virus remains latent within leukocytes, which are the major reservoirs.

Cytomegalovirus Infection in Immunosuppressed Individuals

Immunosuppression-related CMV infection occurs most commonly in recipients of transplants (such as heart, liver, kidney, lung, or hematopoietic stem cell) and in patients with AIDS. This can be either primary infection or reactivation of a latent infection. CMV is the most common opportunistic viral pathogen in AIDS.

In all of these settings, serious disseminated CMV infections primarily affect the lungs (pneumonitis), gastrointestinal tract (colitis), and retina (retinitis); the central nervous system usually is spared. In the lung, infection is associated with typical cytomegalic changes, mononuclear infiltrates, and foci of necrosis, which may progress to acute respiratory distress syndrome. Intestinal necrosis and ulceration can develop and may be extensive, leading to the formation of "pseudomembranes" (Chapter 15) and debilitating diarrhea. CMV retinitis, by far the most common form of opportunistic CMV disease, can occur either alone or in combination with involvement of the lungs and intestinal tract. Diagnosis of CMV infection is made by demonstration of characteristic viral inclusions in tissue sections, successful viral culture, rising anti-viral antibody titer, and qualitative or quantitative PCR assay–based detection of CMV DNA. The latter has revolutionized the approach to monitoring patients after transplantation.

Pneumocystis

P. jiroveci (previously *P. carinii*), an opportunistic infectious agent formerly considered to be a protozoan, is now classified as a fungus. Serologic evidence indicates that virtually all individuals are exposed to *Pneumocystis* during the first few years of life, but in most the infection remains latent. Reactivation with development of clinical disease occurs almost exclusively in immunocompromised individuals. Indeed, patients with AIDS are extremely susceptible to infection with *P. jiroveci*, and it also may infect severely malnourished infants and immunosuppressed individuals (especially after organ transplantation or in individuals receiving cytotoxic chemotherapy or corticosteroids). In patients with AIDS, the risk for acquiring *P. jiroveci* infections increases in inverse proportion to the CD4+ T cell count, with counts less than 200 cells/μL having a strong predictive value. *Pneumocystis* infection is largely confined to the lung, where it produces an interstitial pneumonitis.

MORPHOLOGY

Involved areas of the lung contain a characteristic **intraalveolar foamy, pink-staining exudate** with hematoxylin-eosin (H&E) stain ("cotton candy" exudate) (Fig. 13.41A). The septa are thickened by edema and a minimal mononuclear infiltrate. Special stains are required to visualize the organism. Silver stain of tissue sections reveals **round- to cup-shaped cysts** (4 to 10 μm in diameter) within the alveolar exudates (see Fig. 13.41B).

The diagnosis of *Pneumocystis* pneumonia should be considered in any immunocompromised patient with respiratory symptoms and abnormal findings on chest radiograph. Fever, dry cough, and dyspnea occur in 90% to 95% of patients, in whom radiographic evidence of bilateral perihilar and basilar infiltrates is typical. Hypoxia is frequent; pulmonary function studies show a restrictive lung defect. The most sensitive and effective method of diagnosis is to identify the organism in induced sputum or bronchoalveolar lavage fluid using immunofluorescence. If

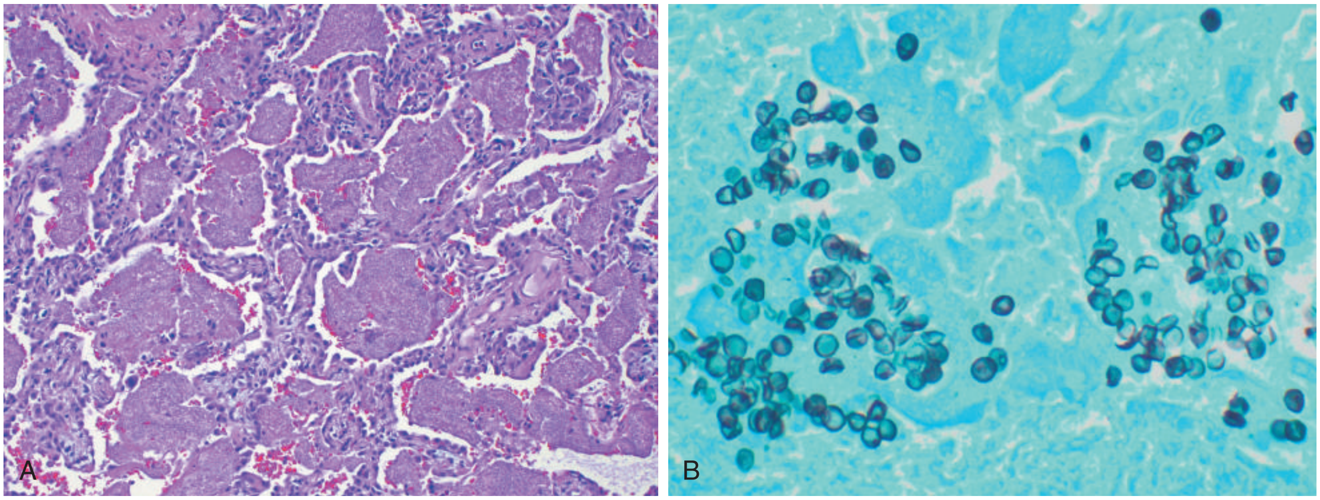

Fig. 13.41 Pneumocystis pneumonia. (A) The alveoli are filled with a characteristic foamy acellular exudate. (B) Silver stain demonstrates cup-shaped and round cysts within the exudate.

treatment is initiated before widespread involvement, the outlook for recovery is good; however, because residual organisms are likely to persist, particularly in patients with AIDS, relapses are common unless the underlying immunodeficiency is corrected or prophylactic therapy is given.

Opportunistic Fungal Infections

Candidiasis

Candida albicans is the most common disease-causing fungus. It is a normal inhabitant of the oral cavity, gastrointestinal tract, and vagina in many individuals. Systemic candidiasis (with associated pneumonia) is a disease restricted to immunocompromised patients that has protean manifestations.

MORPHOLOGY

In tissue sections, *C. albicans* demonstrates yeastlike forms (blastoconidia), pseudohyphae, and true hyphae (Fig. 13.42A). Pseudohyphae are an important diagnostic clue and represent budding yeast cells joined end to end at constrictions, thus simulating true fungal hyphae. The organisms may be visible with routine H&E stains, but a variety of special "fungal" stains (Gomori methenamine-silver, periodic acid–Schiff) commonly are used to better highlight the pathogens.

Clinical Features

Candidiasis can involve the mucous membranes, skin, and deep organs (invasive candidiasis). Among these varied presentations, the following merit brief mention:

- *Superficial infection on mucosal surfaces of the oral cavity (thrush).* This is the most common presentation. Florid proliferation of the fungi creates gray-white, dirty-looking pseudomembranes composed of matted organisms and inflammatory cells and tissue debris. Deep to the surface, there is mucosal hyperemia and inflammation. Thrush is seen in newborns, debilitated patients, and children receiving oral corticosteroids for asthma, and after a course of broad-spectrum antibiotics that destroy competing normal bacterial flora. The other major risk group includes HIV-positive patients; patients with oral thrush not associated with an obvious underlying condition should be evaluated for HIV infection.
- *Vaginitis* is extremely common in women, especially those who are diabetic or pregnant or on oral contraceptive pills.
- *Esophagitis* is common in patients with AIDS and in those with hematolymphoid malignancies. These patients present with dysphagia (painful swallowing) and retrosternal pain; endoscopy demonstrates white plaques and pseudomembranes resembling those found on other mucosal surfaces.
- *Skin infection* can manifest in many different forms, including infection of the nail *(onychomycosis),* nail folds *(paronychia),* hair follicles *(folliculitis),* moist, intertriginous skin such as armpits or webs of the fingers and toes *(intertrigo),* and penile skin *(balanitis). Diaper rash* is a cutaneous candidal infection seen in the perineum of infants, in the region of contact with wet diapers.
- *Chronic mucocutaneous candidiasis* is a chronic refractory disease afflicting the mucous membranes, skin, hair, and nails; it is associated with a variety of underlying T cell defects. These include *Job syndrome,* an inherited condition with a variety of abnormalitles including an defect in Th17 T cell responses, which are important in controlling fungal infections (Chapter 5).
- *Invasive candidiasis* implies blood-borne dissemination of organisms to various tissues or organs. Common patterns include (1) renal abscess, (2) myocardial abscess and endocarditis, (3) brain involvement (most commonly meningitis, but parenchymal microabscesses occur), (4) endophthalmitis (virtually any eye structure can be involved), (5) hepatic abscesses, and (6) *Candida* pneumonia, usually presenting with bilateral nodular infiltrates, resembling *Pneumocystis* pneumonia (see

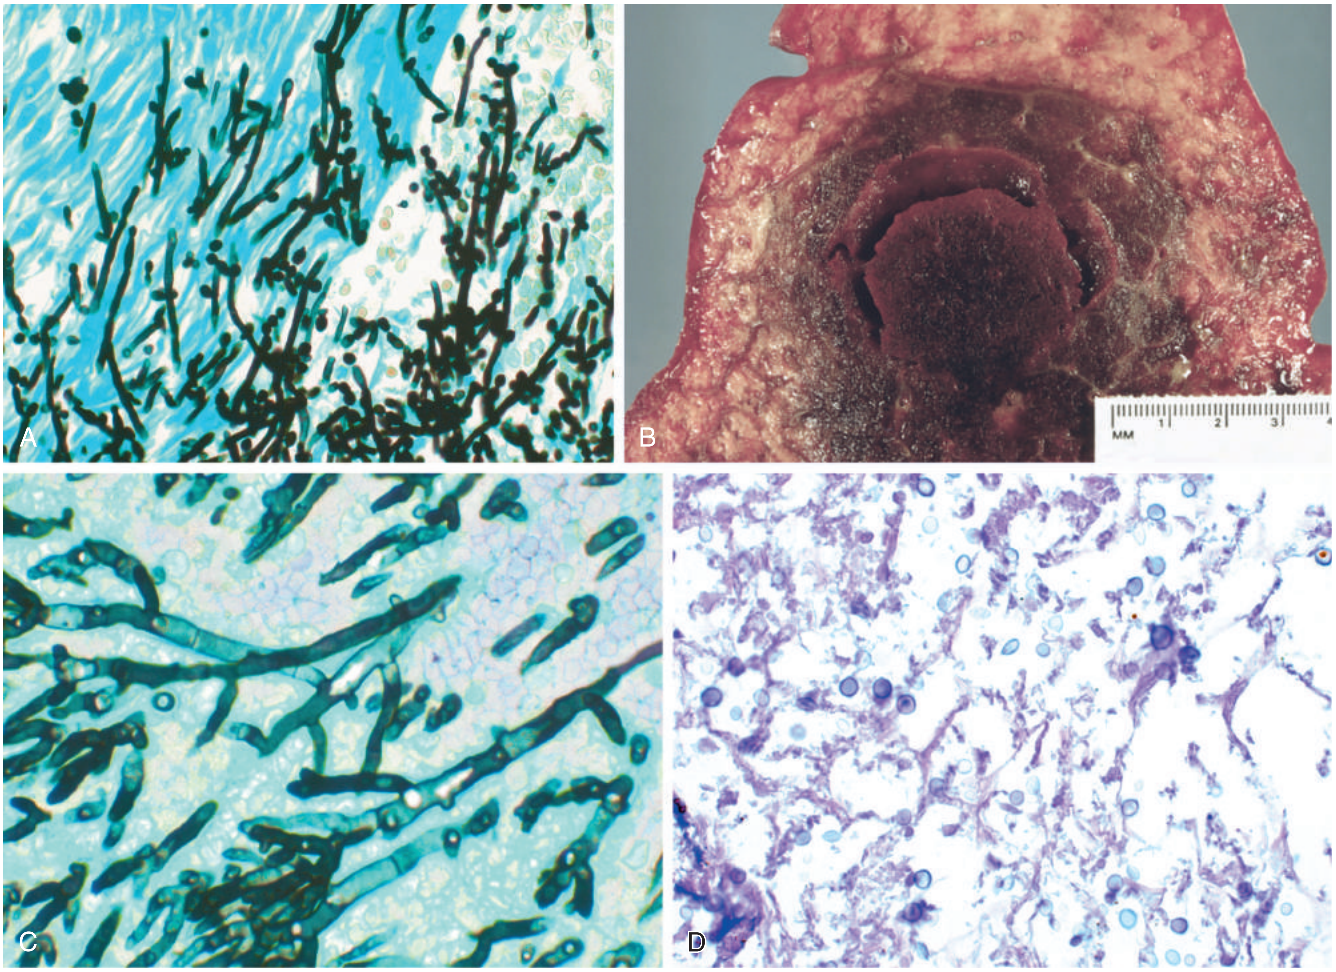

Fig. 13.42 The morphology of fungal infections. (A) Candida organism has pseudohyphae and budding yeasts (silver stain). (B) Invasive aspergillosis (gross appearance) of the lung in a hematopoietic stem cell transplant recipient. (C) Gomori methenamine-silver (GMS) stain shows septate hyphae with acute-angle branching, consistent with Aspergillus. (D) Cryptococcosis of the lung in a patient with AIDS. The organisms are somewhat variable in size. *(B, Courtesy of Dr. Dominick Cavuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

earlier). Patients with acute leukemias who are profoundly neutropenic after chemotherapy are particularly prone to the development of systemic disease. *Candida* endocarditis is the most common fungal endocarditis, usually occurring in patients with prosthetic heart valves or in intravenous drug abusers.

Cryptococcosis

Cryptococcosis, caused by *C. neoformans,* almost exclusively manifests as an opportunistic infection in immunocompromised hosts, particularly patients with AIDS or hematolymphoid malignancies.

MORPHOLOGY

The fungus, a 5- to 10-µm yeast, has a thick, gelatinous capsule and reproduces by budding (see Fig. 13.42D). Unlike in *Candida* infections, however, pseudohyphal or true hyphal forms are not seen. Identification of the capsule is a key diagnostic clue. In routine H&E stains, the capsule is not directly visible, but often a clear "halo" representing the area occupied by the capsule can be seen surrounding the individual fungi. India ink or periodic acid–Schiff staining effectively highlights the fungus. The capsular polysaccharide antigen is the substrate for the cryptococcal latex agglutination assay, which is positive in more than 95% of patients infected with the organism.

Clinical Features

Cryptococcosis usually manifests as pulmonary, central nervous system, or disseminated disease. Cryptococcus is most likely to be acquired by inhalation of aerosolized contaminated soil or bird droppings. The fungus initially localizes in the lungs and then disseminates to other sites, particularly the meninges. Sites of involvement are marked by a variable tissue response, which ranges from florid proliferation of gelatinous organisms with a minimal or absent inflammatory cell infiltrate (in immunodeficient hosts) to a granulomatous reaction (in the more reactive host). In the central nervous system these fungi grow in gelatinous masses within the meninges or expand the

perivascular Virchow-Robin spaces, producing so-called "soap-bubble lesions."

The Opportunistic Molds

Mucormycosis and *invasive aspergillosis* are uncommon infections that are almost always limited to immunocompromised hosts, particularly those with hematolymphoid malignancies and profound neutropenia, those undergoing corticosteroid therapy, or following hematopoietic stem cell transplant recipients.

MORPHOLOGY

Mucormycosis is caused by the class of fungi known as *Zygomycetes. Rhizopus* and *Mucor* are the two fungi of medical importance within the Zygomycetes class. Their hyphae are **nonseptate** and branch at right angles; by contrast, the hyphae of *Aspergillus* organisms are **septate** and branch at more acute angles (see Fig. 13.42C). Both zygomycetes and *Aspergillus* cause a nondistinctive, suppurative, sometimes granulomatous reaction with a **predilection for invading blood vessel walls, causing hemorrahage, vascular necrosis and infarction** (see Fig. 13.42B).

Clinical Features

In *rhinocerebral* and *pulmonary mucormycosis,* zygomycetes have a propensity to colonize the nasal cavity or sinuses and then spread by direct extension into the brain, orbit, and other head and neck structures. Patients with diabetic ketoacidosis are most likely to develop a fulminant invasive form of rhinocerebral mucormycosis. Pulmonary disease can be localized (e.g., cavitary lesions) or may manifest radiologically with diffuse "miliary" involvement.

Invasive aspergillosis preferentially localizes to the lungs, and infection most often manifests as a necrotizing pneumonia (see Fig. 13.42B). Systemic dissemination, especially to the brain, is a complication that is often fatal.

Allergic bronchopulmonary aspergillosis occurs in patients with asthma who develop an exacerbation of symptoms caused by a type I hypersensitivity against the fungus growing in the bronchi. Such patients often have circulating IgE antibodies against *Aspergillus* and peripheral eosinophilia.

Aspergilloma ("fungus ball") formation occurs by fungal colonization of preexisting pulmonary cavities (e.g., dilated bronchi or lung cysts, posttuberculosis cavitary lesions). These masses may act as ball valves to occlude the cavity, thereby predisposing the patient to infection and hemoptysis.

Pulmonary Disease in Human Immunodeficiency Virus Infection

Pulmonary disease continues to be the leading contributor to morbidity and mortality in HIV-infected individuals. Although the use of potent anti-retroviral agents and effective chemoprophylaxis has markedly decreased the incidence and has improved outcomes, the plethora of entities involved makes diagnosis and treatment a distinct challenge.

- Despite the emphasis on "opportunistic" infections, it should be recognized that bacterial lower-respiratory tract infection caused by the "usual" pathogens is exceedingly common in HIV infection. The implicated organisms include *S. pneumoniae, S. aureus, H. influenzae,* and gram-negative rods. Bacterial pneumonias in HIV-infected individuals are more common, more severe, and more often associated with bacteremia than in those without HIV infection.
- Not all pulmonary infiltrates in HIV-infected individuals are infectious. A host of noninfectious diseases, including Kaposi sarcoma (Chapters 5 and 10), pulmonary non-Hodgkin lymphoma (Chapter 12), and primary lung cancer, occur with increased frequency and must be excluded.
- The CD4+ T cell count often is useful in narrowing the differential diagnosis. As a rule of thumb, bacterial and tubercular infections occur with mildly suppressed CD4+ counts (more than 200 cells/μL); *Pneumocystis* pneumonia usually occurs at CD4+ T cell counts below 200 cells/μL, while CMV and *M. avium* complex infections are uncommon until the very late stages of the disease (CD4+ T cell counts below 50 cells/μL).

Finally, an important point is that pulmonary disease in HIV-infected individuals may result from more than one cause, and that even common pathogens may be responsible for disease with atypical manifestations.

LUNG TUMORS

Roughly 95% of primary lung tumors are carcinomas; the remaining 5% span a miscellaneous group that includes carcinoids, mesenchymal malignancies (e.g., fibrosarcomas, leiomyomas), lymphomas, and a few benign lesions. The most common benign tumor is a spherical, small (1 to 4 cm), discrete "hamartoma" that often shows up as a so-called "coin lesion" on chest imaging. It consists mainly of mature cartilage admixed with fat, fibrous tissue, and blood vessels in various proportions. Clonal cytogenetic abnormalities have been demonstrated, indicating that it is actually a benign neoplasm and that the name hamartoma (which implies a developmental anomaly) is a misnomer.

Carcinomas

Carcinoma of the lung is the most important cause of cancer-related deaths in industrialized countries. It has long held this position among males in the United States, accounting for about one-third of cancer deaths in men, and has become the leading cause of cancer deaths in women as well. American Cancer Society estimates for 2016 include approximately 221,200 new cases of lung cancer and 158,040 deaths. The incidence among males is gradually decreasing, but it continues to increase among females, with more women dying each year from lung cancer than from breast cancers since 1987. These sobering

Other unusual morphologic variants
Sarcomatoid carcinoma
Spindle cell carcinoma
Giant cell carcinoma

statistics reflect the fact that the incidence of smoking in women increased markedly over the past half century. The peak incidence of lung cancer is in individuals in their fifties and sixties. At diagnosis, more than 50% of patients already have distant metastases, while an additional one-fourth have disease in the regional lymph nodes. The prognosis remains dismal: the 5-year survival rate for all stages of lung cancer combined is about 16%, a figure that has not changed much over the last 35 years; even with disease localized to the lung, the 5-year survival rate is only 45%.

The four major histologic types of carcinomas of the lung are adenocarcinoma, squamous cell carcinoma, small cell carcinoma (a subtype of neuroendocrine carcinoma), and large cell carcinoma (Table 13.6). In some cases, there is a combination of histologic patterns (e.g., small cell carcinoma and adenocarcinoma). Squamous cell and small cell carcinomas have the strongest association with smoking, but there is also an association with adenocarcinoma. In fact, possibly because of changes in smoking patterns in the United States, adenocarcinoma has replaced squamous cell carcinoma as the most common primary lung tumor in recent years. Adenocarcinomas also are by far the most common primary tumors arising in women, in never-smokers, and in individuals younger than 45 years of age.

Until recently, carcinomas of the lung were classified into two broad groups: small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC), the latter including adenocarcinoma, squamous and large cell carcinoma, and large cell neuroendocrine carcinomas. This classification has been recently replaced by a 2015 World Health Organization classification (a simplified version of which is shown in Table 13.6). The reason for this historic division is that virtually all SCLCs have metastasized by the time of diagnosis. Therefore, they are best treated with systemic chemotherapy, with or without radiation therapy. By contrast, NSCLCs are more likely to be resectable and usually respond poorly to conventional chemotherapy. However, therapies are now available that target specific oncoproteins that are found in a subset of NSCLC, mainly adenocarcinomas but also squamous cell carcinomas. Thus, if adequate tissue is available, NSCLC is subjected to molecular analysis to determine if targeted therapy is warranted. In addition, new immunotherapy approaches (checkpoint blockade, discussed in Chapter 6) are now approved for a subset of NSCLC and are being tested in SCLC.

Etiology and Pathogenesis

Like other cancers, smoking-related carcinomas of the lung arise by a stepwise accumulation of driver mutations that result in transformation of benign progenitor cells in the lung into neoplastic cells possessing all of the hallmarks of cancer. The sequence of molecular changes is not random but tends to follow a sequence that parallels the histologic progression toward cancer. Thus, inactivation of the putative tumor suppressor genes located on the short arm of chromosome 3 (3p) is a very common early event, whereas mutations in the *TP53* tumor suppressor gene and the *KRAS* oncogene occur relatively late. Certain genetic changes, such as loss of chromosomal material on 3p, are found even in benign bronchial epithelium of smokers without lung cancer, suggesting that large areas of the respiratory mucosa are mutagenized by exposure to carcinogens ("field effect"). On this fertile soil, those cells that accumulate additional mutations ultimately develop into cancer.

A subset of adenocarcinomas (about 10% in whites and 30% in Asians), particularly those arising in nonsmoking women, harbor mutations that activate the *epidermal growth factor receptor (EGFR),* a receptor tyrosine kinase that stimulates downstream pro-growth pathways involving RAS, PI3K, and other signaling molecules. Of note, these tumors are sensitive to drugs that inhibit EGFR signaling, although the response is often short-lived. EGFR and KRAS mutations (in 30% of adenocarcinomas) are mutually exclusive, as might be expected since KRAS lies downstream of EGFR. Other "targetable" mutations have been described in a low frequency of adenocarcinomas (4% to 6% overall), including mutations that activate other tyrosine kinases, including ALK, ROS1, HER2, or c-MET. Each of these kinases is optimally targeted by a different drug, which has spurred a new era of "personalized" lung cancer treatment, in which the genetics of the tumor guide therapy.

With regard to carcinogenic influences, **there is strong evidence that cigarette smoking and, to a much lesser extent, other environmental carcinogens are the main culprits responsible for the mutations that give rise to lung cancers.** About 90% of lung cancers occur in active smokers or those who stopped recently. Moreover, there is a nearly linear correlation between the frequency of lung cancer and pack-years of cigarette smoking. The increased risk is 60 times greater among habitual heavy smokers (two packs a day for 20 years) than among nonsmokers. For unclear reasons, women are more susceptibile to carcinogens in tobacco smoke than men. Although cessation of smoking decreases the risk for developing lung cancer over time, it never returns to baseline levels, and genetic changes that predate the full development of lung cancer can persist for many years in the bronchial epithelium of former smokers. Passive smoking (proximity to cigarette smokers) also increases the risk for developing lung cancer, as does smoking of pipes and cigars, albeit only modestly.

Other carcinogenic influences associated with occupational exposures act in concert with smoking and may sometimes be responsible for lung cancer all by themselves; examples include work in uranium mines, work with asbestos, and inhalation of dusts containing arsenic, chromium, nickel, or vinyl chloride. A cardinal example of a synergistic interaction between two carcinogens is found in asbestos and tobacco smoking. Exposure to asbestos in nonsmokers increases the risk for developing lung cancer 5-fold, whereas in heavy smokers exposed to asbestos the risk is elevated approximately 55-fold.

Even though smoking and other environmental influences are paramount in the causation of lung cancer, not all individuals exposed to tobacco smoke develop cancer (about 11% of heavy smokers do). It is very likely that the mutagenic effect of carcinogens is modified by hereditary (genetic) factors. Recall that many chemicals require metabolic activation via the P-450 monooxygenase enzyme system for conversion into ultimate carcinogens (Chapter 6). Individuals with certain polymorphisms involving the P-450 genes have an increased capacity to activate procarcinogens found cigarette smoke, and are thus exposed to larger doses of carcinogens and incur a greater risk of developing lung cancer. Similarly, individuals whose peripheral blood lymphocytes undergo chromosomal breakages after exposure to tobacco-related carcinogens (mutagen sensitive genotype) have a greater than 10-fold increased risk for developing lung cancer over control subjects.

By analogy to the adenoma–carcinoma sequence in the colon, it is proposed that some invasive adenocarcinomas of the lung arise through an atypical adenomatous hyperplasia–adenocarcinoma in situ–invasive adenocarcinoma sequence. Studies of lung injury models in mice have identified a population of multipotent cells at the bronchioloalveolar duct junction, termed *bronchioalveolar stem cells (BASCs).* After lung injury, multipotent BASCs proliferate and replenish the normal cell types (bronchiolar Clara cells and alveolar cells) found in this location, thereby facilitating epithelial regeneration. It is postulated that BASCs incur the initiating hit (for example, a somatic *KRAS* mutation) that enables these cells to escape normal "checkpoint" mechanisms and results in pulmonary adenocarcinomas.

The sequential changes leading development of squamous cell carcinomas are well documented; there is a linear correlation between the intensity of exposure to cigarette smoke and the appearance of ever more worrisome epithelial changes that begin with rather innocuous basal cell hyperplasia and squamous metaplasia and progress to squamous dysplasia and carcinoma in situ, before culminating in invasive cancer.

MORPHOLOGY

Carcinomas of the lung begin as small lesions that typically are firm and gray-white. They may arise as intraluminal masses, invade the bronchial mucosa, or form large bulky masses pushing into adjacent lung parenchyma. **Adenocarcinomas** are usually **peripherally located,** but also may occur closer to the hilum. In general, adenocarcinomas grow slowly and form smaller masses than do the other subtypes, but they tend to metastasize widely at an early stage. They may assume a variety of growth patterns, including **acinar (gland-forming)** (Fig. 13.43C); **papillary; mucinous** which is often multifocal and may manifest as pneumonia-like consolidation); and **solid types.** The solid variant often requires demonstration of intracellular mucin by special stains to establish its adenocarcinomatous differentiation.

The putative precursor of adenocarcinoma is **atypical adenomatous hyperplasia** (AAH) (see Fig. 13.43A), which is thought to progress in a stepwise fashion to adenocarcinoma in situ, minimally invasive adenocarcinoma (<3 cm in diameter with an invasive component of <5 mm), and invasive adenocarcinoma (a tumor of any size with an area of invasion >5 mm). AAH appears as a well-demarcated focus of epithelial proliferation (with a diameter of 5 mm or less) composed of cuboidal to low-columnar cells that demonstrate nuclear hyperchromasia, pleomorphism, and prominent nucleoli. Genetic analyses have shown that AAH is monoclonal and shares many molecular aberrations with adenocarcinomas (e.g., *KRAS* mutations).

Adenocarcinoma in situ (AIS) (formerly bronchioloalveolar carcinoma), often involves peripheral parts of the lung as a single nodule. The key features of AIS are diameter of 3 cm or less, growth along preexisting structures, and preservation of alveolar architecture (see Fig. 13.43B). The tumor cells, which may be nonmucinous, mucinous, or mixed, grow in a monolayer along the alveolar septa, which serve as a scaffold. By definition, AIS does not demonstrate destruction of alveolar architecture or stromal invasion with desmoplasia, features that would merit the diagnosis of invasive adenocarcinoma.

Squamous cell carcinomas are more common in men than in women and are closely correlated with a smoking history; they tend to **arise centrally in major bronchi** and eventually spread to local hilar nodes, but they disseminate outside the thorax later than do other histologic types. Large lesions may undergo central necrosis, giving rise to **cavitation.** The preneoplastic lesions that antedate, and usually accompany, invasive squamous cell carcinoma are well characterized. Squamous cell carcinomas often are preceded by the development, over years, of **squamous metaplasia or dysplasia** in the bronchial epithelium, which then transforms to **carcinoma in situ,** a phase that may last for several years (Fig. 13.44). By this time, atypical cells may be identified in cytologic smears of sputum or in bronchial lavage fluids or brushings, although the lesion is asymptomatic and undetectable on radiographs. Eventually, the small neoplasm reaches a symptomatic stage, when a well-defined tumor mass begins to obstruct the lumen of a major bronchus, often producing distal atelectasis and infection. Simultaneously, the lesion invades surrounding pulmonary substance (Fig. 13.45A). On histologic examination, these tumors range from well-differentiated squamous cell neoplasms showing keratin pearls (see Fig. 13.45B) and intercellular bridges to poorly differentiated neoplasms exhibiting only minimal squamous cell features.

Large cell carcinomas are undifferentiated malignant epithelial tumors that lack the cytologic features of neuroendocrine carcinoma and show no evidence of glandular or squamous differentiation. The cells typically have large nuclei, prominent nucleoli, and moderate amounts of cytoplasm.

Small cell lung carcinomas (SCLCs) generally appear as pale gray, **centrally located masses** that extend into the lung parenchyma. These cancers are composed of relatively small tumor cells with a round to fusiform shape, scant cytoplasm, and finely granular chromatin with a salt and pepper

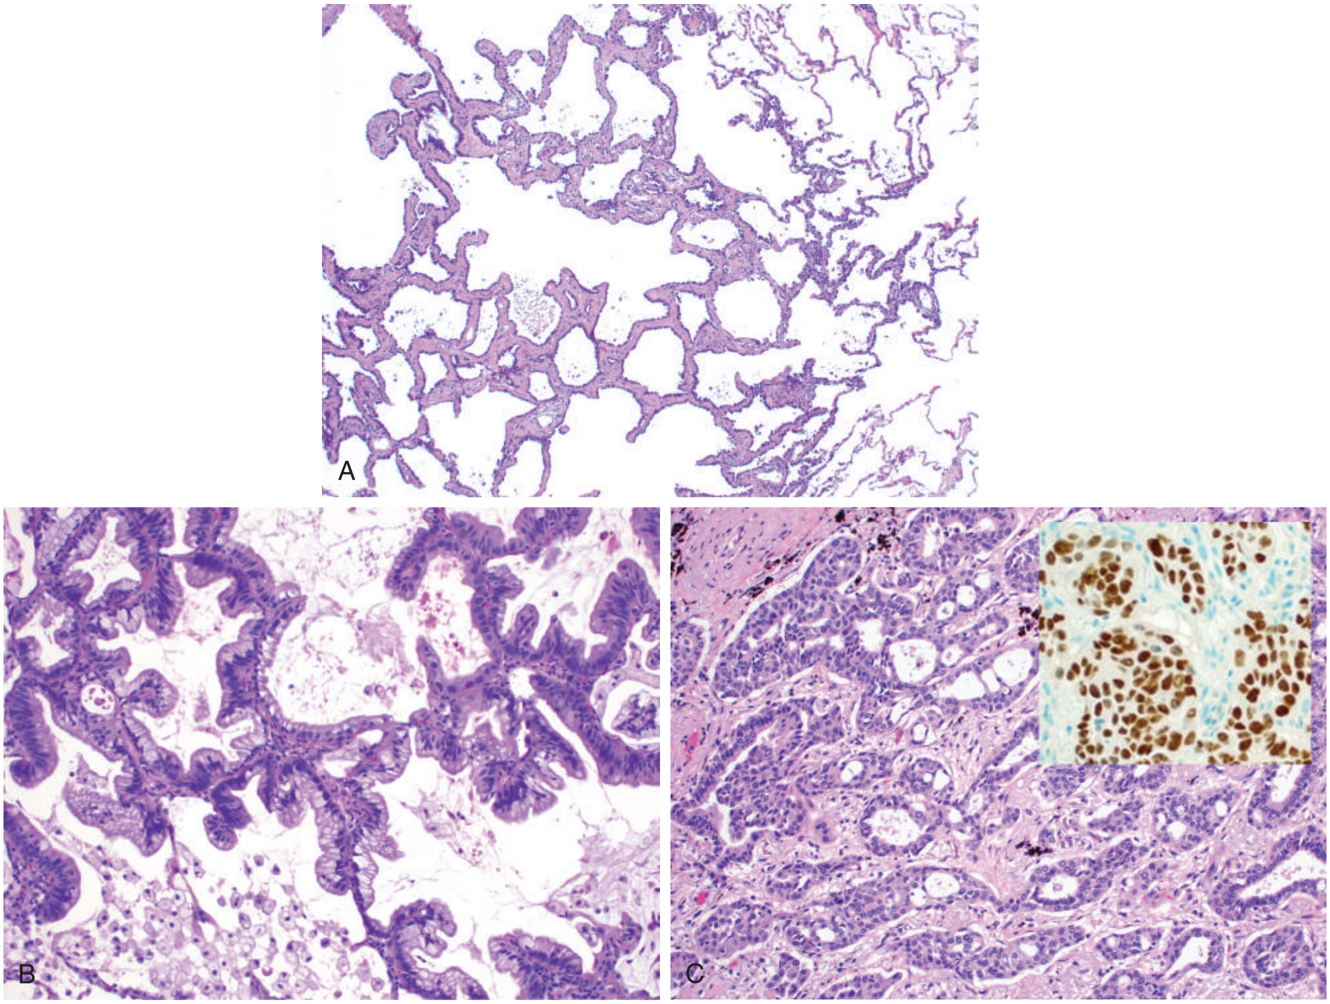

Fig. 13.43 Adenocarcinoma and associated lesions. (A) Atypical adenomatous hyperplasia with cuboidal epithelium and mild interstitial fibrosis. (B) Adenocarcinoma in situ, mucinous subtype, with characteristic growth along preexisting alveolar septa, without invasion. (C) Gland-forming adenocarcinoma; inset shows thyroid transcription factor 1 (TTF-1) positivity, which is seen in a majority of pulmonary adenocarcinomas.

appearance. Numerous mitotic figures are present (Fig. 13.46). Necrosis is invariably present and may be extensive. The tumor cells are fragile and often show fragmentation and "crush artifact" in small biopsy specimens. Another feature, best appreciated in cytologic specimens, is nuclear molding resulting from close apposition of tumor cells that have scant cytoplasm. These tumors express a variety of neuroendocrine markers (Table 13.7) and may secrete a host of polypeptide hormones that may result in paraneoplastic syndromes (see later). By the time of diagnosis, most will have metastasized to hilar and mediastinal lymph nodes. In the 2015 WHO Classification, SCLC is grouped together with large cell neuroendocrine carcinoma, another very aggressive tumor that exhibits neuroendocrine morphology and expresses neuroendocrine markers (synaptophysin, chromogranin, and CD56). **Mixed patterns** (e.g., adenosquamous carcinoma, mixed adenocarcinoma, small cell carcinoma) are seen in 10% or less of lung carcinomas.

Each of these lung cancer subtypes tends to spread to lymph nodes in the carina, the mediastinum, and the neck (scalene nodes) and clavicular regions, and, sooner or later, to distant sites. Involvement of the left supraclavicular node (Virchow node) is particularly characteristic and sometimes calls attention to an occult primary tumor. These cancers, when advanced, often extend into the pleural or pericardial space, leading to inflammation and effusions. They may compress or infiltrate the superior vena cava to cause venous congestion or the vena caval syndrome. Apical neoplasms may invade the brachial or cervical sympathetic plexus, causing severe pain in the distribution of the ulnar nerve or Horner syndrome (ipsilateral enophthalmos, ptosis, miosis, and anhidrosis). Such apical neoplasms are sometimes called **Pancoast tumors,** and the combination of clinical findings is known as **Pancoast syndrome.** Pancoast tumor is often accompanied by destruction of the first and second ribs and sometimes the thoracic vertebrae. As with other cancers, tumor-node-metastasis (TNM) categories are used to indicate the size and spread of the primary neoplasm.

Clinical Features

Carcinomas of the lung are insidious lesions that in many cases have spread so as to be unresectable before they produce symptoms. In some instances chronic cough and

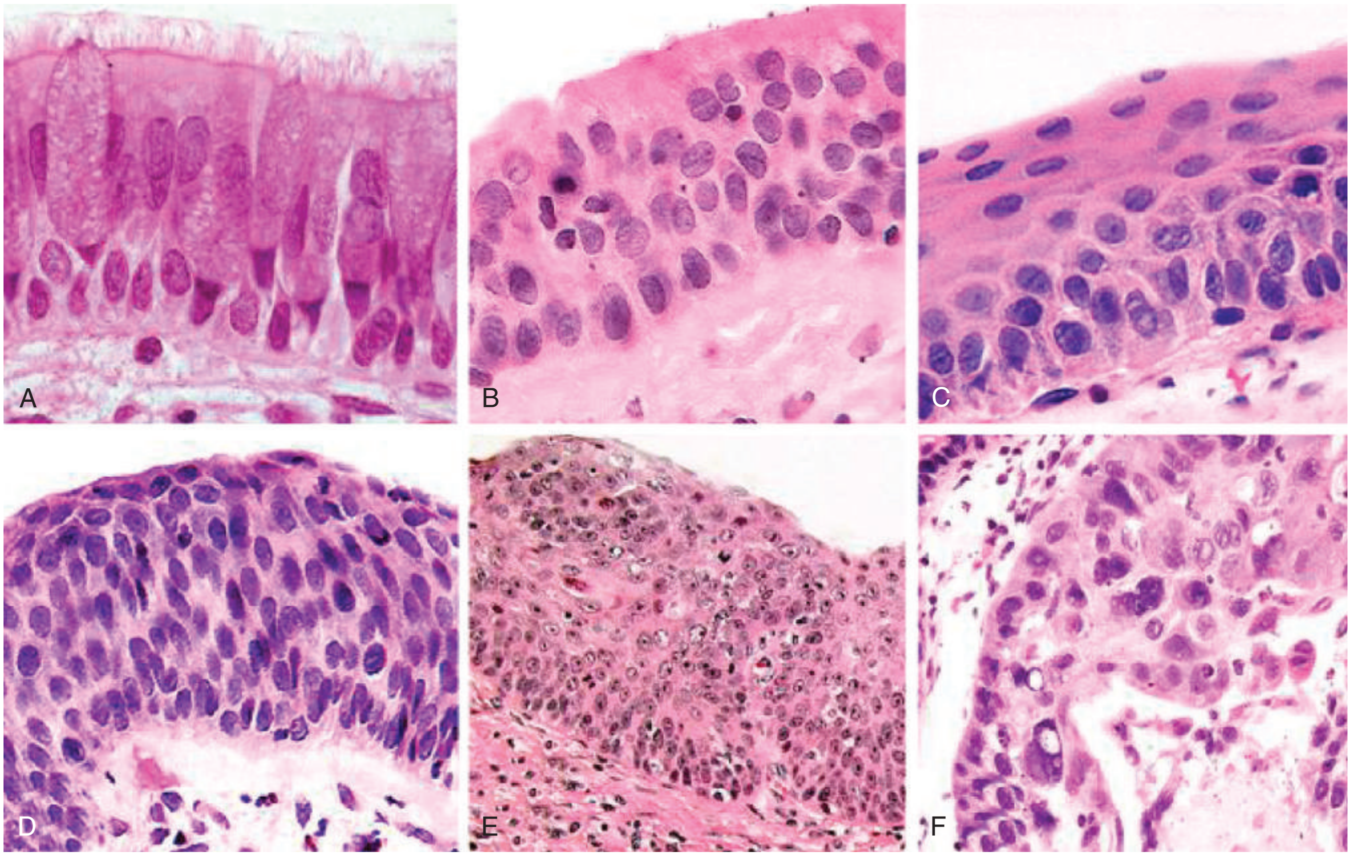

Fig. 13.44 Precursor lesions of squamous cell carcinomas. (A to C) Some of the earliest (and "mild") changes in smoking-damaged respiratory epithelium include goblet cell hyperplasia (A), basal cell (or reserve cell) hyperplasia (B), and squamous metaplasia (C). (D) More ominous changes include the appearance of squamous dysplasia, characterized by the presence of disordered squamous epithelium, with loss of nuclear polarity, nuclear hyperchromasia, pleomorphism, and mitotic figures. (E and F) Squamous dysplasia may, in turn, progress through the stages of mild, moderate, and severe dysplasia. Carcinoma in situ (CIS) (E) is the stage that immediately precedes invasive squamous cell carcinoma (F). Apart from the lack of basement membrane disruption in CIS, the cytologic features of CIS are similar to those in frank carcinoma. *(A to E, Courtesy of Dr. Adi Gazdar, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas. expectoration call attention to localized, resectable disease. By the time other symptoms, such as hoarseness, chest pain, superior vena cava syndrome, pericardial or pleural effusion, or persistent segmental atelectasis or pneumonitis make their appearance, the prognosis is poor. Too often, the tumor presents with symptoms caused by metastatic spread to sites such as the brain (mental or neurologic changes), liver (hepatomegaly), or bones (pain). Although the adrenal glands may be nearly obliterated by metastatic disease, adrenal insufficiency (Addison disease) is uncommon, because islands of cortical cells sufficient to maintain adrenal function usually persist.

Overall, squamous cell carcinoma and adenocarcinoma carry a more favorable prognosis than SCLC. When squamous cell carcinomas or adenocarcinomas are detected before metastasis or local spread (as in high-risk patients undergoing surveillance imaging), cure is possible by lobectomy or pneumonectomy. Unresectable adenocarcinomas associated with targetable mutations in tyrosine kinases such as EGFR may show remarkable responses to specific inhibitors. A few of these patients have long-term remissions on the order of years, but relapse within months to a year or so is typical. Inevitably, resistant tumors are found to have new mutations that either alter the drug target themselves (e.g., an additional mutation in *EGFR* that prevents drug binding) or circumvent tumor dependence on the drug target. Much effort is currently being devoted to understanding the mechanisms of targeted drug resistance in order to develop strategies that prevent it from occurring. Immune checkpoint inhibitors produce responses in a subset of tumors, particularly those that are smoking related (perhaps because of a high burden of tumor

Table 13.7 Comparison of Small Cell Lung Carcinoma and Non–Small Cell Lung Carcinoma (Adenocarcinoma and Squamous Cell Carcinoma)

Feature	Small Cell Lung Carcinoma	Non–Small Cell Lung Carcinoma
Histology		
	Scant cytoplasm; small, hyperchromatic nuclei with fine chromatin pattern; nucleoli indistinct; diffuse sheets of cells	Abundant cytoplasm; pleomorphic nuclei with coarse chromatin pattern; nucleoli often prominent; glandular or squamous architecture
Neuroendocrine Markers		
For example, dense core granules on electron microscopy; expression of chromogranin, synaptophysin, and CD56	Present	Absent
Epithelial Markers		
Epithelial membrane antigen, carcinoembryonic antigen, and cytokeratin intermediate filaments	Present	Present
Mucin	Absent	Present in adenocarcinomas
Peptide hormone production	Adrenocorticotropic hormone, anti-diuretic hormone, gastrin-releasing peptide, calcitonin	Parathyroid hormone–related peptide (PTH-rp) in squamous cell carcinoma
Tumor Suppressor Gene Abnormalities		
3p deletions	>90%	>80%
RB mutations	~90%	~20%
p16/CDKN2A mutations	~10%	>50%
TP53 mutations	>90%	>50%
Dominant Oncogene Abnormalities		
KRAS mutations	Rare	~30% (adenocarcinomas)
EGFR mutations	Absent	~20% (adenocarcinomas, nonsmokers, women)
ALK rearrangements	Absent	4%–6% adenocarcinomas, nonsmokers, often have signet ring morphology
Response to chemotherapy and radiotherapy	Often complete response but recur invariably	Incomplete

neoantigens), and represent a hopeful new avenue for therapy.

By contrast, the picture for SCLC unfortunately has changed little. SCLCs have invariably spread by the time they are detected, even if the primary tumor appears to be small and localized; thus, surgical resection is not a viable option. SCLCs are very sensitive to chemotherapy but invariably recur, and as of yet targeted therapies are unavailable. The median survival even with treatment remains only 1 year, and only 5% are alive at 10 years. Because these tumors have a very high mutation burden, they are likely to be immunogenic. Accordingly, immune checkpoint therapies have produced encouraging responses in patients with advanced SCLC.

In addition to the direct effects of the tumor cells, it is estimated that 3% to 10% of patients with lung cancer develop *paraneoplastic syndromes* (Chapter 6). These include (1) hypercalcemia caused by secretion of a parathyroid hormone–related peptide; (2) Cushing syndrome (from increased production of adrenocorticotropic hormone); (3) syndrome of inappropriate secretion of anti-diuretic hormone; (4) neuromuscular syndromes, including a myasthenic syndrome, peripheral neuropathy, and polymyositis; (5) clubbing of the fingers and hypertrophic pulmonary osteoarthropathy; and (6) coagulation abnormalities, including migratory thrombophlebitis, nonbacterial endocarditis, and disseminated intravascular coagulation. Hypercalcemia most often is encountered with squamous cell neoplasms, the hematologic syndromes with adenocarcinomas, and the neurologic syndromes with small cell neoplasms, but exceptions abound.

SUMMARY

CARCINOMA OF THE LUNG

- The three major histologic subtypes are adenocarcinoma (most common), squamous cell carcinoma, and small cell carcinoma, each of which is clinically and genetically distinct. Adenocarcinomas are the most common cancers overall and are especially common in women and in nonsmokers.
- Smoking is the most important risk factor for lung cancer.
- Precursor lesions include atypical adenomatous hyperplasia and adenocarcinoma in situ for adenocarcinomas and squamous dysplasia for squamous cancer.
- Tumors 3 cm or less in diameter characterized by pure growth along preexisting structures without stromal invasion are called adenocarcinoma in situ.
- SCLCs are best treated with chemotherapy, because almost all are metastatic at presentation. The other carcinomas may be curable by surgery if limited to the lung. Targeted therapies, such as EGFR inhibitor therapy for adenocarcinomas with EGFR mutations, can be effective, an excellent example of personalized cancer therapy. Immunotherapies are under development and show promise.
- Lung cancers commonly cause a variety of paraneoplastic syndromes.

Carcinoid Tumors

Carcinoid tumors are malignant tumors composed of cells that contain dense-core neurosecretory granules in their cytoplasm and, rarely, may secrete hormonally active polypeptides. They are best thought of a low-grade neuroendocrine carcinomas and are subclassified as typical or atypical; both are often resectable and curable. They occasionally occur as part of the multiple endocrine neoplasia syndrome (Chapter 20). Bronchial carcinoids occur in young adults (mean 40 years) and represent about 5% of all pulmonary neoplasms.

MORPHOLOGY

Most carcinoids originate in main bronchi and grow in one of two patterns: (1) an obstructing polypoid, spherical, intraluminal mass (Fig. 13.47A); or (2) a mucosal plaque penetrating the bronchial wall to fan out in the peribronchial tissue—the so-called **collar-button lesion.** Even penetrating lesions push into the lung substance along a broad front and are well demarcated. Peripheral carcinoids are less common. Although 5% to

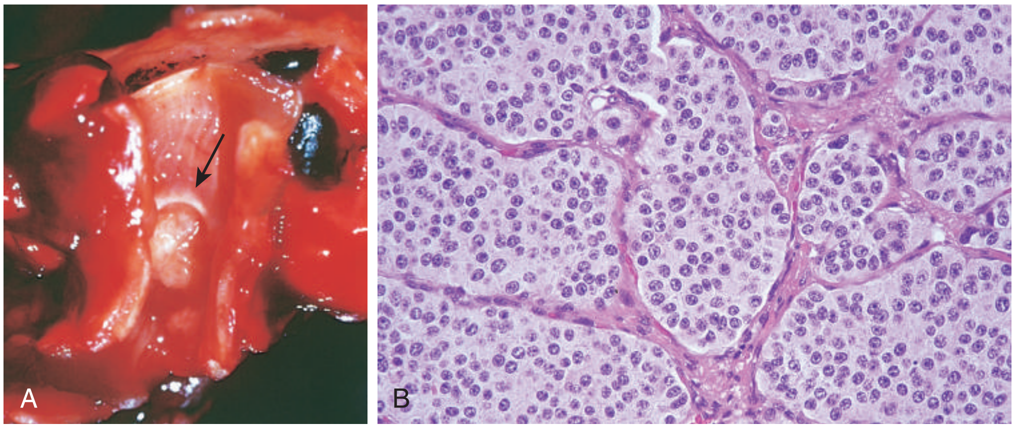

Fig. 13.47 Bronchial carcinoid. (A) Carcinoid growing as a spherical, pale mass *(arrow)* protruding into the lumen of the bronchus. (B) Histologic appearance demonstrating small, rounded, uniform nuclei and moderate cytoplasm. *(Courtesy of Dr. Thomas Krausz, Department of Pathology, University of Chicago Pritzker School of Medicine, Chicago, Illinois.)*

15% of carcinoids have metastasized to the hilar nodes at presentation, distant metastases are rare. Histologically, **typical carcinoids,** like their counterparts in the intestinal tract, are composed of nests of uniform cells that have regular round nuclei with "salt-and-pepper" chromatin, absent or rare mitoses and little pleomorphism (see Fig. 13.47B). **Atypical carcinoid** tumors display a higher mitotic rate and small foci of necrosis. These tumors have a higher incidence of lymph node and distant metastasis than typical carcinoids. Unlike typical carcinoids, the atypical tumors have *TP53* mutations in 20% to 40% of cases. Typical carcinoid, atypical carcinoid, and large cell neuroendocrine and small cell carcinoma can be viewed as a continuum of increasing histologic aggressiveness and malignant potential within the spectrum of pulmonary neuroendocrine neoplasms.

Most carcinoid tumors manifest with signs and symptoms related to their intraluminal growth, including cough, hemoptysis, and recurrent bronchial and pulmonary infections. Peripheral tumors are often asymptomatic and are discovered incidentally on chest radiographs. Only rarely do pulmonary carcinoids induce the *carcinoid syndrome,* characterized by intermittent attacks of diarrhea, flushing, and cyanosis. The reported 5- and 10-year survival rates for typical carcinoids are above 85%, while these rates drop to 56% and 35%, respectively, for atypical carcinoids.

PLEURAL LESIONS

Disease of the pleura usually is a complication of an underlying pulmonary disease. Secondary infections and pleural adhesions are common findings at autopsy. Important primary disorders are (1) primary intrapleural bacterial infections and (2) *malignant mesothelioma,* a primary neoplasm of the pleura.

Pleural Effusion and Pleuritis

Pleural effusions (fluids in the pleural space) can be either transudates or exudates. When the effusion is a transudate, the condition is termed *hydrothorax.* Congestive heart failure is the most common cause of bilateral hydrothorax. An exudate, characterized by protein content greater than 30 g/L and, often, inflammatory cells, suggests pleuritis. The four principal causes of *pleural exudate* formation are (1) microbial invasion through either direct extension of a pulmonary infection or blood-borne seeding (*suppurative pleuritis* or *empyema*); (2) cancer (lung carcinoma, metastatic neoplasms to the lung or pleural surface, mesothelioma); (3) pulmonary infarction; and (4) viral pleuritis. Other, less common causes of exudative pleural effusions are systemic lupus erythematosus, rheumatoid arthritis, and uremia, as well as previous thoracic surgery. Malignant effusions characteristically are large and frequently bloody *(hemorrhagic pleuritis).* Cytologic examination may reveal the malignant cells.

Whatever the cause, transudates and serous exudates usually are resorbed without residual effects if the inciting cause is controlled or remits. By contrast, fibrinous, hemorrhagic, and suppurative exudates may lead to fibrous organization, yielding adhesions or fibrous pleural thickenings that sometimes undergo calcification.

Pneumothorax, Hemothorax, and Chylothorax

Pneumothorax refers to presence of air or other gas in the pleural sac. It may occur in young, apparently healthy adults, usually men without any known pulmonary disease (simple or spontaneous pneumothorax), or as a result of some thoracic or lung disorder (secondary pneumothorax), such as emphysema or a fractured rib. Secondary pneumothorax is the consequence of rupture of any pulmonary lesion situated close to the pleural surface that allows inspired air to gain access to the pleural cavity. Responsible pulmonary lesions include emphysema, lung abscess, tuberculosis, carcinoma, and many other, less common processes. Mechanical ventilatory support with high pressure also may trigger secondary pneumothorax.

There are several possible complications of pneumothorax. A ball-valve leak may create a tension pneumothorax that shifts the mediastinum. Compromise of the pulmonary circulation may follow and may even be fatal. If the leak seals and the lung is not reexpanded within a few weeks (either spontaneously or through medical or surgical intervention), so much scarring may occur that it can never be fully reexpanded. In these cases, serous fluid collects in the pleural cavity, creating hydropneumothorax. With prolonged collapse, the lung becomes vulnerable to infection, as does the pleural cavity when communication between it and the lung persists. Empyema is thus an important complication of pneumothorax (pyopneumothorax).

Hemothorax, the collection of whole blood (in contrast with bloody effusion) in the pleural cavity, may be a complication of a ruptured intrathoracic aortic aneurysm, an event that is almost always fatal. With hemothorax, in contrast with bloody pleural effusions, the blood clots within the pleural cavity.

Chylothorax is a pleural collection of a milky lymphatic fluid containing microglobules of lipid. The total volume of fluid may not be large, but chylothorax is always significant because it implies obstruction of the major lymph ducts, usually by an intrathoracic cancer (e.g., a primary or secondary mediastinal neoplasm, such as a lymphoma).

Malignant Mesothelioma

Malignant mesothelioma has assumed great importance because it is highly related to exposure to airborne asbestos. It is a rare cancer of mesothelial cells, usually arising in the parietal or visceral pleura; it also occurs much less commonly in the peritoneum and pericardium. Approximately 80% to 90% of individuals with this cancer have a history of exposure to asbestos. Those who work directly with asbestos (shipyard workers, miners, insulators) are at greatest risk, but malignant mesotheliomas have appeared in individuals whose only exposure was living in proximity to an asbestos factory or being a relative of an asbestos worker. The latent period for developing malignant mesothelioma after the initial exposure is long, often 25 to 40 years, suggesting that causative driver mutations are

acquired slowly, over a long period of time. As stated earlier, the combination of cigarette smoking and asbestos exposure greatly increases the risk for developing lung carcinoma, but it does not increase the risk for developing malignant mesothelioma.

Once inhaled, asbestos fibers remain in the body for life. Thus, the lifetime risk after exposure does not diminish over time (unlike with smoking, in which the risk decreases after cessation). It has been hypothesized that asbestos fibers preferentially gather near the mesothelial cell layer, where they generate reactive oxygen species that cause DNA damage and mutations. Sequencing of mesothelioma genomes has revealed multiple driver mutations, many of which cluster in pathways involved in DNA repair, cell cycle control, and growth factor signaling. Of interest, one of the most commonly mutated genes in sporadic mesothelioma, *BAP1,* encodes a tumor suppressor involved in DNA repair that also is affected by germ line mutations in families showing a high incidence of mesothelioma.

MORPHOLOGY

Malignant mesotheliomas are often preceded by extensive **pleural fibrosis and plaque formation,** readily seen on computed tomography scans. These tumors begin in a localized area and over time spread widely, either by contiguous growth or by diffuse seeding of pleural surfaces. At autopsy, the affected lung **typically is ensheathed by a layer of yellow-white, firm, variably gelatinous tumor** that obliterates the pleural space (Fig. 13.48). The neoplasm may directly invade the thoracic wall or the subpleural lung tissue, but distant metastases are uncommon. Normal mesothelial cells are biphasic, giving rise to pleural lining cells as well as the underlying fibrous tissue. In line with this potential, mesotheliomas conform to one of three morphologic appearances: (1) **epithelial,** in which cuboidal cells with small papillary buds line tubular and microcystic spaces (this is the most common pattern and also the one most likely to be confused with a pulmonary adenocarcinoma); (2) **sarcomatous,** in which spindled, occasionally fibroblastic-appearing cells grow in sheets; and (3) **biphasic,** having both sarcomatous and epithelial areas.

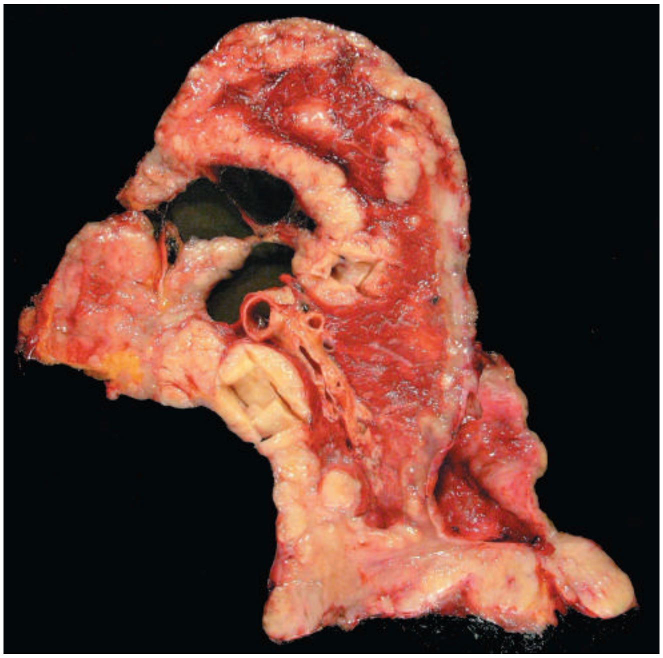

Fig. 13.48 Malignant mesothelioma. Note the thick, firm, white pleural tumor that ensheathes this bisected lung.

LESIONS OF THE UPPER RESPIRATORY TRACT

Acute Infections

Acute infections of the upper respiratory tract are among the most common afflictions of humans, most frequently manifesting as the "common cold." The clinical features are well known: nasal congestion accompanied by watery discharge; sneezing; scratchy, dry sore throat; and a slight increase in temperature that is more pronounced in young children. The most common pathogens are rhinoviruses, but coronaviruses, respiratory syncytial viruses, parainfluenza and influenza viruses, adenoviruses, enteroviruses, and sometimes even group A β-hemolytic streptococci have been implicated. In a significant number of cases (around 40%), the cause cannot be determined; perhaps new viruses will be discovered. Most of these infections occur in the fall and winter and are self-limiting (usually lasting for 1 week or less). In a minority of cases, colds may be complicated by the development of bacterial otitis media or sinusitis.

In addition to the common cold, infections of the upper-respiratory tract may produce signs and symptoms localized to the pharynx, epiglottis, or larynx. *Acute pharyngitis,* manifesting as a sore throat, may be caused by a host of agents. Mild pharyngitis with minimal physical findings frequently accompanies a cold and is the most common form of pharyngitis. More severe forms with tonsillitis, associated with marked hyperemia and exudates, occur with β-hemolytic streptococcal and adenovirus infections. Streptococcal tonsillitis is important to recognize and treat early, because of the associated potential for development of peritonsillar abscesses ("quinsy") or for progression to poststreptococcal glomerulonephritis and acute rheumatic fever. Coxsackievirus A infection may produce pharyngeal vesicles and ulcers (herpangina). Infectious mononucleosis, caused by Epstein-Barr virus (EBV), is an important cause of pharyngitis and bears the moniker of "kissing disease"—reflecting a common mode of transmission in previously nonexposed individuals.

Acute *bacterial epiglottitis* is a syndrome predominantly affecting young children who have an infection of the epiglottis caused by *H. influenzae,* in which pain and airway obstruction are the major findings. The onset is abrupt. Failure to appreciate the need to maintain an open airway for a child with this condition can have fatal consequences. The advent of vaccination against *H. influenzae* has greatly decreased the incidence of this disease.

Acute laryngitis can result from inhalation of irritants or may be caused by allergic reactions. It also may be caused

by agents that produce the common cold and usually involve the pharynx and nasal passages as well as the larynx. Brief mention should be made of two uncommon but important forms of laryngitis: *tuberculous* and *diphtheritic.* The former is almost always a consequence of protracted active tuberculosis, during which infected sputum is coughed up. Diphtheritic laryngitis has fortunately become uncommon because of the widespread immunization of young children against diphtheria toxin. After it is inhaled, *Corynebacterium diphtheriae* implants on the mucosa of the upper airways, where it elaborates a powerful exotoxin that causes necrosis of the mucosal epithelium, accompanied by a dense fibrinopurulent exudate, to create the classic superficial, dirty-gray pseudomembrane of diphtheria. The major hazards of this infection are sloughing and aspiration of the pseudomembrane (causing obstruction of major airways) and absorption of bacterial exotoxins (producing myocarditis, peripheral neuropathy, or other tissue injury).

In children, parainfluenza virus is the most common cause of laryngotracheobronchitis, more commonly known as *croup,* but other agents such as respiratory syncytial virus also may precipitate this condition. Although self-limited, croup may cause frightening inspiratory stridor and harsh, persistent cough. In occasional cases, the laryngeal inflammatory reaction may narrow the airway sufficiently to result in respiratory failure. Viral infections in the upper-respiratory tract predispose the patient to secondary bacterial infection, particularly by staphylococci, streptococci, and *H. influenzae.*

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is a rare neoplasm that merits comment because of (1) the strong epidemiologic links to EBV and (2) the high frequency of this cancer among the Chinese, which raises the possibility of viral oncogenesis on a background of genetic susceptibility. It is thought that EBV infects the host by first replicating in the nasopharyngeal epithelium and then infecting nearby tonsillar B lymphocytes. In some individuals, this leads to transformation of the epithelial cells. Unlike the case with Burkitt lymphoma (Chapter 12), another EBV-associated tumor, the EBV genome is found in virtually all nasopharyngeal carcinomas, including those that occur outside the endemic areas in Asia.

The three histologic variants are keratinizing squamous cell carcinoma, nonkeratinizing squamous cell carcinoma, and undifferentiated carcinoma; the last-mentioned is the most common and the one most closely linked with EBV. The undifferentiated neoplasm is characterized by large epithelial cells with indistinct cell borders (reflecting "syncytial" growth) and prominent eosinophilic nucleoli. In nasopharyngeal carcinomas, the tumor cells are often accompanied by a striking influx of T cells, which are believed to be responding to viral antigens. Nasopharyngeal carcinomas invade locally, spread to cervical lymph nodes, and then metastasize to distant sites. They tend to be radiosensitive, and 5-year survival rates of 50% are reported, even for patients with advanced cancers. Responses to immune checkpoint inhibitors also have been reported, providing a new therapeutic strategy for tumors that do not respond to conventional therapy.

Laryngeal Tumors

A variety of nonneoplastic, benign, and malignant neoplasms of epithelial and mesenchymal origin may arise in the larynx, but only vocal cord nodules, papillomas, and squamous cell carcinomas are sufficiently common to merit comment. In all of these conditions, the most common presenting feature is hoarseness.

Nonmalignant Lesions

Vocal cord nodules ("polyps") are smooth, hemispherical protrusions (usually <0.5 cm in diameter) located, most often, on the true vocal cords. The nodules are composed of fibrous tissue and covered by stratified squamous mucosa that usually is intact but can be ulcerated from contact trauma with the other vocal cord. These lesions occur chiefly in heavy smokers or singers (singer's nodes), suggesting that they are the result of chronic irritation or over use.

Laryngeal papilloma or *squamous papilloma* of the larynx is a benign neoplasm, usually located on the true vocal cords, that forms a soft, raspberry like excrescence rarely more than 1 cm in diameter. Histologically, it consists of multiple slender, fingerlike projections supported by central fibrovascular cores and covered by an orderly, typical, stratified squamous epithelium. When the papilloma is on the free edge of the vocal cord, trauma may lead to ulceration that can be accompanied by hemoptysis.

Papillomas usually are single in adults but often are multiple in children, in whom the condition is referred to as *recurrent respiratory papillomatosis (RRP),* since they typically tend to recur after excision. These lesions are caused by human papillomavirus (HPV) types 6 and 11 and often spontaneously regress at puberty. Cancerous transformation is rare. The most likely cause for their occurrence in children is vertical transmission from an infected mother during delivery. Therefore, the recent availability of an HPV vaccine that can protect women of reproductive age against infection with types 6 and 11 provides an opportunity for prevention of RRP in children.

Carcinoma of the Larynx

Carcinoma of the larynx represents only 2% of all cancers. It most commonly occurs after 40 years of age and is more common in men than in women (with a gender ratio of 7:1). Environmental influences are very important in its causation; nearly all cases occur in smokers, and alcohol and asbestos exposure also may play roles. Human papillomavirus sequences have been detected in about 15% of tumors, which tend to have a better prognosis than other carcinomas.

About 95% of laryngeal cancers are typical squamous cell carcinomas. Rarely, adenocarcinomas are seen, presumably arising from mucous glands. The tumor develops directly on the vocal cords (glottic tumors) in 60% to 75% of cases, but it also may arise above the cords (supraglottic; 25% to 40%) or below the cords (subglottic; <5%). Squamous cell carcinomas of the larynx begin as in situ lesions that later appear as pearly gray, wrinkled plaques on the

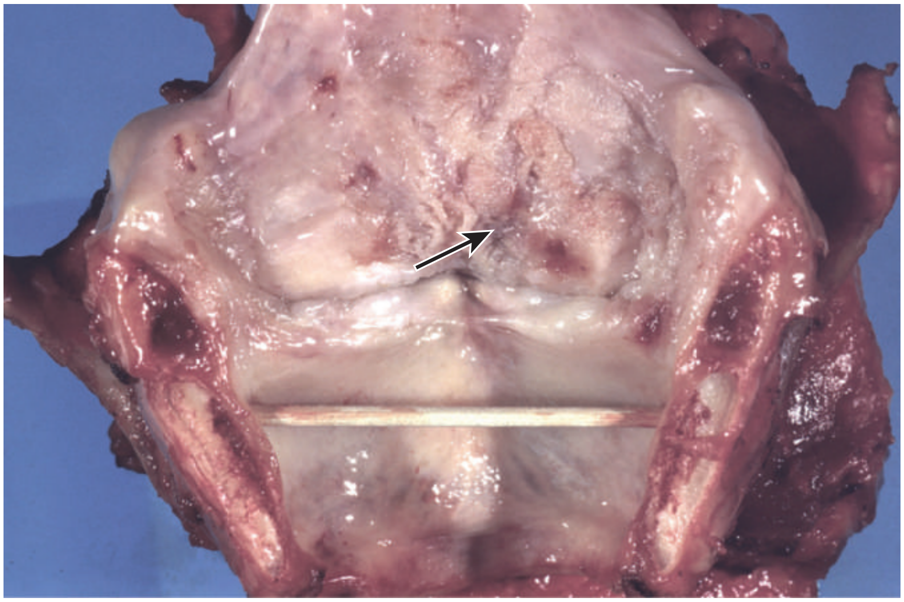

Fig. 13.49 Laryngeal squamous cell carcinoma *(arrow)* arising in a supraglottic location (above the true vocal cord).

mucosal surface, ultimately ulcerating and fungating (Fig. 13.49). The glottic tumors are usually keratinizing, well to moderately differentiated squamous cell carcinomas. As expected with lesions arising from recurrent exposure to environmental carcinogens, adjacent mucosa may demonstrate squamous cell hyperplasia with foci of dysplasia, or even carcinoma in situ.

Carcinoma of the larynx manifests clinically with persistent hoarseness. The location of the tumor within the larynx has a significant bearing on prognosis. For example, about 90% of glottic tumors are confined to the larynx at diagnosis. First, as a result of interference with vocal cord mobility, they develop symptoms early in the course of disease; second, the glottic region has a sparse lymphatic supply, and spread beyond the larynx is uncommon. By contrast, the supraglottic larynx is rich in lymphatic spaces, and nearly one-third of these tumors metastasize to regional (cervical) lymph nodes. The subglottic tumors tend to remain clinically quiescent, usually manifesting as advanced disease. With surgery, radiation therapy, or combination treatment, many patients can be cured, but about one-third die of the disease. The usual cause of death is widespread metastases and cachexia, sometimes complicated by pulmonary infection.

CHAPTER

Kidney and Its Collecting System 14

CHAPTER OUTLINE

The kidney is a structurally complex organ that has evolved to carry out a number of important functions: excretion of the waste products of metabolism, regulation of body water and salt, maintenance of acid balance, and secretion of a variety of hormones and prostaglandins. Diseases of the kidney are as complex as its structure, but their study is facilitated by dividing them into those that affect its four components: glomeruli, tubules, interstitium, and blood vessels. This traditional approach is useful because the early manifestations of diseases that affect each of these compartments tend to be distinctive. Furthermore, some structures seem to be more vulnerable to specific forms of renal injury; for example, glomerular diseases are often immunologically mediated, whereas tubular and interstitial disorders are more likely to be caused by toxic or infectious agents. However, some disorders affect more than one structure, and functional interdependence of structures in the kidney means that damage to one component almost always affects the others. Thus, severe glomerular damage impairs blood flow through the peritubular vascular system; conversely, tubular destruction, by increasing intraglomerular pressure and inducing the production of cytokines and chemokines, may lead to glomerular sclerosis. When chronic kidney disease progresses to its most advanced stage, so-called end-stage renal disease, all four compartments of the kidney are usually damaged. Due to the large functional reserve capacity of the kidney, early signs of kidney disease are often missed, and much renal damage may occur before renal dysfunction becomes clinically apparent. Before discussing individual diseases of the kidney, we describe clinical manifestations of kidney diseases shared by several disorders.

CLINICAL MANIFESTATIONS OF RENAL DISEASES

The clinical manifestations of renal disease can be grouped into reasonably well-defined syndromes. Some are peculiar to glomerular diseases, and others are shared by several renal disorders. Before we list the syndromes, a few terms must be defined.

- *Azotemia* is an elevation of blood urea nitrogen and creatinine levels and usually reflects a decreased glomerular filtration rate (GFR). GFR may be decreased as a consequence of intrinsic renal disease or extrarenal causes. *Prerenal azotemia* is encountered when there is hypoperfusion of the kidneys (usually due to reduced extracellular fluid volume). This decreases GFR in the absence of renal parenchymal damage and is usually reversible if the hypoperfusion is corrected in time. *Postrenal azotemia* results when urine outflow is obstructed. Relief of the obstruction is followed by correction of the azotemia.
- When azotemia gives rise to clinical manifestations and systemic biochemical abnormalities, it is termed *uremia.* Uremia is characterized not only by failure of renal excretory function but also by a host of metabolic and endocrine alterations incident to renal damage. In addition, there is secondary gastrointestinal (e.g., uremic gastroenteritis); neuromuscular (e.g., peripheral

neuropathy); and cardiovascular (e.g., uremic fibrinous pericarditis) involvement.

Below is a brief summary of the various clinical manifestations and syndromes of renal diseases with their defining features. The two most common syndromes associated with glomerular diseases, nephrotic and nephritic, are discussed in detail.

- *Nephrotic syndrome* is characterized by the following:
  - *Proteinuria,* with daily protein loss in the urine of 3.5 g or more in adults (said to be in the "nephrotic range")
  - *Hypoalbuminemia,* with plasma albumin levels less than 3 g/dL
  - *Generalized edema,* the most obvious clinical manifestation
  - *Hyperlipidemia* and lipiduria

  The nephrotic syndrome has diverse causes that share a common pathophysiology, a derangement in the capillary walls of the glomeruli that results in increased permeability to plasma proteins. Increased permeability of the glomerular basement membrane (GBM) may result from structural or physicochemical alterations in the GBM. With long-standing or heavy proteinuria, serum albumin is decreased, giving rise to hypoalbuminemia and a drop in plasma colloid osmotic pressure, which in turn leads to leakage of fluid from the blood into extravascular spaces. As discussed in Chapter 4, the resulting decrease in intravascular volume and renal blood flow triggers increased release of renin from renal juxtaglomerular cells. Renin in turn stimulates the angiotensin-aldosterone axis, which promotes the retention of salt and water by the kidney. This tendency is exacerbated by reductions in the cardiac secretion of natriuretic factors attributed to decreased intravascular volume. In the face of continuing proteinuria, salt and water retention further aggravates the edema and if unchecked may lead to the development of generalized edema (termed *anasarca*). At the onset, there is little or no azotemia, hematuria, or hypertension.

  The genesis of the hyperlipidemia is more obscure. Presumably, hypoalbuminemia triggers increased synthesis of lipoproteins in the liver, or massive proteinuria causes loss of an inhibitor of their synthesis. There also is abnormal transport of circulating lipid particles and impairment of peripheral breakdown of lipoproteins. The associated lipiduria reflects the increased permeability of the GBM to lipoproteins.

  The most important of the primary glomerular lesions that characteristically lead to the nephrotic syndrome are focal segmental glomerulosclerosis and minimal-change disease. The latter is more important in children; the former is more important in adults. The nephrotic syndrome is also commonly seen in two other primary kidney diseases, membranous nephropathy and membranoproliferative glomerulonephritis, and as a complication of the systemic disease diabetes mellitus.
- By contrast, *nephritic syndrome* is characterized by the following:
  - *Hematuria* (red cells and red cell casts in urine)
  - *Proteinuria* (usually in the subnephrotic range) with or without edema
  - *Azotemia*
  - *Hypertension*

  The nephritic syndrome usually has an acute onset and is caused by inflammatory lesions of glomeruli. The lesions that cause the nephritic syndrome have in common proliferation of the cells within the glomeruli, often accompanied by an infiltrate of leukocytes. The inflammatory reaction injures the capillary walls, permitting blood to pass into the urine, and induces hemodynamic changes that lead to a reduction in the GFR. The reduced GFR is manifested clinically by oliguria, fluid retention, and azotemia. Hypertension probably is a result of both the fluid retention and augmented renin release from the ischemic kidneys. The acute nephritic syndrome may be caused by primary glomerular diseases, such as postinfectious glomerulonephritis (GN) and various forms of crescentic GN, or as a result of systemic disorders such as systemic lupus erythematosus.
- *Asymptomatic hematuria* or nonnephrotic proteinuria or a combination of the two is the typical clinical presentation of IgA nephropathy, Alport syndrome, or mild forms or early presentations of other glomerular diseases.
- *Rapidly progressive glomerulonephritis (RPGN*) results in rapid loss of renal function in a few days or weeks, typically in the setting of nephritic syndrome. The characteristic histologic finding associated with RPGN is the presence of crescents (crescentic GN). Rapidly progressive glomerulonephritis is a clinical syndrome and not a specific etiologic form of GN. If untreated, it leads to death from renal failure within a period of weeks to months.
- *Acute kidney injury* refers to abrupt onset of renal dysfunction characterized by an acute increase in serum creatinine often associated with oliguria or anuria (decreased or no urine flow). It can result from glomerular injury (such as rapidly progressive GN), interstitial injury, vascular injury (such as thrombotic microangiopathy), or acute tubular epithelial cell injury.
- *Chronic kidney disease* results from progressive scarring in the kidney of any cause. It is characterized by various metabolic and electrolyte abnormalities such as hyperphosphatemia, dyslipidemia, and metabolic acidosis. However, it is often asymptomatic until the most advanced stages, when symptoms of uremia develop.
- *End-stage renal disease (ESRD)* is irreversible loss of renal function requiring dialysis or transplantation typically due to severe progressive scarring in the kidney from any cause.
- *Urinary tract infection (UTI)* is characterized by bacteriuria and pyuria (bacteria and leukocytes in the urine). It may be symptomatic or asymptomatic, and may affect the kidney (pyelonephritis) or the bladder (cystitis) only.
- *Nephrolithiasis* refers to formation of stones in the collecting system and is manifested by renal colic and hematuria (without red cell casts).

GLOMERULAR DISEASES

The glomerulus consists of an anastomosing network of capillaries invested by two layers of epithelium. The visceral epithelium (composed of podocytes) is part of the

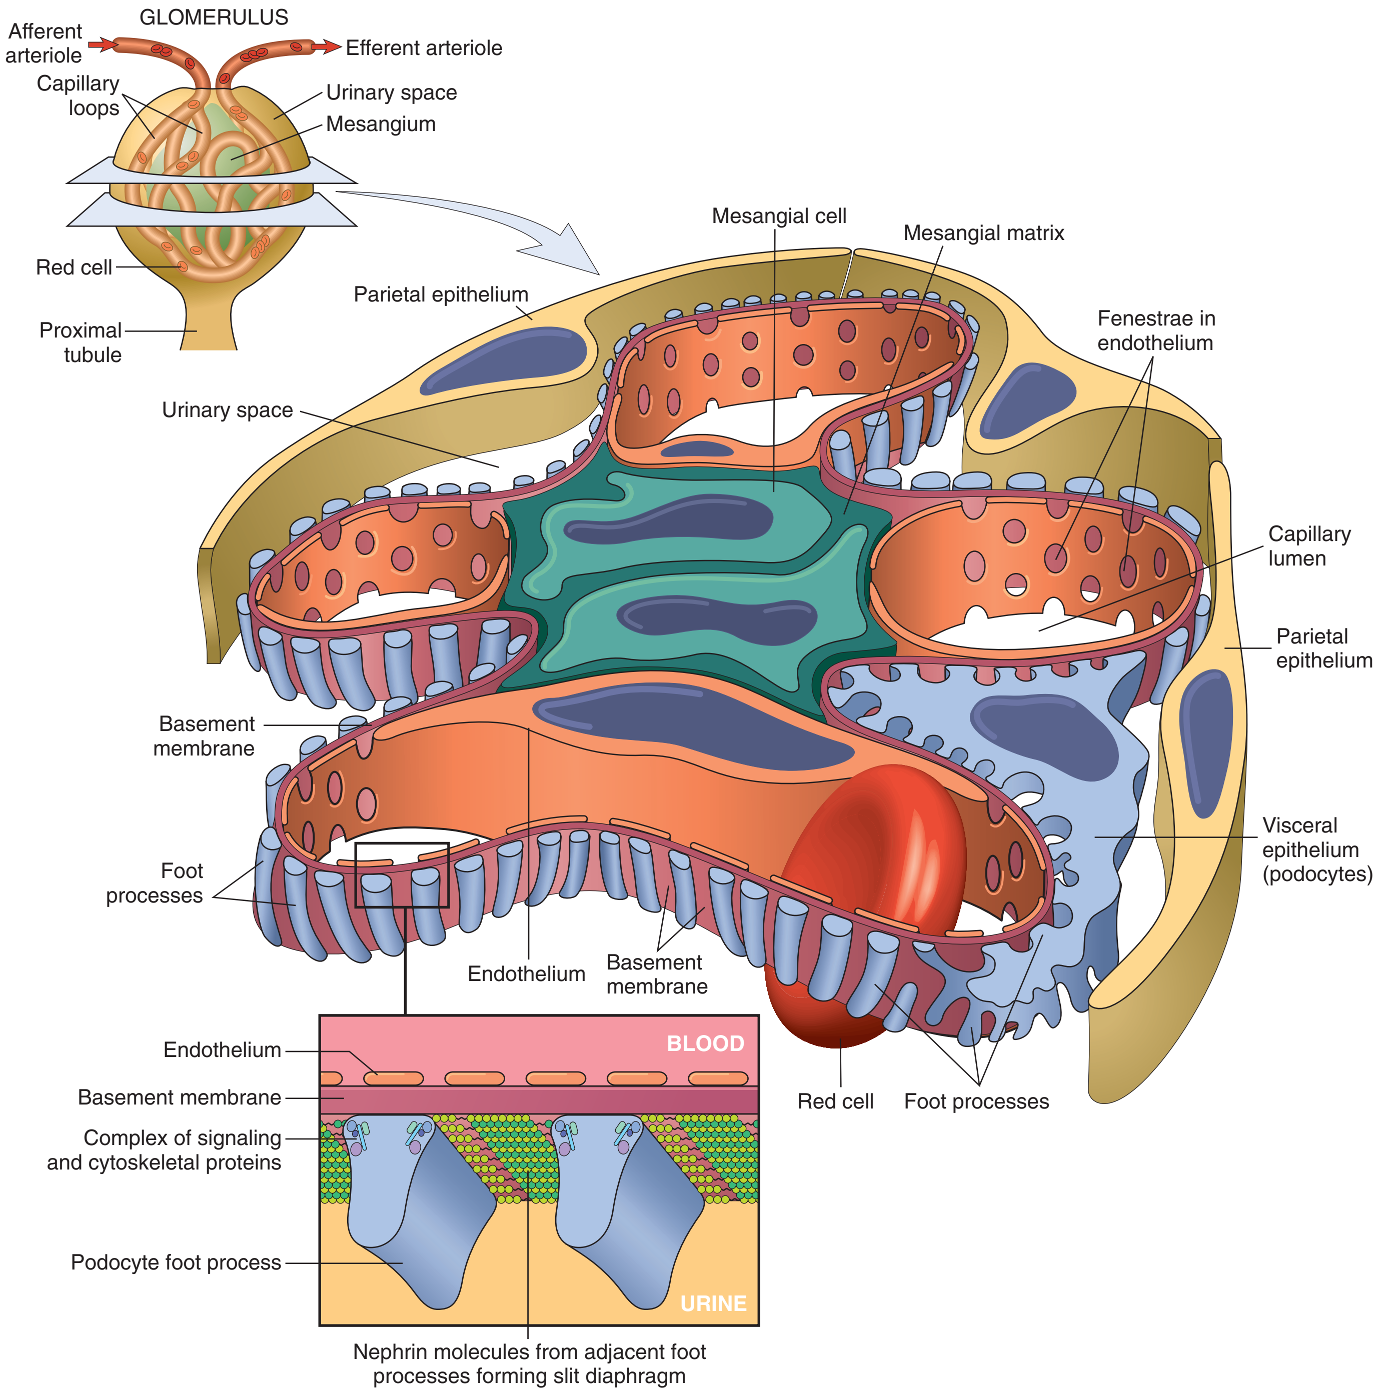

Fig. 14.1 Schematic diagram of a portion of a normal glomerulus.

capillary wall, whereas the parietal epithelium encircles Bowman space (urinary space), the cavity in which filtrate of plasma collects. The glomerular capillary is the filtration unit and consists of the following components (Figs. 14.1 and 14.2):

- Fenestrated *endothelial cells,* with each fenestra being 70 to 100 nm in diameter.
- The *glomerular basement membrane* (GBM), which has a thick, electron-dense central layer called the *lamina densa,* and two thinner, electron-lucent peripheral layers, the *lamina rara interna* and *lamina rara externa.* The GBM consists of collagen (mostly type IV), laminin, polyanionic proteoglycans, fibronectin, and several other glycoproteins.
- *Podocytes,* cells that possess interdigitating foot processes that are embedded in and adherent to the lamina rara externa. Adjacent foot processes are separated by 20- to 30-nm–wide *filtration slits,* which are bridged by a thin slit diaphragm composed mainly of the protein nephrin (see later).
- *Mesangial cells,* which lie in a mesangial matrix between the capillaries that supports the glomerular tuft. These

cells, of mesenchymal origin, are contractile and are capable of proliferation, of laying down collagen and other matrix components, and of secreting a number of biologically active mediators in response to cytokines and other factors (described later).

Normally, the glomerular filtration system is highly permeable to water and small solutes and almost completely impermeable to molecules of the size and molecular charge of albumin (a 70,000-kDa protein). This selective permeability discriminates among protein molecules according to size (the larger, the less permeable), charge (the more cationic, the more permeable), and shape. Podocyte slit diaphragms are important diffusion barriers for plasma proteins, and podocytes are also largely responsible for synthesis of GBM components. *Nephrin,* a transmembrane glycoprotein, is the major component of the slit diaphragms between adjacent foot processes. The intracellular part of nephrin interacts with several cytoskeletal and signaling proteins (see Fig. 14.1). Nephrin and its associated proteins, including *podocin,* have a crucial role in maintaining the selective permeability of the glomerular filtration barrier. This is dramatically illustrated by rare hereditary diseases in which mutations of nephrin or its partner proteins lead to abnormal leakage of plasma proteins into the urine and the nephrotic syndrome. As might be expected, acquired defects in podocytes and slit diaphragms, which are seen in a number of renal diseases, also are associated with proteinuria of varying severity.

Mechanisms of Glomerular Injury and Disease

Glomeruli may be injured by diverse mechanisms in the course of a number of systemic diseases (Table 14.1). These are termed *secondary glomerular diseases* to differentiate them from those in which the kidney is the only or predominant organ involved. The latter constitute the various types of *primary glomerular diseases,* which are discussed later in this section. The glomerular alterations in systemic diseases are discussed elsewhere.

Immune mechanisms underlie most types of primary glomerular diseases and many of the secondary glomerular diseases. Under experimental conditions, GN can be readily induced by antibodies, and glomerular deposits of immunoglobulins, often with various components of complement, are found frequently in patients with GN. Two mechanisms of antibody deposition in the glomerulus have been established: (1) deposition of circulating antigen-antibody complexes in the glomerular capillary wall or mesangium, and (2) antibodies reacting in situ within the glomerulus, either with fixed (intrinsic) glomerular antigens or with extrinsic molecules that are planted in the glomerulus (Fig. 14.3). These pathways are not mutually exclusive, and in humans all may contribute to injury. Abnormal activation and glomerular deposition of complement may be the sole culprit in some forms of GN. Cell-mediated immune mechanisms also may play a role in certain glomerular diseases.

Glomerulonephritis Caused by Circulating Immune Complexes

Deposition of circulating immune complexes in the glomerulus initiates complement (and/or Fc receptor) mediated leukocyte activation, resulting in glomerular injury. The pathogenesis of immune complex diseases is discussed in detail in Chapter 5. Presented here is a brief review of the salient features that relate to glomerular injury in GN.

In circulating immune complex–mediated diseases, the complexes may be formed with endogenous antigens, as in the GN associated with systemic lupus erythematosus, or the antigens may be exogenous, as is probable in the GN that follows certain bacterial (streptococcal), viral (hepatitis B), parasitic (*Plasmodium falciparum* malaria), and spirochetal *(Treponema pallidum)* infections. Often the inciting

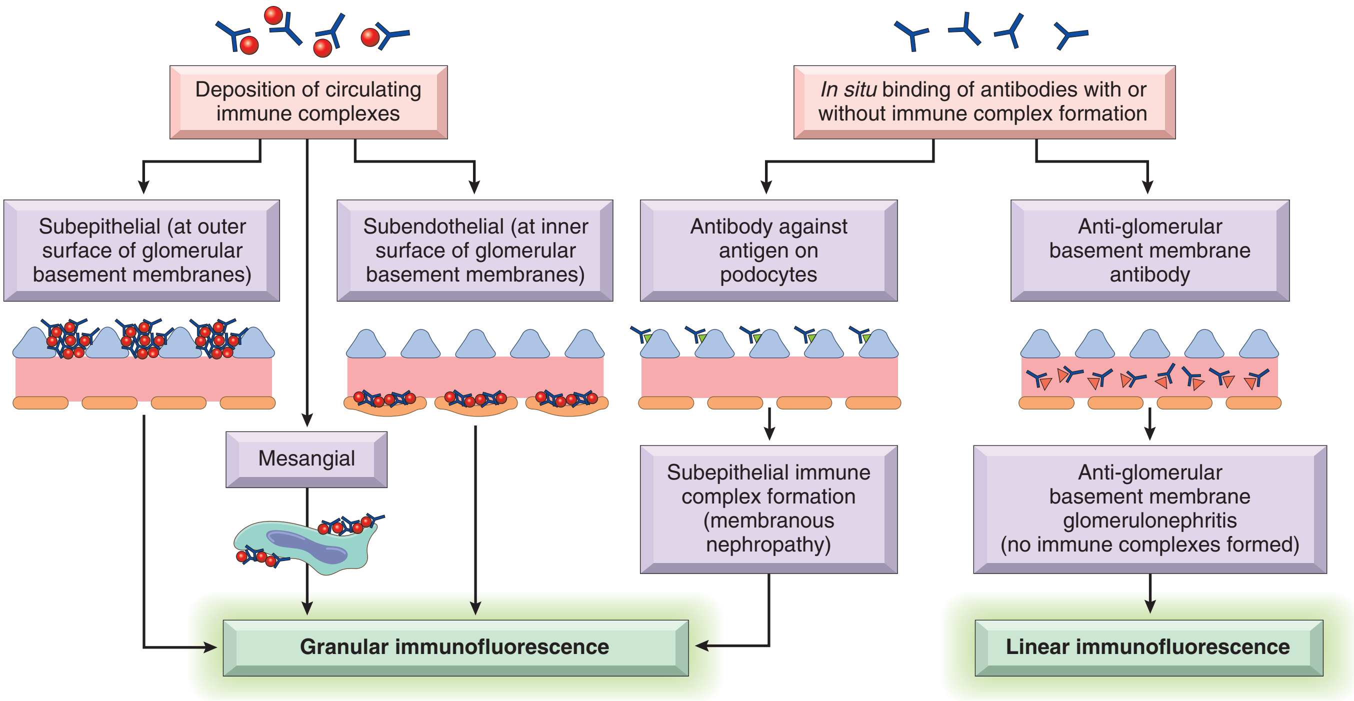

Fig. 14.3 Antibody-mediated glomerular injury. Injury can result either from the deposition of circulating immune complexes or from antibody-binding to glomerular components followed by formation of complexes in situ. Deposition of circulating immune complexes gives a granular immunofluorescence pattern. Anti-glomerular basement membrane (anti-GBM) antibody glomerulonephritis is characterized by a linear immunofluorescence pattern; there is no immune deposit formation in this disease.

antigen is unknown, as in most cases of membranoproliferative GN.

Once antigen-antibody complexes are deposited or formed in the glomeruli, they produce injury by activating complement and recruiting leukocytes. Binding of immune complexes to Fc receptors on leukocytes also may contribute to activation of the cells and injury. Morphologically, affected glomeruli exhibit leukocytic infiltrates and variable proliferation of mesangial and parietal epithelial cells. Electron microscopy reveals electron-dense immune deposits in one or more of three locations: between the endothelial cells and the GBM (subendothelial deposits), between the outer surface of the GBM and the podocytes (subepithelial deposits), or in the mesangium. The localization of antigen, antibody, or immune complexes determines the glomerular injury response. Studies in experimental models have shown that complexes deposited in the endothelium or subendothelium elicit an inflammatory reaction in the glomerulus with infiltration of leukocytes and exuberant proliferation of glomerular resident cells. By contrast, antibodies directed to the subepithelial region of glomerular capillaries are often noninflammatory, as seen in primary membranous nephropathy (discussed later). The presence of immunoglobulins and complement in these deposits can be demonstrated by immunofluorescence microscopy. **The pattern of immune complex deposition by immunofluorescence microscopy is granular**, given the rather picturesque description of "lumpy-bumpy" by pathologists (Fig. 14.4A).

Once deposited in the kidney, immune complexes may eventually be cleared by degradation or phagocytosis, mostly by infiltrating leukocytes and mesangial cells. The inflammatory reaction may then subside if the exposure to the inciting antigen is short-lived and limited, as in most cases of poststreptococcal or acute infection–related GN. However, if exposure to antigen is sustained, repeated cycles of immune complex formation, deposition, and injury occur, leading to chronic GN. In some cases, the source of chronic antigenic exposure is clear, such as in hepatitis B virus infection and self nuclear antigens in systemic lupus erythematosus, but more often the antigen is unknown. Although immune complex deposition is a common mechanism of injury, circulating complexes are almost never identified in human disease, likely because of technical limitations.

Glomerulonephritis Caused by Immune Complexes Formed in Situ

Deposition of antibodies specific for fixed (intrinsic) or planted (from outside) antigens in the glomerulus is another major pathway of glomerular injury. Antigens expressed by podocytes have been implicated in membranous nephropathy. Antibodies also may react in situ with previously "planted" nonglomerular antigens, which deposit and become concentrated in the kidney through interaction with various glomerular components. Planted antigens include nucleosomal complexes, mainly derived from breakdown of apoptotic cells, in patients with systemic lupus erythematosus; bacterial products, such as endostreptosin, a protein expressed by group A streptococci; and large aggregated proteins (e.g., aggregated immunoglobulin G [IgG]), which tend to deposit in the mesangium. Locally formed immune complexes may also grow in size through additional interactions with

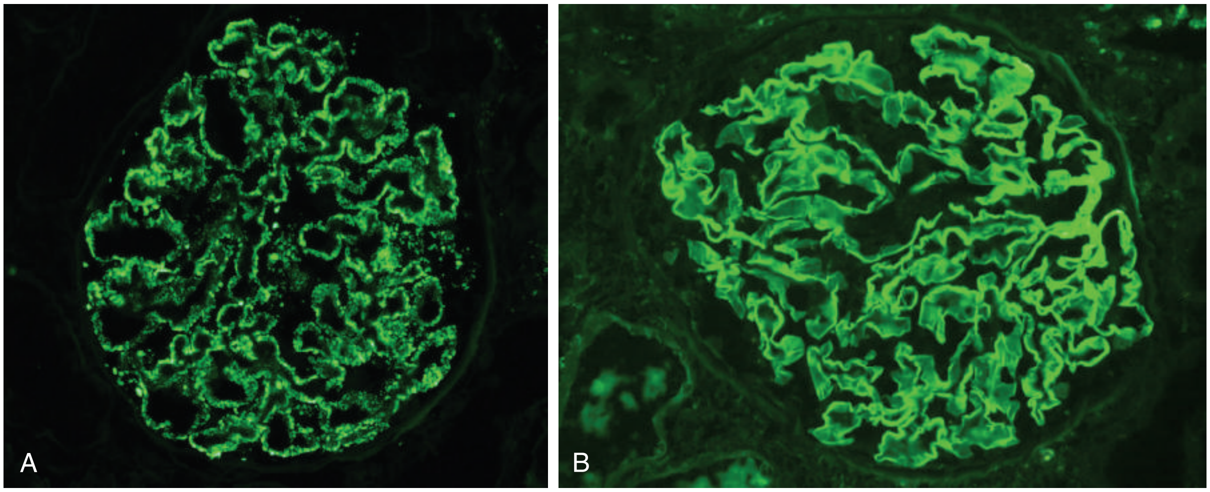

Fig. 14.4 Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy. (A) Granular, characteristic of circulating and in situ immune complex deposition. (B) Linear, characteristic of classic anti-glomerular basement membrane (anti-GBM) antibody glomerulonephritis. *(A, Courtesy of Dr. J. Kowalewska, Department of Pathology, University of Washington, Seattle, Washington.)*

circulating free antibodies and antigens. Most of these planted antigens, as with circulating immune complexes deposited on the GBM, show a granular pattern of deposition by immunofluorescence microscopy.

Anti-Glomerular Basement Membrane Antibody–Mediated Glomerulonephritis

Antibody-mediated GN results from the glomerular deposition of autoantibodies directed against protein components of the GBM. The best-characterized disease in this group is anti-GBM antibody–mediated crescentic GN (see Fig. 14.3), also known as *Goodpasture disease.* In this type of injury, antibodies are directed against fixed antigens in the GBM, creating a linear pattern of staining when visualized with immunofluorescence microscopy (Fig. 14.4B). This pattern is useful in the diagnosis of glomerular disease. A known antigen that is the target of anti-GBM antibodies is the α3 chain of the type IV collagen of the GBM. Sometimes the anti-GBM antibodies cross-react with basement membranes of lung alveoli, resulting in simultaneous lung and kidney lesions (Goodpasture syndrome, Chapter 13).

Glomerular Diseases Caused by Complement Activation

The primary cause of these diseases is unregulated activation of the alternative complement pathway, which may be triggered by acquired autoantibodies against complement components or inherited abnormalities of complement regulatory proteins. Ensuing complement-mediated injury may result in renal and systemic disease. Two forms of GN (dense deposit disease and C3 GN) and one form of a systemic disease with significant renal manifestations (complement-mediated thrombotic microangiopathy [TMA] or atypical hemolytic uremic syndrome) belong to this category. Although complement-mediated thrombotic microangiopathy is a systemic condition, renal manifestation represents the major morbidity of the disease.

Mediators of Immune Injury

A major pathway of antibody-initiated glomerular injury involves complement activation and recruitment of leukocytes. Activation of complement via the classical pathway leads to the generation of chemotactic agents (mainly C5a) for *neutrophils and monocytes*. Neutrophils release proteases, which cause GBM degradation; oxygen-derived free radicals, which cause cell damage; and arachidonic acid metabolites, which contribute to reduction in GFR. In other types of GN in which neutrophils are not prominent, complement-dependent injury may occur through assembly of the C5b-C9 membrane attack complex. There is evidence that the membrane attack complex injures epithelial cells, inducing them to secrete various inflammatory mediators. The alternative and lectin pathways of complement can be activated by cell injury or apoptosis, and also perhaps by deposited IgA.

In addition to neutrophils and monocytes, which are recruited by antibodies and complement, *T lymphocytes* activated during the immune reaction also have been implicated in glomerular injury. *Platelets* may aggregate and release mediators, including prostaglandins. Resident *glomerular cells* (epithelial, mesangial, and endothelial) can be stimulated to secrete mediators such as cytokines (interleukin-1), arachidonic acid metabolites, growth factors, and nitric oxide.

Thus, virtually all of the mediators described in the discussion of inflammation in Chapter 3 may contribute to glomerular injury.

Non-immune Mechanisms of Glomerular Injury

Mechanisms other than inflammation contribute to glomerular abnormalities in certain primary renal disorders. Two that deserve special mention are podocyte injury and nephron loss.

Podocyte Injury

Podocyte injury can be induced by antibodies to podocyte antigens; by toxins; conceivably by certain cytokines; or by still poorly characterized circulating factors, as in some cases of focal segmental glomerulosclerosis (discussed later). Podocyte injury produces morphologic changes

including effacement of foot processes, vacuolization, and retraction and detachment of cells from the GBM, and often results in the development of proteinuria. Of these changes, it is the loss of normal slit diaphragms that is most highly associated with proteinuria. Germline mutations in the structural components of slit diaphragms, such as nephrin and podocin, also are associated with functional alterations that lead to rare hereditary forms of the nephrotic syndrome.

Nephron Loss

Once renal disease, glomerular or otherwise, destroys sufficient nephrons to reduce the GFR to 30% to 50% of normal, symptoms appear and progression to end-stage renal disease proceeds at varying rates. Affected individuals have proteinuria, and their glomeruli show widespread scarring, called *glomerulosclerosis.* Such progressive sclerosis is exacerbated by adaptive changes that occur in response to the loss of nephrons. Specifically, intact glomeruli undergo hypertrophy to maintain renal function, an alteration that is associated with hemodynamic changes, including increases in single-nephron GFR, blood flow, and transcapillary pressure (capillary hypertension). These alterations are ultimately "maladaptive" and lead to further endothelial and podocyte injury, increased glomerular permeability to proteins, and accumulation of proteins and lipids in the mesangial matrix. This is followed by capillary obliteration, increased deposition of mesangial matrix and plasma proteins, and finally segmental (affecting a portion) or global (complete) sclerosis of glomeruli. The latter results in further reduction of nephron mass, initiating a vicious cycle of progressive glomerulosclerosis.

SUMMARY

CLINICAL SYNDROMES AND GLOMERULAR INJURY

- The clinical manifestations of renal disease include nephrotic syndrome, nephritic syndrome, asymptomatic hematuria, rapidly progressive glomerulonephritis, acute kidney injury, chronic kidney disease, and end-stage renal disease.
- The dominant feature of nephrotic syndrome is significant (i.e., "nephrotic range") proteinuria, while nephritic syndrome is characterized by proteinuria and hematuria often in association with functional impairment.
- Glomerular injury is most often caused by depositon of antibodies or immune complexes, activation of complement and leukocyte recruitment and activation.
  - The most common forms of glomerulonephritis (GN) are caused by the formation of immune complexes, which may be deposited from the circulation or form in situ. Immune complexes show a granular pattern of deposition.
  - Autoantibodies against components of the GBM are the cause of anti-GBM-antibody–mediated disease, often associated with severe injury. The pattern of antibody deposition is linear.
- Less frequently, complement may be activated in the absence of antibody, because of acquired or hereditary defects in its regulation.

We now turn to a consideration of specific types of GN and the syndromes they produce (Table 14.2). Many primary glomerular disease cause the nephrotic syndrome, but in adults this syndrome is most often secondary to diabetes, amyloidosis, and systemic lupus erythematosus (Table 14.3). The renal lesions produced by lupus and amyloidosis are discussed in Chapter 5, and those caused by diabetes in Chapter 20.

Minimal-Change Disease

Minimal-change disease, a relatively benign disorder, is the most frequent cause of the nephrotic syndrome in children and is characterized by glomeruli that have a normal appearance by light microscopy. Diffuse effacement of podocyte foot processes is seen with electron microscopy. It may develop at any age, but is most common between 1 and 7 years of age.

Pathogenesis

A popular hypothesis for the pathogenesis of minimal-change disease is that some circulating molecules injure podocytes and cause proteinuria with effacement of foot processes. Although there are numerous reports of candidate serum "factors" produced by lymphocytes and other cells, none has been characterized biochemically or definitively established as being causative in the disease. Thus, the pathogenesis of minimal-change disease remains unknown.

MORPHOLOGY

Under the light microscope, the glomeruli appear normal, thus giving rise to the name (Fig. 14.5A). The cells of the proximal convoluted tubules often are heavily laden with protein droplets and lipids due to tubular reabsorption of the lipoproteins passing through the diseased glomeruli. The only obvious glomerular abnormality is the **diffuse effacement of the foot processes of the podocytes** (see Fig. 14.5B). The cytoplasm of the podocytes appears flattened over the external aspect of the GBM, obliterating the network of arcades between the podocytes and the GBM. Other changes in podocytes include vacuolization, microvillus formation, and occasional focal detachments, suggesting some form of podocyte injury. With reversal of the changes in the podocytes in response to corticosteroids, the proteinuria remits.

Clinical Features

The disease typically manifests with *abrupt development of the nephrotic syndrome* in an otherwise healthy child. There is no hypertension, and renal function is preserved in most of these patients. The protein loss usually is confined to smaller plasma proteins, chiefly albumin (selective proteinuria). The prognosis for children with this disorder is favorable. More than 90% of children respond to a short course of corticosteroid therapy; however, proteinuria recurs in more than two-thirds of the initial responders, some of whom become steroid-dependent with proteinuria recurring when steroids are withdrawn. Less than 5% develop chronic kidney disease after 25 years, and it is likely that most individuals in this subgroup had nephrotic syndrome caused by focal segmental glomerulosclerosis

Table 14.2 Summary of Major Primary Glomerular Diseases

Disease	Most Frequent Clinical Presentation	Pathogenesis	Glomerular Pathology		
			Light Microscopy	Fluorescence Microscopy	Electron Microscopy
Minimal-change disease	Nephrotic syndrome	Unknown; podocyte injury	Normal	Negative	Effacement of foot processes; no deposits
Focal segmental glomerulosclerosis	Nephrotic syndrome; nonnephrotic range proteinuria	Unknown: reaction to loss of renal mass; plasma factor?	Focal and segmental sclerosis and hyalinosis	Usually negative; IgM and C3 may be present in areas of scarring	Effacement of foot processes; epithelial denudation
Membranous nephropathy	Nephrotic syndrome	In situ immune complex formation; PLA2R antigen in most cases of primary disease	Diffuse capillary wall thickening and subepithelial "spike" formation	Granular IgG and C3 along GBM	Subepithelial deposits
Membranoproliferative glomerulonephritis (MPGN) type I	Nephrotic/nephritic syndrome	Immune complex	Membranoproliferative pattern; GBM splitting	Granular IgG, C3, C1q and C4 along GBM and mesangium	Subendothelial deposits
C3 glomerulopathy (dense deposit disease and C3 glomerulonephritis)	Nephrotic/nephritic syndrome; nonnephrotic proteinuria	Activation of alternative complement pathway; antibody-mediated or hereditary defect in regulation	Mesangial proliferative or membranoproliferative patterns	C3	Mesangial, intramembranous and subendothelial electron-dense or "waxy" deposits
Acute postinfectious glomerulonephritis	Nephritic syndrome	Immune complex mediated; circulating or planted antigen	Diffuse endocapillary proliferation; leukocytic infiltration	Granular IgG and C3 along GBM and mesangium	Primarily subepithelial humps
IgA nephropathy	Recurrent hematuria or proteinuria	Immune complexes containing IgA	Mesangial or focal endocapillary proliferative glomerulonephritis	IgA ± IgG, IgM, and C3 in mesangium	Mesangial and paramesangial dense deposits
Anti-GBM disease (e.g. Goodpasture syndrome)	Rapidly progressive glomerulonephritis	Autoantibodies against collagen type IV $\alpha3$ chain	Extracapillary proliferation with crescents; necrosis	Linear IgG and C3; fibrin in crescents	No deposits; GBM disruptions; fibrin
Pauci-immune glomerulonephritis	Rapidly progressive glomerulonephritis	Anti-neutrophil cytoplasmic antibody	Extracapillary proliferation with crescents; necrosis	Fibrin in crescents	No deposits; GBM disruptions; fibrin

GBM, Glomerular basement membrane; *IgA*, immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M.

not detected by biopsy. Because of its responsiveness to therapy in children, minimal-change disease must be differentiated from other causes of the nephrotic syndrome in nonresponders. Adults with this disease also respond to steroid therapy, but the response is slower and relapses are more common.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is characterized by sclerosis of some (but not all) glomeruli that involves only a part of each affected glomerulus. FSGS may be primary (idiopathic) or secondary to one of the following conditions:

- *HIV infection* (HIV nephropathy). FSGS is seen in 5–10% of patients infected with HIV, but the incidence is decreasing with improved antiviral therapy.
- *Heroin abuse* (heroin nephropathy)
- Secondary to other forms of GN (e.g., IgA nephropathy)
- As a maladaptation to nephron loss (as discussed earlier)
- Inherited forms, including autosomal dominant forms associated with mutations in cytoskeletal proteins and podocin, both of which are required for the integrity of podocytes.

Primary FSGS accounts for approximately 20% to 30% of all cases of the nephrotic syndrome. It is an increasingly common cause of nephrotic syndrome in adults and remains a frequent cause in children.

Pathogenesis

Injury to podocytes is thought to represent the initiating event of primary FSGS. However, what causes this injury remains unknown. Some investigators have suggested that FSGS and minimal-change disease are part of a continuum and that minimal-change disease may transform into FSGS, but others believe them to be distinct clinicopathologic entities from the outset. As with minimal-change disease, permeability-increasing factors produced

Table 14.3 Causes of Nephrotic Syndrome

Cause	Prevalence (%)* Children	Adults
Primary Glomerular Disease		
Minimal-change disease	65	10
Focal segmental glomerulosclerosis	10	35
Membranous nephropathy	5	30
Membranoproliferative glomerulonephritis	10	10
IgA nephropathy and others	10	15
Systemic Diseases With Renal Manifestations		
Diabetes mellitus		
Amyloidosis		
Systemic lupus erythematosus		
Ingestion of drugs (gold, penicillamine, "street heroin")		
Infections (malaria, syphilis, hepatitis B, HIV)		
Malignancy (carcinoma, melanoma)		
Miscellaneous (bee sting allergy, hereditary nephritis)		

HIV, Human immunodeficiency virus.
*Approximate prevalence of primary disease is 95% of the cases in children and 60% in adults. Approximate prevalence of systemic disease is 5% of the cases in children and 40% in adults.

by lymphocytes are suspected but remain unproven. The deposition of hyaline in the glomeruli is caused by the entrapment of plasma proteins and lipids in foci of injury where sclerosis develops. The recurrence of proteinuria in patients underoing renal transplantion for FSGS, sometimes within 24 hours of transplantation, supports the idea that a circulating mediator leads to podocyte damage in some cases.

MORPHOLOGY

Primary FSGS initially affects only the juxtamedullary glomeruli. With progression, eventually all levels of the cortex are affected. The lesions occur in some tufts within a glomerulus while sparing others (Fig. 14.6). The affected glomeruli exhibit **increased mesangial matrix, obliterated capillary lumina, deposition of hyaline (hyalinosis) and foamy (lipid-laden) macrophages.** In affected glomeruli, immunofluorescence microscopy often reveals nonspecific trapping of immunoglobulins, usually IgM, and complement in the areas of hyalinosis. On electron microscopy, the podocytes exhibit **effacement of foot processes,** as in minimal-change disease.

With time, progression leads to global sclerosis of the glomeruli, pronounced tubular atrophy, and interstitial fibrosis. This advanced picture is difficult to differentiate from other forms of chronic glomerular disease, discussed later.

A morphologic variant called **collapsing glomerulopathy** is characterized by collapse of the glomerular tuft and epithelial cell hyperplasia. This more severe manifestation of FSGS may be idiopathic or may be associated with HIV infection, drug-induced toxicities, and some microvascular injuries. It carries a particularly poor prognosis.

Clinical Course

It is important to distinguish FSGS from minimal-change disease, because the clinical courses and responses to therapy are markedly different. Both are associated with nephrotic syndrome, but the incidence of hematuria and hypertension is higher in individuals with FSGS. Also, unlike minimal change disease, FSGS-associated proteinuria is nonselective, and in general the response to corticosteroid therapy is poor. At least 50% of patients with FSGS develop end-stage renal disease within 10 years of diagnosis.

Membranous Nephropathy

Membranous nephropathy is characterized by subepithelial immunoglobulin-containing deposits along the GBM. Early in the disease, the glomeruli may appear normal by light microscopy, but well-developed cases show *diffuse thickening of the capillary wall.* It usually presents in adults between the ages of 30 and 60 years and follows an indolent and slowly progressive course.

Up to 80% of cases of membranous nephropathy are primary, caused by autoantibodies against podocyte

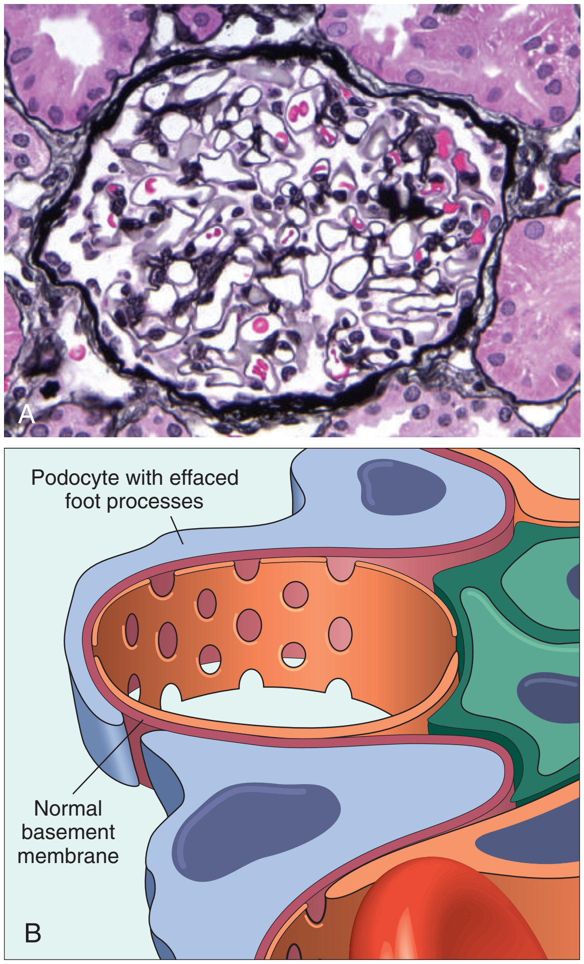

Fig. 14.5 Minimal-change disease. (A) When viewed with a light microscope, the silver methenamine–stained glomerulus appears normal, with a delicate basement membrane. (B) Schematic diagram illustrating diffuse effacement of foot processes of podocytes with no immune deposits.

Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts.)*

antigens. In the remainder, it occurs secondary to other conditions, including the following:

- *Infections* (chronic hepatitis B, syphilis, schistosomiasis, malaria)
- *Malignant neoplasms,* particularly carcinoma of the lung and colon and melanoma
- *Autoimmune diseases, particularly systemic lupus erythematosus*
- *Exposure to inorganic salts* (gold, mercury)
- *Drugs* (penicillamine, captopril, nonsteroidal anti-inflammatory agents)

Pathogenesis

Membranous nephropathy is a form of chronic immune complex glomerulonephritis induced by antibodies reacting in situ to endogenous or planted glomerular antigens. Antibodies against the podocyte antigen phospholipase A_2 receptor (PLA2R) are frequently present but it is not established that they are causative. Formation of subepithelial immune deposits leads to complement activation on the surface of podocytes and generates the membrane attack complex (C5-C9). This in turn causes podocyte injury and proteinuria.

MORPHOLOGY

The main histologic feature of membranous nephropathy is **diffuse thickening of the capillary wall** on routine H&E stains (Fig. 14.7A). Electron microscopy reveals that this apparent thickening is caused in part by **subepithelial deposits,** which nestle against the GBM and are separated from each other by small, spikelike protrusions of GBM matrix that form in reaction to the deposits **(spike and dome pattern)** (see Fig. 14.7B). As the disease progresses, these spikes close over the deposits, incorporating them into the GBM. In addition, as in other causes of nephrotic syndrome, the podocytes show **effacement of foot processes.** Later in the disease, the incorporated deposits may be broken down and eventually disappear, leaving cavities within the GBM. Continued deposition of basement membrane matrix leads to progressive thickening of basement membranes. With further progression, glomeruli may become sclerosed. Immunofluorescence microscopy shows typical **granular deposits** of immunoglobulins and complement along the GBM (see Fig. 14.4A).

Clinical Features

Most cases of membranous nephropathy are sudden in onset and present as *full-blown nephrotic syndrome,* usually without antecedent illness; other individuals have lesser degrees of proteinuria. In contrast to minimal-change disease, the proteinuria is nonselective, and usually fails to respond to corticosteroid therapy. Secondary causes of

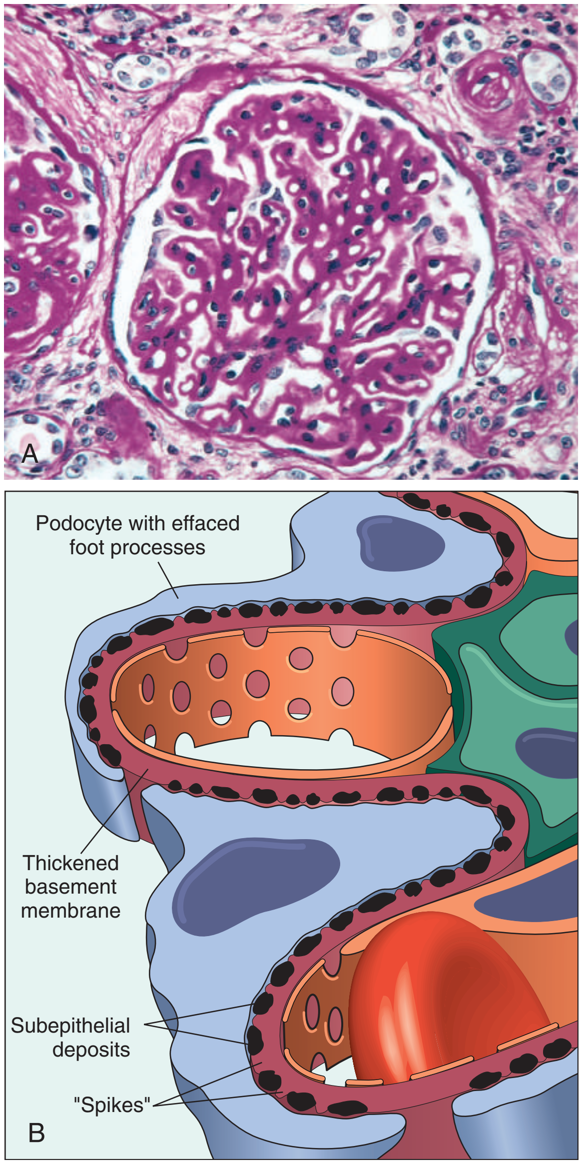

Fig. 14.7 Membranous nephropathy. (A) Diffuse thickening of the glomerular basement membrane (periodic acid–Schiff stain). (B) Schematic diagram illustrating subepithelial deposits, effacement of foot processes, and the presence of spikes of basement membrane material between the immune deposits.

membranous nephropathy should be ruled out. Membranous nephropathy follows a notoriously variable and often indolent course. Overall, although proteinuria persists in greater than 60% of patients, only about 40% progress to renal failure over a period of 2 to 20 years. An additional 10% to 30% of cases have a more benign course with partial or complete remission of proteinuria.

Membranoproliferative Glomerulonephritis

MPGN is manifested histologically by alterations in the GBM and mesangium and by proliferation of glomerular cells. It accounts for 5% to 10% of cases of idiopathic nephrotic syndrome in children and adults. Some patients present only with hematuria or proteinuria in the nonnephrotic range; others exhibit a combined nephrotic-nephritic picture. In the past, MPGN was subclassified into two types (I and II) on the basis of distinct ultrastructural, immunofluorescence, light microscopic, and pathogenic findings. These are now recognized to be distinct entities, termed *MPGN type I* and *dense deposit disease* (formerly *MPGN type II*). Of the two types of disease, MPGN type I is far more common (about 80% of cases) and is discussed here. Dense deposit disease will be discussed later along with the related condition of C3 glomerulonephritis.

Pathogenesis

Type I MPGN may be caused by deposition of circulating immune complexes or by in situ immune complex formation with a planted antigen. The inciting antigen is not known.

MORPHOLOGY

By light microscopy the glomeruli are large, have an accentuated lobular appearance, and show **proliferation of mesangial and endothelial cells as well as infiltrating leukocytes** (Fig. 14.8A). The GBM is thickened, and the glomerular capillary wall often shows a double contour, or "tram track," appearance, especially evident with use of silver or periodic acid–Schiff (PAS) stains. This "splitting" of the GBM is due to extension of processes of mesangial and inflammatory cells into the peripheral capillary loops and deposition of mesangial matrix as well as subepithelial immune complexes (see Fig. 14.8B). The characteristic light microscopic glomerular manifestations are often referred to as *membranoproliferative pattern of glomerular injury.*

By electron microscopy, type I MPGN is characterized by **discrete subendothelial deposits** (see Fig. 14.8B). By immunofluorescence microscopy, C3 is deposited in an irregular granular pattern, and IgG and early complement components (C1q and C4) also often are present, indicative of an immune complex pathogenesis.

Clinical Features

The mode of presentation in approximately 50% of cases is the nephrotic syndrome, although it may begin as acute nephritis or mild proteinuria. The prognosis generally is poor. In one study, none of the 60 patients followed for 1 to 20 years showed complete remission; 40% progressed to end-stage renal failure, 30% had variable degrees of renal insufficiency, and the remaining 30% had persistent

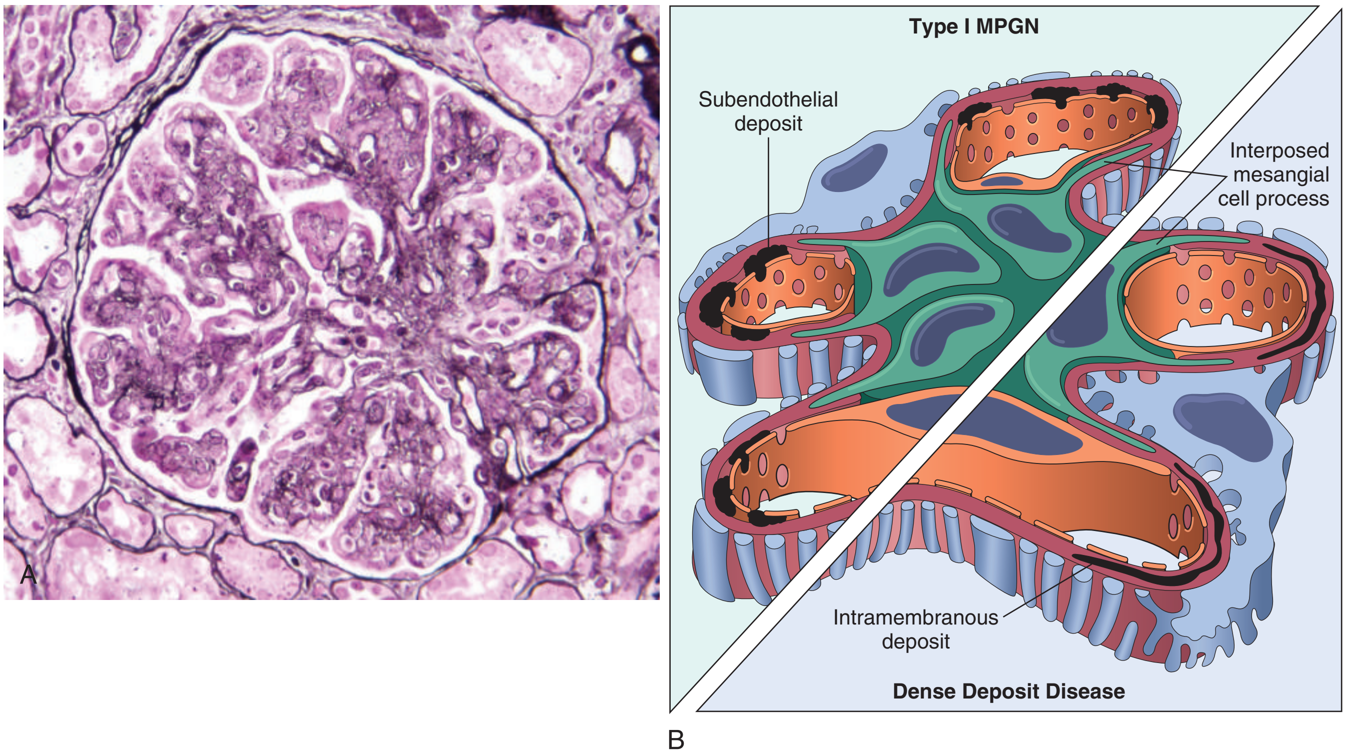

Fig. 14.8 (A) Membranoproliferative glomerulonephritis (MPGN), showing mesangial cell proliferation, basement membrane duplication, leukocyte infiltration, and accentuation of lobular architecture. (B) Schematic representation of the two patterns of MPGN. In type I, there are subendothelial deposits; in type II, now called *dense deposit disease*, intramembranous characteristically dense deposits are seen. In both types, mesangial interposition gives the appearance of split basement membranes when viewed by light microscopy.

nephrotic syndrome without renal failure. MPGN type I also may occur in association with other disorders (secondary MPGN), such as systemic lupus erythematosus, hepatitis B and C, chronic liver disease, and chronic bacterial infections. Indeed, many so-called "idiopathic" cases are believed to be associated with hepatitis C and related cryoglobulinemia.

C3 Glomerulopathy

The term *C3 glomerulopathy* encompasses two conditions, *dense deposit disease* (formerly *MPGN, type II*) and *C3 glomerulonephritis*. These are relatively rare diseases with certain shared clinical, morphologic, and pathogenic features that may be part of a spectrum of injury. They are set apart by differences in the electron microscopic appearance. Patients may present with nephrotic or nephritic syndrome, however, cases with only mild proteinuria also occur. Patients with dense deposit disease are usually younger and more likely to have low serum C3 levels than patients with C3 GN, although these distinctions are subtle.

Pathogenesis

Complement dysregulation due to acquired or hereditary abnormalities of the alternative pathway of complement activation is the underlying cause of dense deposit disease and C3 GN. Some patients have an autoantibody against C3 convertase, called *C3 nephritic factor (C3NeF),* that causes uncontrolled cleavage of C3 by the alternative complement pathway. In other patients, mutations in various complement regulatory proteins, such as Factor H, Factor I, and membrane cofactor protein (MCP), or autoantibodies to Factor H, are the cause of unregulated activation of the alternative pathway of complement.

MORPHOLOGY

Although glomerular changes in dense deposit disease and C3 GN vary from relatively subtle to severe, the classic light microscopic presentation is similar to that seen in MPGN, type 1. The glomeruli are hypercellular, the capillary walls show duplicated basement membranes, and the mesangial matrix is increased. By immunofluorescence microscopy, there is **bright mesangial and glomerular capillary wall staining for C3** in both dense deposit disease and C3 GN. In dense deposit disease, C3 staining also may be seen along the tubular basement membranes. IgG and the early components of the classical complement pathway (C1q and C4) are usually absent in both conditions. By electron microscopy, C3 GN features mesangial and subendothelial electron-dense "waxy" deposits; similar deposits also may be seen along the tubular basement membranes. By contrast, in the aptly named dense deposit disease, the lamina densa and the subendothelial space of the GBM are transformed into an irregular, ribbonlike, extremely electron-dense structure, resulting from the deposition of C3-containing material.

Clinical Features

Both dense deposit disease and C3 GN carry a relatively poor prognosis and both tend to recur posttransplantation at a rate of up to 85%. In a recent study of 70 patients with dense deposit disease or C3 GN, 29% of patients progressed to end-stage renal failure after a median of 28 months.

Acute Postinfectious (Poststreptococcal) Glomerulonephritis

Acute postinfectious GN is caused by glomerular deposition of immune complexes resulting in proliferation of and damage to glomerular cells and infiltration of leukocytes, especially neutrophils. The classic pattern is seen in poststreptococcal GN. Infections by organisms other than streptococci also may be associated with postinfectious GN. These include certain pneumococcal and staphylococcal infections as well as several common viral diseases such as mumps, measles, chickenpox, and hepatitis B and C.

The typical case of poststreptococcal GN develops in a child 1 to 4 weeks after he or she recovers from a group A streptococcal infection. Only certain "nephritogenic" strains of β-hemolytic streptococci evoke glomerular disease. In most cases, the initial infection is localized to the pharynx or skin. In rare cases, the disease can develop during the infection.

Pathogenesis

Poststreptococcal GN is an immune complex disease in which tissue injury is primarily caused by complement activation by the classical pathway. Typical features of immune complex disease, such as hypocomplementemia and granular deposits of IgG and complement on the GBM, are seen. The relevant antigens probably are streptococcal proteins. Specific antigens implicated in pathogenesis include streptococcal exotoxin B (Spe B) and streptococcal glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Both have an affinity for glomerular proteins and plasmin. It is not clear if immune complexes are formed mainly in the circulation or in situ (the latter by binding of antibodies to bacterial antigens "planted" in the GBM).

MORPHOLOGY

By light microscopy, the most characteristic change in postinfectious GN is **increased cellularity** of the glomerular tufts that affects nearly all glomeruli—hence the term *diffuse GN* (Fig. 14.9A). The increased cellularity is caused both by proliferation and swelling of endothelial and mesangial cells and by infiltrating neutrophils and monocytes. Sometimes there is necrosis of the capillary walls. In a few cases, "crescents" (discussed later) may be observed within the urinary space, formed in response to the severe injury. Electron microscopy shows deposited immune complexes arrayed as subendothelial, intramembranous, or, most often, **subepithelial "humps"** nestled against the GBM (see Fig. 14.9B). Mesangial deposits also are occasionally present. Immunofluorescence studies reveal scattered **granular deposits of IgG and complement** within the capillary walls and some mesangial areas, corresponding to the deposits visualized by electron microscopy. These deposits usually are cleared over a period of about 2 months.

Clinical Features

The most common clinical presentation is *acute nephritic syndrome*. Edema and hypertension are common, with mild to moderate azotemia. Characteristically, there is gross

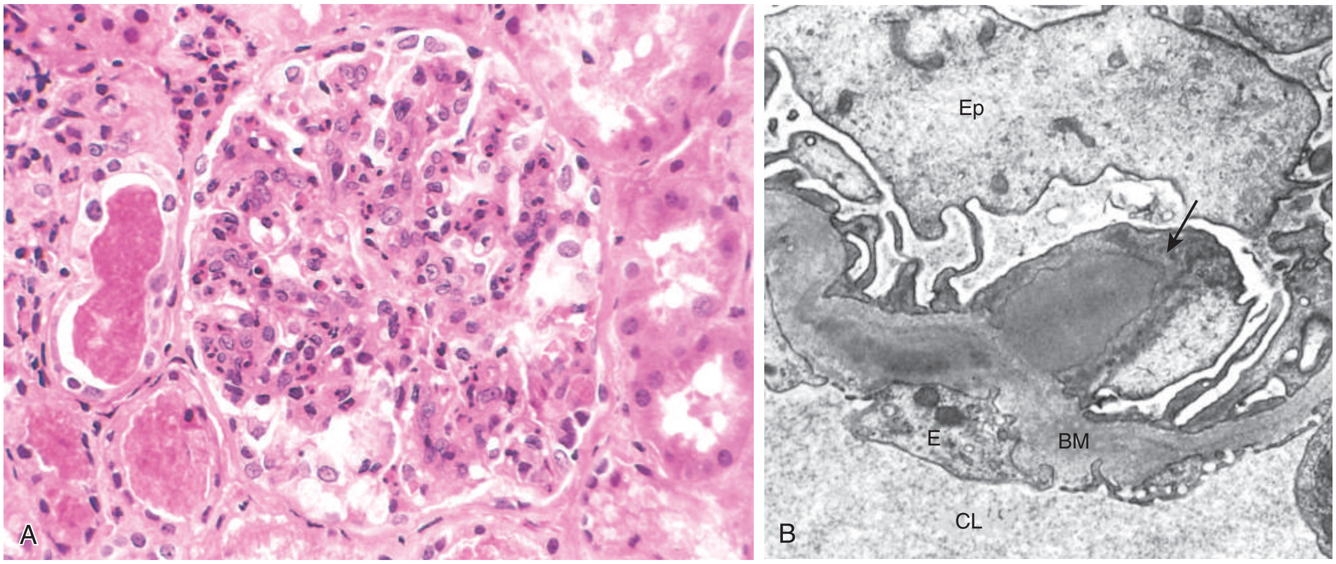

Fig. 14.9 Poststreptococcal glomerulonephritis. (A) Glomerular hypercellularity is caused by intracapillary leukocytes and proliferation of intrinsic glomerular cells. Note the red blood cell casts in the tubules. (B) Typical electron-dense subepithelial "hump" *(arrow)* and intramembranous deposits. *BM*, Basement membrane; *CL*, capillary lumen; *E*, endothelial cell; *Ep*, visceral epithelial cells (podocytes).

hematuria, the urine appearing smoky brown rather than bright red due to oxidation of hemoglobin to methemoglobin. Some degree of proteinuria is a constant feature, and, as mentioned earlier, it occasionally may be severe enough to produce the nephrotic syndrome. Serum complement levels are low during the active phase of the disease, and serum anti–streptolysin O antibody titers are elevated in poststreptococcal cases.

Recovery occurs in most children with poststreptococcal disease, but some develop rapidly progressive GN owing to severe injury with formation of crescents, or chronic renal disease from secondary scarring. The prognosis in sporadic cases is less clear. In adults, 15% to 50% of affected individuals develop end-stage renal disease over a few years or 1 to 2 decades, depending on the clinical and histologic severity. By contrast, in children with sporadic cases of acute postinfectious GN, the progression to chronicity is much lower.

IgA Nephropathy

IgA nephropathy is one of the most common causes of recurrent microscopic or gross hematuria and is the most common glomerular disease revealed by renal biopsy worldwide. This condition usually affects children and young adults and begins as an episode of gross hematuria that occurs within 1 or 2 days of a nonspecific upper-respiratory tract infection. Typically, the hematuria lasts several days and then subsides, but it recurs periodically, usually in the setting of a viral infection. It may be associated with local pain.

The hallmark of the disease is the deposition of IgA in the mesangium. Some experts have considered IgA nephropathy to be a localized variant of *Henoch-Schönlein purpura,* also characterized by IgA deposition in the mesangium. In contrast with IgA nephropathy, which is confined to the kidney, Henoch-Schönlein purpura is a systemic syndrome also involving the skin (purpuric rash), gastrointestinal tract (abdominal pain), and joints (arthritis).

Pathogenesis

An abnormally glycosylated IgA1 (i.e., galactose-deficient IgA1 [Gd-IgA1]) immunoglobulin is thought to play a central role in the pathogenesis. This abnormal IgA may elicit an autoimmune response, and autoantibodies may form large immune complexes with circulating IgA. These complexes deposit in the glomerular mesangium; this unusual location may be related to physicochemical features of the IgA and may be facilitated by an IgA1 receptor (CD71) on mesangial cells. The presence of C3 in the mesangium and the absence of C1q and C4 points to activation of the alternative complement pathway in the pathogenesis. A genetic influence is suggested by the occurrence of IgA nephropathy in families and in HLA-identical siblings, and increased frequency of certain HLA and complement genotypes in some populations. Taken together, these data suggest that in genetically susceptible individuals, respiratory or gastrointestinal exposure to microbial or other antigens (e.g., viruses, bacteria, food proteins) may lead to increased IgA synthesis, some of which is abnormally glycosylated, and deposition of IgA and IgA-containing immune complexes in the mesangium, where they activate the alternative complement pathway and initiate glomerular injury. In support of this scenario, IgA nephropathy occurs with increased frequency in individuals with celiac disease, in whom intestinal mucosal defects are seen, and in liver disease, in which there is defective hepatobiliary clearance of IgA complexes *(secondary IgA nephropathy).*

MORPHOLOGY

Histologically, the lesions in IgA nephropathy vary considerably. The glomeruli may be normal or may show mesangial widening and segmental inflammation confined to some glomeruli (focal

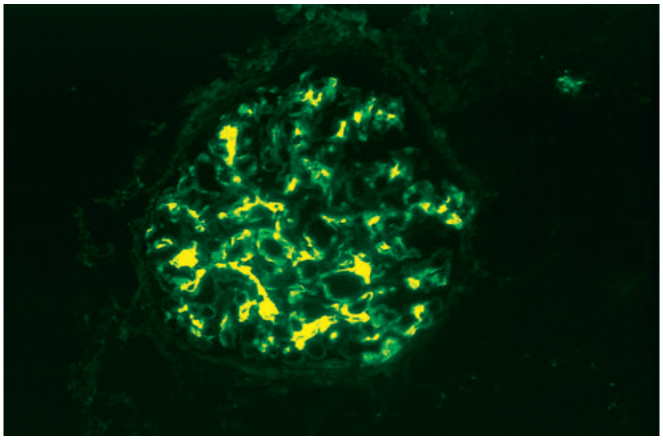

Fig. 14.10 IgA nephropathy. Characteristic immunofluorescence deposition of IgA, principally in mesangial regions, is evident. *IgA,* Immunoglobulin A.

proliferative GN); diffuse mesangial proliferation (mesangioproliferative GN); or (rarely) overt crescentic GN. The characteristic immunofluorescence picture is of **mesangial deposition of IgA,** often with C3 and properdin and smaller amounts of IgG or IgM (Fig. 14.10). Early components of the classical complement pathway usually are absent. Electron microscopy confirms the presence of electron-dense deposits in the mesangium.

Clinical Features

IgA nephropathy most often affects children and young adults. More than half of those affected present with *gross hematuria* after an infection of the respiratory or, less commonly, gastrointestinal or urinary tract; 30% to 40% have only microscopic hematuria, with or without proteinuria, and 5% to 10% develop a typical acute nephritic syndrome. The hematuria typically lasts for several days and initially subsides, but then recurs periodically, usually in the setting of a viral infection. The course is highly variable. Many patients maintain normal renal function for decades. Slow progression to end-stage renal disease occurs in 25% to 50% of cases over a period of 20 years. Renal biopsy findings may help identify those with a poorer prognosis, as indicated by diffuse mesangial proliferation, segmental sclerosis, endocapillary proliferation, or tubulointerstitial fibrosis.

Hereditary Nephritis

Hereditary nephritis refers to a group of glomerular diseases caused by mutations in genes encoding GBM proteins. The most common of these rare diseases are *Alport syndrome* and *thin basement membrane disease.* In Alport syndrome, nephritis is accompanied by sensorineural deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy. Thin basement membrane disease is the most common cause of benign familial hematuria with no systemic manifestations.

Pathogenesis

The GBM is composed largely of type IV collagen, which is made up of heterotrimers of α3, α4, and α5 type IV collagen. This form of type IV collagen is crucial for normal function of the lens, cochlea, and glomerulus. Mutation of any one of the α chains results in defective heterotrimer assembly and, consequently, the manifestations of Alport syndrome.

MORPHOLOGY

On histologic examination, glomeruli in hereditary nephritis appear unremarkable until late in the course. With progression, increasing glomerulosclerosis, vascular sclerosis, tubular atrophy, and interstitial fibrosis are typical changes. Under the electron microscope, the **GBM is thin** and attenuated early in the course, but over time develops irregular foci of thickening or attenuation with pronounced splitting and lamination of the lamina densa, yielding a **"basketweave"** appearance. In contrast to Alport syndrome, diffuse and uniform thinning of the glomerular basement membranes is the only morphologic finding in thin basement membrane disease.

Clinical Features

The majority of Alport syndrome patients have X-linked disease as a result of mutation of the gene on the X chromosome encoding the α5 chain of type IV collagen. Males therefore are affected more frequently and more severely than females and are more likely to develop end-stage renal disease and deafness. Rare autosomal recessive or dominant cases are linked to defects in the genes that encode α3 or α4 type IV collagen. Individuals with hereditary nephritis present at 5 to 20 years of age with gross or microscopic *hematuria and proteinuria*, and progress to overt renal failure by the ages of 20 to 50 years. Female carriers of X-linked Alport syndrome or carriers of either gender of the autosomal forms usually present with persistent asymptomatic hematuria and follow a benign nonprogressive clinical course. Heterozygous mutations in the genes encoding the α3 and α4 chains of type IV collagen are found in 40% of patients with thin basement membrane disease.

Rapidly Progressive Glomerulonephritis

RPGN is characterized by the presence of crescents *(crescentic GN)* and in most cases appears to be immunologically mediated. It is a clinical syndrome and not a specific etiologic form of GN. RPGN is characterized by rapid loss of renal function, laboratory findings typical of the nephritic syndrome, and often severe oliguria. If untreated, it can rapidly lead to renal failure within a period of weeks to months.

Pathogenesis

Crescentic GN may be caused by a number of different diseases, some restricted to the kidney and others systemic. RPGN may be associated with a number of diseases, as follows:

- *Anti-GBM antibody–mediated crescentic GN* (Goodpasture disease) is characterized by linear deposits of IgG and, in many cases, C3 in the GBM. In some patients, the anti-GBM antibodies also bind to pulmonary alveolar capillary basement membranes to produce the clinical picture of pulmonary hemorrhages associated with

renal failure. These patients are said to have *Goodpasture syndrome*. Anti-GBM antibodies are present in the serum and are helpful in diagnosis. It is important to recognize anti-GBM antibody–mediated crescentic GN, because affected individuals benefit from plasmapheresis, which removes pathogenic antibodies from the circulation.

- *Immune complex–mediated crescentic GN* may complicate any of the immune complex nephritides, including poststreptococcal GN, systemic lupus erythematosus, IgA nephropathy, and Henoch-Schönlein purpura. In other cases, immune complexes are demonstrated but the underlying cause is undetermined. This type of RPGN frequently shows cellular proliferation and influx of leukocytes within the glomerular tuft, in addition to crescent formation. A consistent finding is the characteristic granular pattern of staining of the GBM and/or mesangium for immunoglobulin and/or complement on immunofluorescence studies. This disorder usually does not respond to plasmapheresis.
- *Pauci-immune type crescentic GN* is defined by the lack of anti-GBM antibodies or significant immune complex deposition. Anti-neutrophil cytoplasmic antibodies (ANCA) typically are found in the serum, which, as discussed in Chapter 10, have a pathogenic role in some vasculitides. In some instances, therefore, crescentic GN is a component of a systemic vasculitis such as microscopic polyangiitis or granulomatosis with polyangiitis. In many cases, however, pauci-immune crescentic GN is limited to the kidney.

MORPHOLOGY

The light microscopic changes are similar although not identical in various forms of crescentic glomerulonephritis. The glomeruli show cellular proliferation outside the capillary loops, sometimes in association with segmental capillary necrosis, breaks in GBM, and deposition of fibrin in Bowman's space. These distinctive proliferative lesions outside the capillary loops are called **crescents** owing to their shape as they fill Bowman's space. Crescents are formed both by proliferation of epithelial cells and by migration of monocytes/macrophages into Bowman's space (Fig. 14.11). Smaller numbers of other types of leukocytes also may be present. In addition to crescents, cellular proliferation also is seen within the capillary loops and/or in the mesangial areas in cases with immune complex-mediated pathogenesis, such as postinfectious GN, lupus nephritis, or IgA nephropathy. In contrast, in cases with anti-GBM antibody–mediated or pauci-immune crescentic GN, there is no endocapillary hypercellularity. Immunofluorescence studies reveal the characteristic strong **linear staining** with IgG and C3 along the GBM in anti-GBM antibody-mediated disease, a **granular pattern** of glomerular staining in immune complex-mediated GN, while in pauci-immune GN the stains are negative. Electron microscopy shows electron-dense immune complex deposits within the glomeruli in immune complex–mediated GN, but not in biopsies from those with anti-GBM and pauci-immune crescentic GN. Electron microscopy may show distinct **ruptures in the GBM,** signifying severe glomerular injury that is characteristic of this form of GN. The crescents eventually obliterate Bowman's space and compress the glomeruli. In time, crescents may undergo scarring, and glomerulosclerosis develops.

Clinical Features

The onset of RPGN is much like that of the nephritic syndrome, except that the *oliguria and azotemia* are more pronounced. Proteinuria sometimes approaching the nephrotic range may occur. Some affected individuals become anuric and require long-term dialysis or transplantation. The prognosis is roughly predicted by the fraction of involved glomeruli, as patients in whom crescents are present in less than 80% of the glomeruli have a more favorable prognosis than those in whom the percentage of crescents is higher. Plasma exchange may be of benefit in those with anti-GBM antibody GN and in some cases of ANCA-related pauci-immune crescentic GN.

SUMMARY

GLOMERULAR DISEASES

Diseases That Present Mostly With Nephrotic Syndrome

- *Minimal-change disease* is the most frequent cause of nephrotic syndrome in children. It is manifested by proteinuria and effacement of glomerular foot processes without antibody deposits.
- *Focal segmental glomerulosclerosis* (FSGS) may be primary or secondary (e.g., as a consequence of previous glomerulonephritis, hypertension, or infection such as HIV). Glomeruli show focal and segmental obliteration of capillary lumina and loss of foot processes.
- *Membranous nephropathy* is caused by an autoimmune response, most often directed against the PLA2R on podocytes. It is characterized by granular subepithelial deposits of antibodies with GBM "spike" formation, thickening and loss of foot processes but little or no inflammation.
- *Membranoproliferative glomerulonephritis type I* is an immune complex–mediated disease with immune deposits in the subendothelial location.

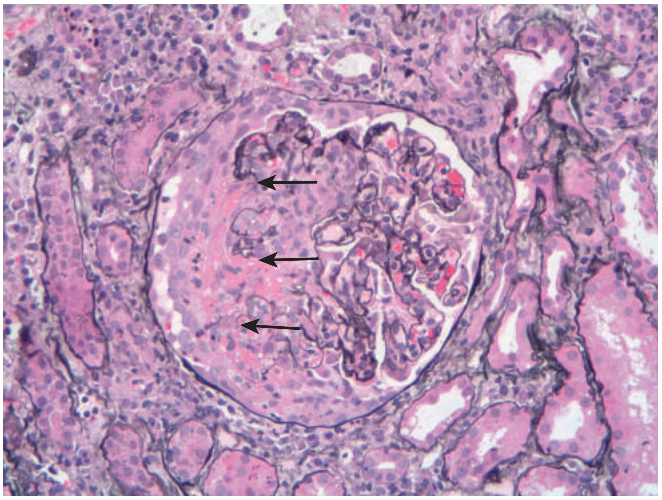

Fig. 14.11 Crescentic glomerulonephritis (silver stain). Arrows indicate areas of necrosis and crescent formation. The segmental distribution in this case is typical of ANCA (anti-neutrophil cytoplasmic antibody)–associated crescentic glomerulonephritis.

- *Dense deposit disease* and *C3 glomerulonephritis* are caused by unregulated activation of the alternative complement pathway. Immunofluorescence is positive for C3 in both conditions.

Glomerulonephritis That Presents With Nephritic Syndrome

- *Acute postinfectious glomerulonephritis* typically occurs after streptococcal infection in children and young adults but may occur following infection with many other organisms. It is caused by deposition of immune complexes, mainly in the subepithelial spaces, with abundant neutrophils and proliferation of glomerular cells.

Diseases That Present Mostly With Asymptomatic Hematuria

- *IgA nephropathy,* characterized by mesangial deposits of IgA-containing immune complexes, is the most common form of glomerulonephritis worldwide. Recurrent asymptomatic hematuria is the most common clinical presentation. It commonly affects children and young adults and has a variable course.
- *Hereditary nephritis (Alport syndrome)* is caused by mutations in genes encoding GBM collagen. It manifests as hematuria and slowly progressing proteinuria and declining renal function. Thin basement membrane disease is also caused by mutations encoding the GBM collagen, however, unlike Alport syndrome, this is usually a benign nonprogressive disorder.

Rapidly Progressive Glomerulonephritis

- RPGN is a clinical entity with features of the nephritic syndrome and rapid loss of renal function.
- It is commonly associated with severe glomerular injury with necrosis and GBM breaks and subsequent proliferation of parietal epithelium (crescents).
- RPGN may be mediated by autoantibodies to the GBM (anti-GBM antibody disease), by immune complex deposition, or it can be pauci-immune often associated with anti-neutrophil cytoplasmic antibodies (pauci-immune GN).

DISEASES AFFECTING TUBULES AND INTERSTITIUM

Most forms of tubular injury also involve the interstitium, so the two are discussed together. Presented under this heading are diseases characterized by (1) inflammatory involvement of the tubules and interstitium *(tubulointerstitial nephritis)* and (2) ischemic or toxic tubular injury, leading to *acute tubular injury* and the clinical syndrome of *acute kidney injury.*

Tubulointerstitial Nephritis

Tubulointerstitial nephritis (TIN) refers to a group of inflammatory kidney diseases that primarily involve the interstitium and tubules. The glomeruli may be spared altogether or affected only late in the course. In cases of TIN caused by bacterial infection, the renal pelvis is prominently involved—hence the more descriptive term *pyelonephritis* (from *pyelo,* "pelvis"). The term *interstitial nephritis* generally is reserved for cases of TIN that are nonbacterial in origin. These include tubular injury resulting from drugs, metabolic disorders such as hypokalemia, irradiation, viral infections, and immune reactions. On the basis of clinical features and the character of the inflammatory exudate, TIN can be divided into acute and chronic categories. Discussed next is acute pyelonephritis followed by consideration of other forms of interstitial nephritis.

Acute Pyelonephritis

Acute pyelonephritis, a common suppurative inflammation of the kidney and the renal pelvis, is caused by bacterial infection. It is an important manifestation of urinary tract infection (UTI), which can involve the lower (cystitis, prostatitis, urethritis) or upper (pyelonephritis) urinary tract, or both. As we will see, the great majority of cases of pyelonephritis are associated with infections of the lower urinary tract, which are very common. Fortunately, most infections of the lower urinary tract remain localized and do not spread to the kidney.

Pathogenesis

The principal causative organisms in acute pyelonephritis are enteric gram-negative bacilli. *Escherichia coli* is by far the most common. Other important organisms are *Proteus, Klebsiella, Enterobacter,* and *Pseudomonas;* these usually are associated with recurrent infections, especially in individuals who undergo urinary tract manipulations or have congenital or acquired anomalies of the lower urinary tract (see later). Staphylococci and *Streptococcus faecalis* also may cause pyelonephritis, but they are uncommon pathogens in this setting.

Bacteria can reach the kidneys from the lower urinary tract (ascending infection) or through the bloodstream (hematogenous infection) (Fig. 14.12). **Ascending infection from the lower urinary tract is the most important and frequent route by which bacteria reach the kidney.** Adhesion of bacteria to mucosal surfaces is followed by colonization of the distal urethra (and the introitus in females). Genetically determined properties of both the urothelium and the bacterial pathogens may facilitate adhesion to the urothelial lining by bacterial fimbriae (proteins that attach to receptors on the surface of urothelial cells), conferring susceptibility to infection. The organisms then reach the bladder, by expansive growth of the colonies and by moving against the flow of urine. This may occur during urethral instrumentation, including catheterization and cystoscopy.

In the absence of instrumentation, UTI most commonly affects females. Because of the close proximity of the female urethra to the rectum, colonization by enteric bacteria can occur more readily in females. Furthermore, the short urethra and trauma to the urethra during sexual intercourse facilitate the entry of bacteria into the urinary bladder. Normally, bladder urine is sterile, because of the anti-microbial properties of the bladder mucosa and the flushing mechanism associated with periodic voiding of urine. With outflow obstruction or bladder dysfunction, however, the natural defense mechanisms of the bladder are overwhelmed, setting the stage for UTI. In the presence of stasis, bacteria introduced into the bladder can multiply undisturbed, without being flushed out or

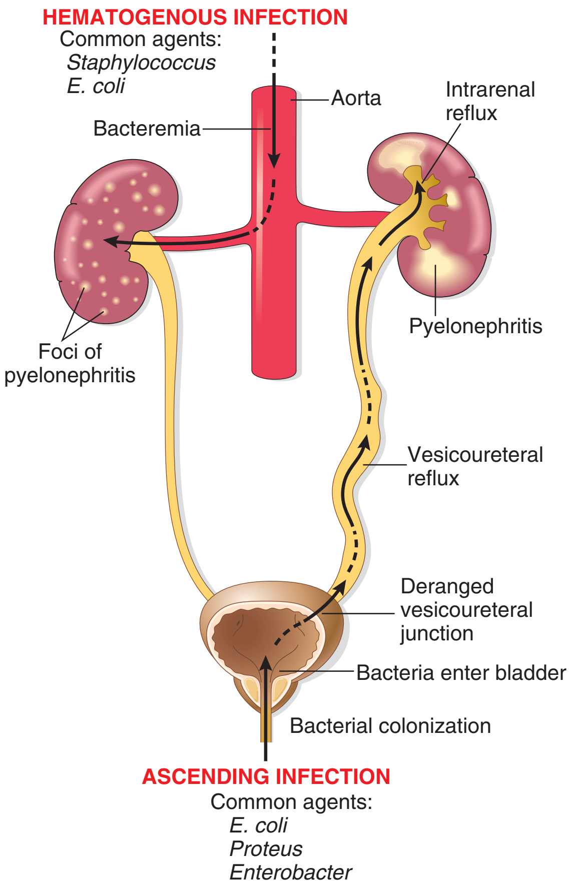

Fig. 14.12 Pathways of renal infection. Hematogenous infection results from bacteremic spread. More common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux.

destroyed by the bladder wall. Accordingly, UTI is particularly frequent among patients with urinary tract obstruction, as may occur with benign prostatic hyperplasia and uterine prolapse. From the contaminated bladder urine, the bacteria ascend along the ureters to infect the renal pelvis and parenchyma. The frequency of UTI also is increased in diabetes because of the increased susceptibility to infection and neurogenic bladder dysfunction, which predispose to urine stasis. Increased incidence of UTI during pregnancy is attributed to urine stasis due to pressure on the bladder and ureters from the growing uterus.

Incompetence of the vesicoureteral orifice, resulting in vesicoureteral reflux (VUR), is an important cause of ascending infection. The reflux allows bacteria to ascend the ureter into the pelvis. VUR is present in 20% to 40% of young children with UTI, usually as a consequence of a congenital defect that results in incompetence of the ureterovesical valve. VUR also can be acquired in individuals with a flaccid bladder resulting from spinal cord injury or with bladder dysfunction secondary to diabetes. VUR results in residual urine after voiding in the urinary tract, which favors bacterial growth. Furthermore, VUR affords a ready mechanism by which the infected bladder urine can be propelled up to the renal pelvis and further into the renal parenchyma through open ducts at the tips of the papillae (intrarenal reflux). Additional risk factors for UTI include preexisting renal conditions with renal scarring and intraparenchymal obstruction and also immunosuppressive therapy and immunodeficiency.

Although *hematogenous spread* is far less common than ascending infection, acute pyelonephritis may result from seeding of the kidneys by bacteria in the course of septicemia or infective endocarditis.

MORPHOLOGY

One or both kidneys may be involved. The affected kidney may be normal in size or enlarged. Characteristically, **discrete, yellowish, raised abscesses are grossly apparent on the renal surface** (Fig. 14.13). They may be widely scattered or limited to one region of the kidney, or they may coalesce to form a single large area of suppuration.

The characteristic histologic feature of acute pyelonephritis is liquefactive necrosis and abscess formation within the renal parenchyma. In the early stages, pus formation (suppuration) is limited to the tubular lumina, but later abscesses rupture into the interstitial tissue. Large masses of intratubular neutrophils frequently extend within involved nephrons into the collecting ducts, giving rise to characteristic white blood cell casts in the urine. Typically, the glomeruli are not affected.

When obstruction is prominent, the pus does not drain and may fill the renal pelvis, calyces, and ureter, producing **pyonephrosis.**

A second (rare) form of pyelonephritis is **papillary necrosis,** which has three predisposing conditions: diabetes, urinary tract obstruction, and sickle cell anemia. This lesion is marked by ischemic and suppurative necrosis of the tips of the renal pyramids (renal papillae). The pathognomonic gross feature is sharply defined gray-white to yellow necrosis of the apical two-thirds of

Fig. 14.13 Acute pyelonephritis. The cortical surface is studded with focal pale abscesses, more numerous in the upper pole and middle region of the kidney; the lower pole is relatively unaffected. Between the abscesses, there is dark congestion of the renal surface.

the pyramids. One papilla or several or all papillae may be affected. Microscopically, the papillary tips show coagulative necrosis surrounded by a neutrophilic infiltrate.

Involvement of the prostate can give rise to acute or chronic prostatitis, particularly in older males with benign prostatic hyperplasia.

Clinical Features

Acute pyelonephritis often is associated with predisposing conditions, as described earlier in the discussion of pathogenetic mechanisms. After the first year of life (an age by which congenital anomalies in males commonly become evident) and up to approximately 40 years of age, infections are much more frequent in females. Up to 6% of pregnant women develop bacteriuria some time during pregnancy, and 20% to 40% of these eventually develop symptomatic urinary infection if not treated. With increasing age, the incidence in males rises as a result of the development of prostatic hyperplasia, which causes urinary outflow obstruction.

The onset of uncomplicated acute pyelonephritis usually is sudden, with pain at the costovertebral angle and systemic evidence of infection, such as chills, fever, nausea, malaise, and localizing urinary tract signs of dysuria, frequency, and urgency. The urine appears turbid due to the contained pus (*pyuria*). The disease usually is unilateral, and affected individuals thus do not develop renal failure. In cases in which predisposing factors are present, the disease may become recurrent or chronic and is more likely to be bilateral. The development of papillary necrosis is associated with a much poorer prognosis.

Chronic Pyelonephritis and Reflux Nephropathy

Chronic pyelonephritis is a clinicopathologic entity in which interstitial inflammation and scarring of the renal parenchyma are associated with grossly visible scarring and deformity of the pelvicalyceal system in patients with a history of UTI. Chronic pyelonephritis is an important cause of chronic kidney disease. It can be divided into two forms: chronic obstructive pyelonephritis and chronic reflux–associated pyelonephritis.

Chronic Obstructive Pyelonephritis

As noted, obstruction predisposes the kidney to infection. Recurrent infections superimposed on diffuse or localized obstructive lesions lead to recurrent bouts of renal inflammation and scarring, which eventually cause chronic pyelonephritis. The disease can be bilateral, as with congenital anomalies of the urethra (e.g., posterior urethral valves), or unilateral, such as occurs with calculi and unilateral obstructive lesions of the ureter.

Chronic Reflux–Associated Pyelonephritis (Reflux Nephropathy)

Chronic reflux–associated pyelonephritis is the most common cause of chronic pyelonephritis. It results from superimposition of a UTI on congenital vesicoureteral reflux and intrarenal reflux. Both the reflux and the attendant renal damage may be unilateral or bilateral, the latter potentially leading to chronic renal insufficiency.

MORPHOLOGY

One or both kidneys may be involved, either diffusely or in patches. Even when involvement is bilateral, the kidneys are not equally damaged and therefore are not equally contracted. This **uneven scarring** is useful in differentiating chronic pyelonephritis from the more symmetrically contracted kidneys associated with vascular sclerosis (often referred to as *benign nephrosclerosis*) and chronic GN. The hallmark of chronic pyelonephritis is **scarring involving the pelvis or calyces,** or both, leading to papillary blunting and marked **calyceal deformities** (Fig. 14.14).

The microscopic changes are largely nonspecific, and similar alterations may be seen with other chronic tubulointerstitial disorders such as analgesic nephropathy. The parenchyma shows the following features:

- Uneven interstitial fibrosis and an inflammatory infiltrate of lymphocytes, plasma cells, and occasionally neutrophils
- Dilation or contraction of tubules, with atrophy of the epithelial lining. Many of the dilated tubules contain pink to blue, glassy-appearing PAS-positive casts, known as *colloid casts,* that suggest the appearance of thyroid tissue—hence the descriptive term *thyroidization*. Often, neutrophils are seen within the tubules
- Chronic inflammatory cell infiltration and fibrosis involving the calyceal mucosa and wall
- Arteriolosclerosis may be caused by associated hypertension
- Glomerulosclerosis that usually develops as a secondary process caused by nephron loss (a maladaptation discussed earlier)

Clinical Features

Many patients with chronic pyelonephritis come to medical attention relatively late in the course of the disease, because of the gradual onset of renal insufficiency or because signs of kidney disease are noticed on routine laboratory tests. In other cases, the renal disease is heralded by the development of hypertension. The radiologic image is characteristic: affected kidneys are asymmetrically contracted, with

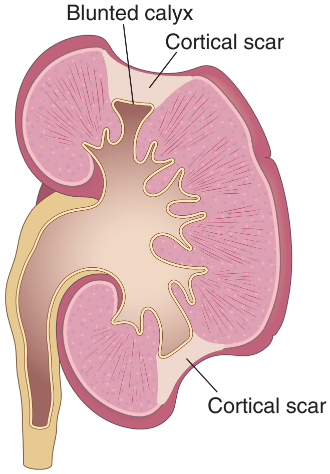

Fig. 14.14 Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually located at the upper or lower poles of the kidney and are associated with underlying blunted calyces.

some degree of blunting and deformity of the calyceal system (caliectasis). The presence or absence of significant bacteriuria is not particularly helpful, as its absence does not rule out chronic pyelonephritis. If the disease is bilateral and progressive, tubular dysfunction leads to an inability to concentrate the urine *(hyposthenuria),* manifested by polyuria and nocturia.

As noted earlier, some individuals with chronic pyelonephritis or reflux nephropathy ultimately develop secondary glomerulosclerosis, associated with proteinuria; eventually, these injuries all contribute to progressive chronic kidney disease.

Drug-Induced Tubulointerstitial Nephritis

Acute drug-induced TIN occurs as an adverse reaction to any one of an increasing number of drugs. It is associated most frequently with penicillins (methicillin, ampicillin), other antibiotics (rifampin), diuretics (furosemide), proton pump inhibitors (omeprazole), nonsteroidal anti-inflammatory agents, and numerous other drugs (phenindione, cimetidine, immune checkpoint inhibitors).

Pathogenesis

Many features of the disease suggest an immune mechanism. Clinical features consistent with a hypersensitivity reaction include latent period between drug exposure and development of lesions, eosinophilia and rash, the idiosyncratic nature of the drug reaction (i.e., the lack of dose dependence), and the recurrence of the reaction following reexposure to the same drug or others of similar structure. Serum IgE levels are increased in some individuals, suggesting immediate (type I) hypersensitivity. In other cases, the nature of the inflammatory infiltrate and the presence of positive skin tests to drugs suggest a T cell–mediated (type IV) hypersensitivity reaction.

The most likely sequence of pathogenic events is that the drugs act as haptens that, during secretion by tubules, covalently bind to some cytoplasmic or extracellular component of tubular cells and become immunogenic. The resultant tubulointerstitial injury is then caused by IgE- or T cell–mediated immune reactions to tubular cells or their basement membranes.

MORPHOLOGY

The abnormalities in acute drug-induced nephritis are in the interstitium, which shows pronounced edema and infiltration by mononuclear cells, principally lymphocytes and macrophages (Fig. 14.15). Eosinophils and neutrophils may be present, often in large numbers. With some drugs (e.g., methicillin, thiazides, rifampin), T cell mediated reaction may give rise to interstitial nonnecrotizing granulomas with giant cells. The glomeruli are normal except in some cases caused by nonsteroidal anti-inflammatory agents, in which the hypersensitivity reaction also leads to podocyte foot process effacement and the nephrotic syndrome.

Clinical Features

The disease begins about 15 days after exposure to the drug and is characterized by *fever, eosinophilia* (which may be transient), *rash* (in about 25% of individuals), and *renal abnormalities.* Urinary findings include hematuria, minimal or no proteinuria, and leukocyturia (sometimes including eosinophils). A rising serum creatinine or acute kidney injury with oliguria develops in about 50% of cases, particularly in older patients. Clinical recognition of drug-induced kidney injury is imperative, because withdrawal of the offending drug is followed by recovery, although it may take several months for renal function to return to normal.

SUMMARY
TUBULOINTERSTITIAL NEPHRITIS

- TIN consists of inflammatory disease primarily involving the renal tubules and interstitium.
- *Acute pyelonephritis* is a bacterial infection caused either by ascending infection as a result of reflux, obstruction, or other abnormality of the urinary tract, or much less commonly by hematogenous spread of bacteria; it is characterized by abscess formation in the kidneys, sometimes with papillary necrosis.
- *Chronic pyelonephritis* usually is associated with urinary obstruction or reflux; it results in scarring of the pelvicalyceal system and the interstium of the involved kidney and gradual progression of chronic kidney disease.
- *Drug-induced interstitial nephritis* is an IgE- or T cell–mediated immune reaction to a drug; it is characterized by interstitial inflammation, often with abundant eosinophils, and edema.

Acute Tubular Injury/Necrosis

Acute tubular injury (ATI) is a clinicopathologic entity characterized by damage to tubular epithelial cells and an acute decline in renal function, often associated with shedding of granular casts and tubular cells into the urine. Clinicians use the term *acute tubular necrosis,* but frank necrosis is rarely observed in a kidney biopsy, so pathologists prefer the term *acute tubular injury.* The constellation of changes, broadly termed *acute kidney injury,* manifests clinically as decreased GFR with concurrent

elevation of serum creatinine. ATI is the most common cause of acute kidney injury and may produce oliguria (defined as urine output of <400 mL/day).

There are two forms of ATI that differ in the underlying causes.

- *Ischemic ATI* is most often the result of a period of inadequate blood flow to all or some peripheral organs such as the kidney, sometimes in the setting of marked hypotension and shock. This can be caused by a variety of conditions, including severe trauma, blood loss, acute pancreatitis and septicemia. Ischemia to tubules may also result from reduced intrarenal blood flow, as in microscopic polyangiitis, malignant hypertension, and thrombotic microangiopathies. Mismatched blood transfusions and other hemolytic crises, as well as myoglobinuria, also produce a clinical picture resembling that of ischemic ATI.
- *Nephrotoxic ATI* is caused by a variety of poisons, including heavy metals (e.g., mercury); organic solvents (e.g., carbon tetrachloride); and a multitude of drugs such as gentamicin and other antibiotics, and radiographic contrast agents.

Pathogenesis

Proximal tubular epithelial cells are particularly sensitive to hypoxemia and also are vulnerable to toxins (Fig. 14.16). Several factors predispose these cells to toxic and ischemic injury, including elevated intracellular concentrations of various molecules that are resorbed or secreted across the proximal tubule, exposure to high concentrations of luminal solutes that are concentrated by the resorption of water from the glomerular filtrate, and a high rate of oxygen consumption, which is required to generate the ATP that is needed for transport and reabsorption functions.

Ischemia causes numerous structural alterations in epithelial cells. Loss of cell polarity is an early reversible event caused by ischemia. It leads to the redistribution of membrane proteins (e.g., Na^+,K^+-ATPase) from the basolateral to the luminal surface of tubular cells, resulting in decreased sodium reabsorption by proximal tubules and hence increased sodium delivery to distal tubules. The latter, through a tubuloglomerular feedback mechanism, contributes to afferent arteriolar vasoconstriction and a decrease in GFR, further worsening the perfusion (discussed below). Injury to the epithelial cells causes detachment of the damaged cells from the basement membranes, and their shedding into the urine. If sufficient tubular debris builds up, it can block the outflow of urine (obstruction by casts), increasing intratubular pressure and thereby exacerbating the decline in GFR. Additionally, fluid from the damaged tubules may leak back into the interstitium, resulting in decreased urine output, increased interstitial pressure, and collapse of the tubules. Ischemic tubular cells also express chemokines, cytokines, and adhesion molecules such as P-selectin that recruit leukocytes (interstitial inflammation) and can participate in tissue injury. Necrotic tubular cells also may elicit an inflammatory reaction that contributes to the tubular injury and functional derangements.

Tubular injury is exacerbated by severe hemodynamic alterations that cause reduced GFR. The major one is *intrarenal vasoconstriction,* which results in both reduced glomerular plasma flow and reduced oxygen delivery to the tubules in the outer medulla (thick ascending limb and straight segment of the proximal tubule) (see Fig. 14.16). Although a number of vasoconstrictor pathways have been implicated in this phenomenon (e.g., renin-angiotensin, thromboxane A_2, sympathetic nerve activity), the current opinion is that vasoconstriction is mediated by sublethal endothelial injury, leading to increased release of the endothelial vasoconstrictor endothelin and decreased production of vasodilatory nitric oxide and prostaglandins. Finally, some evidence points to a direct effect of ischemia or toxins on the glomerulus, causing a reduced effective glomerular filtration surface.

The patchiness of tubular necrosis and maintenance of the integrity of the basement membrane along many segments allow repair of the injured foci and recovery of function if the precipitating cause is removed. This repair is dependent on the capacity of reversibly injured epithelial cells to proliferate and differentiate.

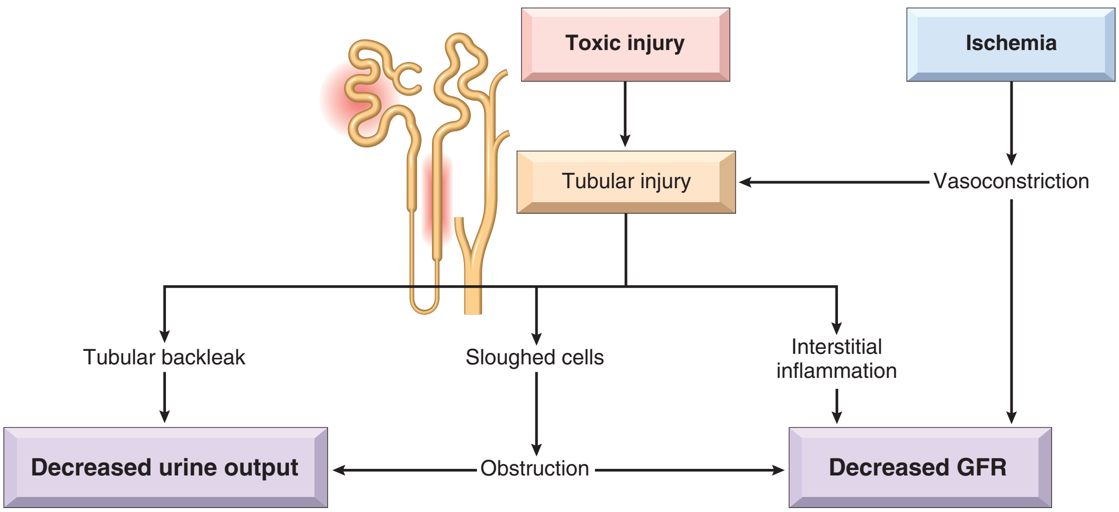

Fig. 14.16 Postulated sequence in ischemic or toxic tubular injury.

MORPHOLOGY

Ischemic ATI is characterized by lesions in the straight portions of the proximal tubule and the ascending thick limbs, but no segment of the proximal or distal tubules is spared. There is often a variety of **tubular injuries,** including attenuation of proximal tubular brush borders, blebbing and sloughing of brush borders, vacuolization of cells, and detachment of tubular cells from their underlying basement membranes with sloughing of cells into the urine (Fig. 14.17). A striking additional finding is the presence of proteinaceous casts in the distal tubules and collecting ducts, which consist of Tamm-Horsfall protein (normally secreted by tubular epithelium) along with hemoglobin and other plasma proteins. When crush injuries have produced ATI, the casts also contain myoglobin. The interstitium usually shows generalized edema along with a mild inflammatory infiltrate consisting of neutrophils, lymphocytes, and plasma cells. The histologic picture in **nephrotoxic ATI** is basically similar, with some differences. Overt necrosis is usually more prominent in the proximal tubule than in ischemic ATI, and the tubular basement membranes generally are spared.

If the patient survives, epithelial regeneration becomes apparent in the form of a low cuboidal epithelial covering and mitotic activity in the surviving tubular epithelial cells. In some cases, for reasons that are not entirely clear, acute kidney injury with underlying acute tubular injury as its cause may result in tubular atrophy and interstitial fibrosis rather than repair.

Clinical Features

The clinical course of ischemic ATI initially is dominated by the inciting medical, surgical or obstetric event. Affected patients often present with manifestations of acute kidney injury, including oliguria and decreased GFR. Not all patients have oliguria; both anuric and non-oligouric forms are seen. The clinical picture is often dominated by electrolyte abnormalities, acidosis, and the signs and symptoms of uremia and fluid overload. The prognosis varies depending upon the severity and nature of the underlying injury and comorbid conditions. In the absence of supportive treatment or dialysis, patients may die. When the cause of acute kidney injury is ATI, repair and tubular regeneration lead to gradual clinical improvement. With supportive care, patients who survive have a good chance of recovering renal function, but a single severe episode of ATI also may result in chronic kidney disease. In those with preexisting chronic kidney disease, complete recovery is less frequent, and progression to end-stage renal disease is unfortunately common.

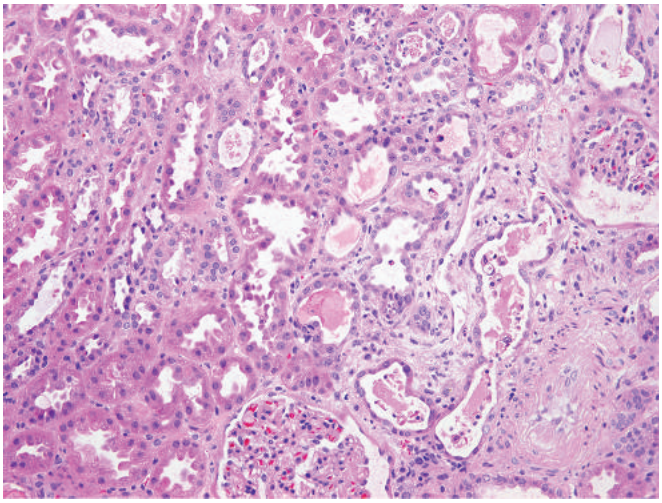

Fig. 14.17 Acute tubular epithelial cell injury with blebbing at the luminal pole, detachment of tubular cells from their underlying basement membranes, and granular casts.

SUMMARY

ACUTE TUBULAR INJURY

- ATI is the most common cause of acute kidney injury; its clinical manifestations are electrolyte abnormalities, acidosis, uremia, and signs of fluid overload, often with oliguria.
- ATI results from ischemic or toxic injury to renal tubules, and is associated with intrarenal vasoconstriction resulting in reduced GFR and diminished delivery of oxygen and nutrients to tubular epithelial cells.
- ATI is characterized morphologically by injury or necrosis of segments of the tubules (typically the proximal tubules), proteinaceous casts in distal tubules, and interstitial edema.

DISEASES INVOLVING BLOOD VESSELS

Nearly all diseases of the kidney affect the renal blood vessels secondarily. Systemic vascular diseases, such as various forms of vasculitis, also involve renal blood vessels, and often produce clinically important effects on renal function (Chapter 10). Conversely, the kidney is intimately involved in the pathogenesis of both essential and secondary hypertension. This section covers the renal lesions associated with hypertension.

Nephrosclerosis

***Nephrosclerosis* refers to sclerosis of small renal arteries and arterioles that is strongly associated with hypertension.** The characteristic morphologic alterations of the small arterioles are called *hyaline arteriolosclerosis*, while the arteries show fibrous intimal and medial thickening often resulting in luminal narrowing. The vascular changes cause ischemia, which leads to various combinations of interstitial fibrosis, tubular atrophy, and focal global glomerulosclerosis. Some degree of nephrosclerosis, albeit mild, is present in many individuals older than 60 years of age. The frequency and severity of the lesions are increased at any age when hypertension or diabetes are present. Of note, many renal diseases cause hypertension, which in turn is associated with nephrosclerosis. Thus, this renal lesion often is superimposed on other primary kidney diseases.

Pathogenesis

The arterial lesions associated with hypertension are the result mainly of endothelial dysfunction and platelet

activation (Chapter 10). Two processes participate in the arterial lesions of nephrosclerosis:

- Medial and intimal thickening, as a response to hemodynamic changes, aging, genetic defects, or some combination of these
- Hyalinization of arteriolar walls, caused by extravasation of plasma proteins through injured endothelium and by increased deposition of basement membrane matrix

MORPHOLOGY

Grossly, the kidneys are **symmetrically atrophic.** Typically the renal surface shows diffuse, fine granularity that resembles grain leather. Microscopically, the most prominent change is hyaline thickening of the walls of the arterioles, known as **hyaline arteriolosclerosis.** This appears as a homogeneous, pink hyaline thickening, at the expense of the vessel lumina, with loss of underlying cellular detail (Fig. 14.18). The narrowing of the lumen results in markedly decreased blood flow through the affected vessels, with consequent ischemia and renal atrophy. In advanced cases of arterionephrosclerosis, the glomerular tufts may become sclerosed. Diffuse tubular atrophy and interstitial fibrosis are present, but inflammatory infiltrates are absent or scant. The larger blood vessels (interlobar and arcuate arteries) show intimal thickening with replication of internal elastic lamina along with fibrous thickening of the media **(fibroelastic hyperplasia).**

Clinical Features

This renal lesion alone rarely causes damage severe enough to produce renal failure, except in individuals from some, possibly genetically susceptible, groups, such as African Americans, in whom it may lead to uremia and death. However, all patients usually show some functional impairment, such as loss of concentrating ability or a variably diminished GFR. A mild degree of proteinuria is a frequent finding.

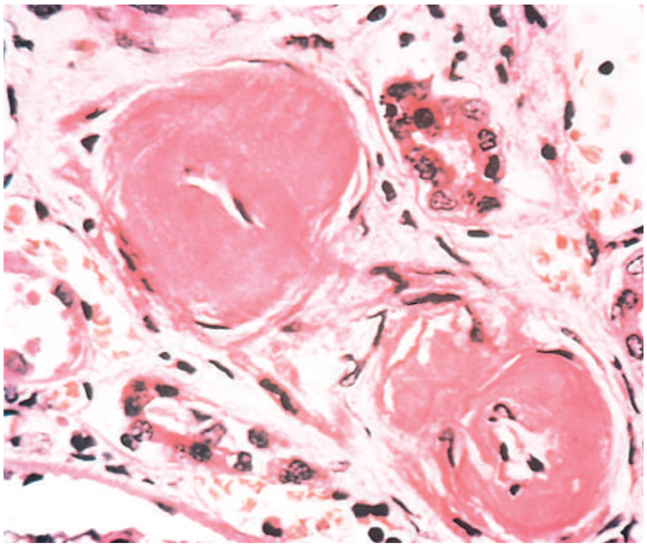

Fig. 14.18 Benign nephrosclerosis. High-power view of two arterioles with hyaline deposition, marked thickening of the walls, and a narrowed lumen. *(Courtesy of Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Texas.)*

Malignant Hypertension

Malignant hypertension, defined as blood pressure usually greater than 200/120 mm Hg, is far less common in the United States than essential hypertension and occurs in only about 5% of hypertensive individuals. It may arise de novo (i.e., without preexisting hypertension), or it may appear suddenly in an individual who had mild hypertension. The prevalence of malignant hypertension is higher in developing countries. It may present with severe acute kidney injury and renal failure. Renal changes are confined to the vasculature and may include thrombotic microangiopathy.

Pathogenesis

The renal changes are related to hypertension and the reactions to it.

- Injury resulting from long-standing hypertension causes increased permeability of the vessels to fibrinogen and other plasma proteins, endothelial injury, and platelet deposition. This leads to the appearance of *fibrinoid necrosis* of arterioles and small arteries and intravascular thrombosis
- Mitogenic factors from platelets (e.g., platelet-derived growth factor) and plasma cause intimal hyperplasia of vessels, resulting in *hyperplastic arteriosclerosis*. Because of the luminal narrowing, the kidneys become markedly ischemic, which leads to further elevation of blood pressure via the renin-angiotensin system.

MORPHOLOGY

The kidney may be normal in size or shrunken, depending on the duration and severity of the hypertensive disease. Small, **pinpoint petechial hemorrhages** may appear on the cortical surface from rupture of arterioles or glomerular capillaries, giving the kidney a peculiar, **flea-bitten appearance.**

The microscopic changes reflect the pathogenetic events discussed earlier. Damage to the small vessels is manifested as **fibrinoid necrosis** of the arterioles (Fig. 14.19A). The vessel walls show a homogeneous, granular eosinophilic appearance masking underlying detail. In the interlobular arteries and larger arterioles, proliferation of intimal cells after acute injury produces an *onion-skin* appearance (see Fig. 14.19B). This name is derived from the concentric arrangement of cells whose origin is believed to be intimal smooth muscle, although this issue has not been finally settled. This lesion, called **hyperplastic arteriolosclerosis,** causes marked narrowing of arterioles and small arteries, to the point of total obliteration. Necrosis also may involve glomeruli, with microthrombi within the glomeruli as well as necrotic arterioles. Similar lesions are seen in individuals with acute thrombotic microangiopathies (discussed later), and in patients with scleroderma in renal crisis.

Clinical Features

The full-blown syndrome of malignant hypertension is characterized by papilledema, encephalopathy, cardiovascular abnormalities, and renal failure. Most often, the early symptoms are related to *increased intracranial pressure* and include headache, nausea, vomiting, and visual impairment, particularly the development of scotomas, or "spots" before the

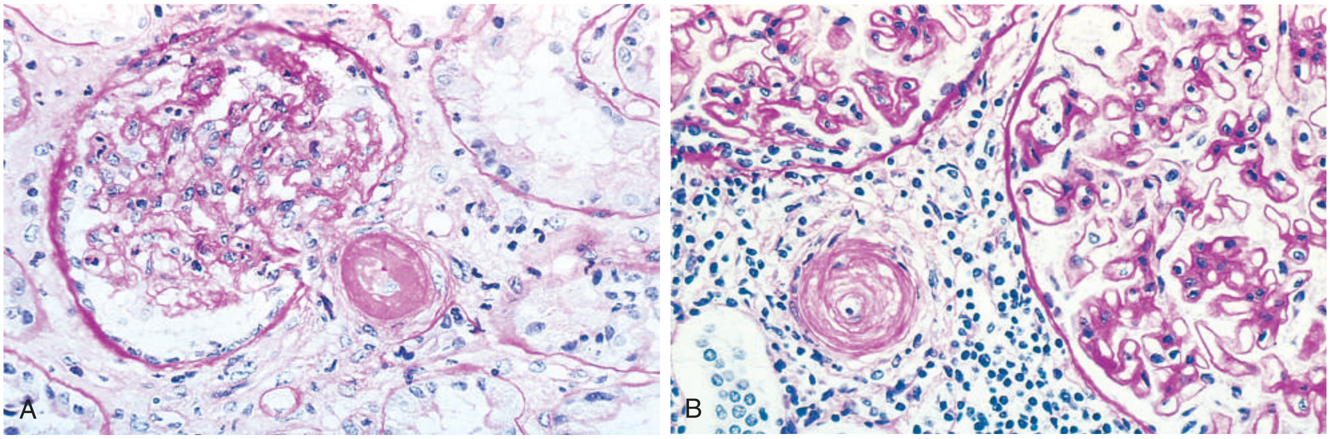

Fig. 14.19 Malignant hypertension. (A) Fibrinoid necrosis of afferent arteriole (periodic acid–Schiff stain). (B) Hyperplastic arteriolosclerosis (onion-skin lesion). *(Courtesy of Dr. H. Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts.)*

eyes. At the onset of rapidly mounting blood pressure, there is marked proteinuria and microscopic, or sometimes macroscopic, hematuria but no significant alteration in renal function. Soon, however, *acute kidney injury* develops. The syndrome represents a true medical emergency that requires prompt and aggressive anti-hypertensive therapy before irreversible renal lesions develop. About 50% of patients survive at least 5 years; 90% of deaths are caused by uremia, and the other 10% are caused by cerebral hemorrhage or cardiac failure.

Thrombotic Microangiopathies

As discussed in Chapter 10, the term *thrombotic microangiopathy (TMA)* refers to lesions seen in various clinical syndromes characterized by microvascular thrombosis accompanied by *microangiopathic hemolytic anemia, thrombocytopenia,* and, in certain instances, *renal failure.* The primary forms of TMA include those with a known etiology, while the secondary forms develop in the background of other diseases or conditions without well-defined etiology. Common primary forms of TMA include *Shiga toxin–mediated hemolytic uremic syndrome (HUS); atypical HUS,* also called complement-mediated TMA because excessive complement activation is an important pathogenic mechanism; *thrombotic thrombocytopenic purpura (TTP)*; and some of the *drug-mediated TMAs.* Malignant hypertension and scleroderma-associated TMA represent examples of the secondary forms.

Pathogenesis

The major pathogenetic factors in the thrombotic microangiopathies are endothelial cell injury and platelet activation and aggregation. They can be caused by diverse insults, including external toxins, drugs, autoantibodies, and inherited mutations, which can lead to excessive small vessel thrombosis in the capillaries and arterioles in various organs. Vascular compromise results in ischemic injury and organ dysfunction. The classic laboratory manifestations of thrombotic microangiopathy are thrombocytopenia caused by excessive platelet consumption, and microangiopathic hemolytic anemia due to mechanical injury (shearing) of red cells as they pass through vascular channels narrowed by thrombi. In the primary forms of thrombotic microangiopathies, the etiology is well-defined (Table 14.4), while the secondary forms are associated with various underlying conditions and diseases, such as malignant hypertension, scleroderma, pregnancy, chemotherapy, anti-phospholipid antibodies, and transplant rejection, with less well-defined etiology and pathogenesis. Only the three major forms of primary thrombotic microangiopathies are sufficiently common to merit discusson.

- *Shiga toxin–mediated HUS.* As many as 75% of cases follow intestinal infection with Shiga toxin–producing *E. coli,* such as occurs following ingestion of contaminated ground meat (e.g., in hamburgers) and infections with *Shigella dysenteriae* type I. The pathogenesis is related to the effects of Shiga toxin. The basis for thrombus formation in small vessels, particularly in the kidney, is complex, but most studies suggest endothelial damage has a central role. Renal glomerular endothelial cells are vulnerable because they express the membrane receptor for Shiga toxin. At low doses, the toxin activates endothelial cells, leading to leukocyte adhesion,

Table 14.4 Etiologic Classification of the Major Forms of Primary Thrombotic Microangiopathy

	Forms	Etiology
Shiga toxin–mediated HUS	Acquired	Shiga toxin–producing *E. coli Shigella dysenteriae* serotype 1
Atypical HUS (complement-mediated TMA)	Inherited	Complement dysregulation due to genetic abnormalities (relatively common)
	Acquired	Acquired complement dysregulation due to autoantibodies (rare)
TTP	Inherited	Genetic ADAMTS13 deficiency (rare)
	Acquired	ADAMTS13 deficiency due to autoantibodies (relatively common)

ADAMTS13, von Willebrand factor cleaving protease; *HUS*, hemolytic uremic syndrome; *TMA*, thrombotic microangiopathy; *TTP*, thrombotic thrombocytopenic purpura.

increased endothelin production and decreased nitric oxide production (both favoring vasoconstriction), as well as other changes that may promote platelet adhesion and activation. At high doses, the toxin causes endothelial cell death. All of these alterations may contribute to the formation of thrombi, which tend to be most prominent in glomerular capillaries, afferent arterioles, and interlobular arteries.

- *Atypical HUS* is caused by acquired or hereditary abnormalities of factors that dampen activation of complement by the alternative pathway. Their absence leads to excessive activation of complement, with ensuing microvascular injury and microvascular thrombosis. The C5-9 membrane attack complex appears to have a central role, as a therapeutic antibody that inhibits this complex turns off platelet consumption and improves renal function. Interestingly, abnormalities of the alternative pathway of complement activation also may lead to C3 glomerulonephritis and dense deposit disease, as discussed earlier.
- *TTP* is caused by acquired or inherited deficiencies in ADAMTS13 (a disintegrin and metalloprotease with thrombospondin-like motifs), a plasma protease that cleaves von Willebrand factor (vWF) multimers into smaller sizes. Acquired defects in ADAMTS13 are caused by inhibitory autoantibodies directed against ADAMTS13, while inherited deficiencies stem from mutations in the ADAMTS13 gene. Deficiencies of ADAMTS13 result in the formation of abnormally large vWF multimers that activate platelets spontaneously, leading to platelet aggregation and thrombosis in multiple organs, including the kidney.

MORPHOLOGY

The morphologic lesions are very similar in all forms of TMA regardless of the etiology. Thrombi are seen in glomerular capillaries and also the arterioles and sometimes the larger arteries in more severe cases. Additional glomerular changes resulting from endothelial injury include widening of the subendothelial space, duplication or splitting of GBMs, and lysis of mesangial cells. Cortical necrosis also may occur in severe cases. If TMA persists, scarring of glomeruli may develop. Except for varying amounts of fibrinogen in the glomeruli and arterioles, immunofluorescence studies are typically negative.

Clinical Features

The clinical course varies according to the etiology and the severity of the morphologic changes. More severe vascular changes are typically associated with a less favorable outcome.

Shiga toxin–associated HUS is characterized by the sudden onset, usually after a gastrointestinal or flulike prodromal episode, of bleeding manifestations (especially hematemesis and melena), severe oliguria, hematuria, microangiopathic hemolytic anemia, and (in some individuals) prominent neurologic changes. *This disease is one of the main causes of acute kidney injury in children.* If the acute kidney injury is managed properly with dialysis, most patients recover in a matter of weeks. The long-term prognosis (over 15–25 years), however, is not uniformly favorable, as about 25% of affected children eventually develop renal insufficiency.

The onset of atypical HUS is usually sudden, without prodromal diarrhea. The outcome is significantly poorer than in Shiga toxin–mediated HUS. The case-fatality ratio is approximately 20%, and only 60% to 70% of patients recover renal function. Plasma exchange can be used to temporarily restore missing factors (in those with inherited disease) or remove pathogenic antibodies. Since most complement factors are produced in the liver, liver transplantation can be curative. More recently, antibody inhibitors of the membrane attack complex have been shown to be effective in reducing thrombosis and improving renal function, and are now considered to be the first-line therapy in "complement-mediated" forms of HUS.

The typical onset of TTP is also sudden, with a dominant involvement of the central nervous system, and the kidneys are less commonly involved than in Shiga toxin and atypical HUS. Without therapy, TTP typically follows a rapidly fatal course, with survival rates of approximately 10%. With the advent of plasma exchange therapy that replaces ADAMTS 13, the prognosis has improved dramatically. In those patients who survive, residual renal abnormalities are rare.

SUMMARY

VASCULAR DISEASES OF THE KIDNEY

- *Arterionephrosclerosis:* Progressive, chronic renal damage associated with hypertension. Characteristic features are hyaline arteriolosclerosis and narrowing of vascular lumina with resultant cortical atrophy.
- *Malignant hypertension:* Acute kidney injury associated with severe elevation of blood pressure. Arteries and arterioles show fibrinoid necrosis and hyperplasia of smooth muscle cells; petechial hemorrhages appear on the cortical surface.
- *Thrombotic microangiopathies:* Disorders characterized by fibrin thrombi in glomeruli and small vessels resulting in acute kidney injury. Typical HUS is usually caused by endothelial injury by an *E. coli* toxin; TTP is often caused by abnormalities in von Willebrand factor leading to excessive thrombosis, with platelet consumption. The most common cause of atypical HUS is complement-mediated endothelial injury due to complement dysregulation.

CHRONIC KIDNEY DISEASE

Chronic kidney disease is a broad term that describes the final common pathway of progressive nephron loss resulting from any type of kidney disease. Alterations in the function of remaining intact nephrons are ultimately maladaptive and cause further scarring. This eventually results in an end-stage kidney with sclerosed glomeruli, tubules, interstitium and vessels, regardless of the anatomic site of the original injury. Unless the disorder is treated with dialysis or transplantation, death from uremia, electrolyte disturbances, or other complications of end-stage renal disease results.

Pathogenesis

As progressive renal damage destroys more and more nephrons, adaptive mechanisms are initated that try to maintain renal function. Among such adaptive mechanisms, glomerular hyperfiltration tends to compensate for decreased glomerular filtration rate resulting from the loss of nephrons. An increase in the rate of excretion of solutes per nephron via increased plasma concentrations (for creatinine), decreased tubular reabsorption (for sodium, phosphate, and calcium), or increased tubular secretion (for potassium and hydrogen ions) helps to maintain homeostasis until the late stages of chronic kidney disease. The rate of functional decline varies based on the original disease; however, renal function often deteriorates progressively even when the original insult is controlled. Uncontrolled hypertension, regardless of the etiology, results in more rapid renal functional decline.

MORPHOLOGY

Classically, the kidneys are **symmetrically contracted,** and their surfaces are red-brown and **diffusely granular** when the underlying disorder affects blood vessels or glomeruli. Kidneys damaged by chronic pyelonephritis are typically unevenly involved and have deep scars. Microscopically, the feature common to all cases is advanced scarring of the glomeruli, sometimes to the point of complete sclerosis (Fig. 14.20). This **obliteration of the glomeruli** is the end point of many diseases, and it is impossible to ascertain from such kidneys the nature of the initial lesion. There also is marked **interstitial fibrosis,** associated with atrophy and dropout of many of the tubules in the cortex, and diminution and loss of portions of the peritubular capillary network. The small- and medium-sized arteries frequently are thick-walled, with narrowed lumina, secondary to hypertension. Lymphocytic (and, rarely, plasma cell) infiltrates are present in the fibrotic interstitial tissue. As damage to all structures progresses, it may become difficult to ascertain whether the primary lesion was glomerular, vascular, tubular, or interstitial. Such markedly damaged kidneys have been designated **end-stage kidneys.**

Clinical Features

Chronic kidney disease may develop insidiously and be discovered late in its course, because it is often asymptomatic. Frequently, renal disease is first detected by the discovery of proteinuria, hypertension, or azotemia on routine medical examination. Disease-specific findings may precede development of chronic kidney disease. In patients with glomerular disease resulting in nephrotic syndrome, as the glomeruli undergo sclerotic changes and result in nephron loss, the avenue for protein loss is progressively lessened, and the nephrotic syndrome thus becomes less severe with advanced disease. Some degree of proteinuria, however, is present in almost all cases. Hypertension is very common. Although microscopic hematuria is usually present, grossly bloody urine is infrequent at this late stage.

Without treatment, the prognosis is poor; relentless progression to uremia and death is the rule. The rate of progression is extremely variable.

CYSTIC DISEASES OF THE KIDNEY

Cystic diseases of the kidney are a heterogeneous group comprising hereditary, developmental, and acquired disorders. They often present diagnostic problems for clinicians, radiologists, and pathologists and can occasionally be confused with malignant tumors. Some forms, such as adult polycystic disease, constitute major causes of chronic kidney disease.

An emerging theme in the pathophysiology of the hereditary cystic diseases is that the underlying defect is in the cilia-centrosome complex of tubular epithelial cells. Such defects may interfere with fluid absorption or cellular maturation, resulting in cyst formation. A brief overview of simple cysts, the most common form, is presented next, followed by a more detailed discussion of polycystic kidney disease. Renal dysplasia, the most common form of cystic renal disease in childhood, is discussed under congenital and developmental anomalies later in the chapter.

Simple Cysts

Simple cysts are generally innocuous lesions that occur as multiple or single cystic spaces of variable size. Commonly, they are 1 to 5 cm in diameter; translucent; lined by a gray, glistening, smooth membrane; and filled with clear fluid. On microscopic examination, these membranes are seen to be composed of a single layer of cuboidal or flattened cuboidal epithelium, which in many instances may be completely atrophic. The cysts usually are confined to the cortex. Rarely, massive cysts as large as 10 cm in diameter are encountered.

Simple cysts are a common postmortem finding that has no clinical significance. The main importance of cysts lies in their differentiation from kidney tumors, when they are discovered either incidentally or during evaluation of hemorrhage and pain. Radiographic studies show that in contrast with renal tumors, renal cysts have smooth contours, are almost always avascular, and produce fluid rather than solid tissue signals on ultrasonography.

Acquired cystic kidney disease occurs in patients with end-stage renal disease who have undergone dialysis for many years. Multiple cysts may be present in both the cortex and the medulla and may bleed, causing hematuria. The risk for renal neoplasms, particularly cystic ones, in this setting is over 100 times greater than in the general population.

Autosomal Dominant (Adult) Polycystic Kidney Disease

Adult polycystic kidney disease is characterized by multiple expanding cysts affecting both kidneys that ultimately destroy the intervening parenchyma. It is seen in approximately 1 in 500 to 1000 individuals and accounts for 10% of cases of chronic kidney disease. This disease is genetically heterogeneous. It can be caused by inheritance of one of at least two autosomal dominant genes of very high penetrance.

Pathogenesis

In 85% to 90% of families, *PKD1,* on the short arm of chromosome 16, is the defective gene. This gene encodes a large (460-kDa) and complex cell membrane–associated protein called *polycystin-1.* The polycystin-1 protein has a large extracellular domain and multiple transmembrane regions. The extracellular domains have regions that can bind to extracellular matrix. Polycystin-1 localizes to the primary cilium of tubular cells (as do nephrocystins linked to medullary cystic disease, discussed later), giving rise to the concept of renal cystic diseases as a type of *ciliopathy.* Cilia are hairlike organelles that project into the lumina from the apical surface of tubular cells, where they serve as mechanosensors of fluid flow. Current evidence suggests that polycystin mutations produce defects in mechanosensing (Fig. 14.21). This, in turn, alters downstream signaling events involving calcium influx, leading to dysregulation of cell polarity, proliferation, and cell–cell and cell–matrix adhesion. The increase in intracellular calcium is thought to stimulate proliferation and secretion from the tubular epithelial cells, which together lead to the formation of cysts, which progressively enlarge over time. Mediators in cyst fluid derived from the epithelial cells can further enhance fluid secretion and induce inflammation. In addition, the calcium-induced signals alter the interaction of epithelial cells with extracellular matrix, and this too is thought to contribute to the cyst formation and interstitial fibrosis that are characteristic of progressive polycystic kidney disease. It is interesting to note that whereas germline mutations of the *PKD1* gene are present in all renal tubular cells of affected individuals, cysts develop in only some tubules. This is most likely due to loss of both alleles of *PKD1.* Thus, as with tumor suppressor genes, a second "somatic hit" is required for cyst development.

The *PKD2* gene, implicated in 10% to 15% of cases, resides on chromosome 4 and encodes *polycystin-2,* a smaller, 110-kDa protein. Polycystin-2 is thought to function as a calcium-permeable membrane channel, and is also localized to cilia. Although structurally distinct, polycystins 1 and 2 are believed to act together by forming heterodimers. Thus, mutation in either gene gives rise to essentially the same phenotype, although patients with *PKD2* mutations have a slower rate of disease progression compared to patients with *PKD1* mutations.

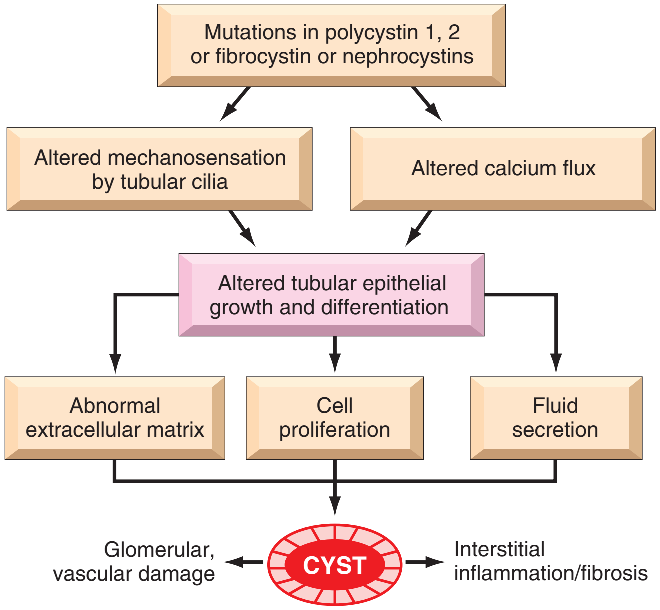

Fig. 14.21 Possible mechanisms of cyst formation in cystic kidney diseases (see text).

MORPHOLOGY

In autosomal dominant adult polycystic kidney disease, the kidney may reach enormous size; weights of up to 4 kg for each kidney have been recorded. These very large kidneys are readily palpable abdominally as masses extending into the pelvis. On gross examination, the kidney seems to be composed solely of cysts of up to 3 or 4 cm in diameter with no intervening parenchyma. The cysts are filled with fluid, which may be clear, turbid, or hemorrhagic (Fig. 14.22).

Cysts may arise at any level of the nephron, from tubules to collecting ducts, and therefore they have a variable, often atrophic, lining. Occasionally, Bowman's capsules are involved in the cyst formation, and in these cases glomerular tufts may be seen within the cystic space. The pressure of the expanding cysts leads to ischemic atrophy of the intervening renal substance. Some normal parenchyma may be dispersed among the cysts. Evidence of superimposed hypertension or infection is common. Asymptomatic liver cysts also occur in one-third of patients.

Clinical Features

Polycystic kidney disease in adults usually *does not produce symptoms until the fourth decade of life,* by which time the kidneys are quite large. The most common presenting complaint is *flank pain* or a heavy, dragging sensation. Acute distention of a cyst, either by intracystic hemorrhage or by obstruction, may cause excruciating pain. Sometimes attention is first drawn to the lesion on palpation of an abdominal mass. *Intermittent gross hematuria* commonly occurs. The most important complications, because of their deleterious effect on already marginal renal function, are *hypertension and urinary infection.* Hypertension of variable severity develops in about 75% of individuals with this

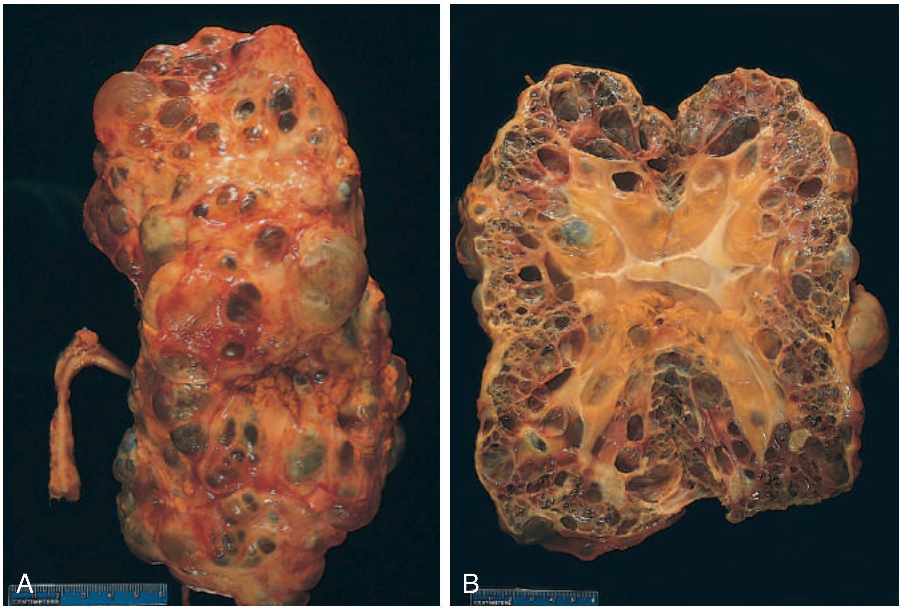

Fig. 14.22 Autosomal dominant adult polycystic kidney, viewed from the external surface (A) and bisected (B). The kidney is markedly enlarged (centimeter rule is shown for scale), with numerous dilated cysts.

disorder. Saccular aneurysms of the circle of Willis (Chapter 23) are present in 10% to 30% of patients and are associated with a high incidence of subarachnoid hemorrhage.

Although the disease is ultimately fatal, the outlook is generally more favorable than with most chronic kidney diseases. The condition progresses very slowly. End-stage renal disease occurs at about 50 years of age, but there is wide variation in the course, and nearly normal life spans are reported. Patients in whom the disease progresses to renal failure are treated by renal transplantation. Death usually results from uremia or hypertensive complications.

Autosomal Recessive (Childhood) Polycystic Kidney Disease

The childhood form of polycystic kidney disease is a rare autosomal recessive disorder that is genetically distinct from adult polycystic kidney disease. It occurs in approximately 1 in 20,000 live births. Perinatal, neonatal, infantile, and juvenile subcategories have been defined, depending on age at presentation and the presence of associated hepatic lesions. All types result from mutations in the *PKHD1* gene, coding for a putative membrane receptor protein called *fibrocystin.* Fibrocystin is found in cilia in tubular epithelial cells, but its function remains unknown.

MORPHOLOGY

In autosomal recessive polycystic kidney disease, **numerous small cysts** in the cortex and medulla give the kidney a sponge-like appearance. Dilated, elongated channels at right angles to the cortical surface completely replace the medulla and cortex. The cysts have a uniform lining of cuboidal cells, reflecting their origin from the collecting tubules. The disease is invariably bilateral. In almost all cases, findings include multiple epithelium-lined **liver cysts** and proliferation of portal bile ducts.

Clinical Features

Perinatal and neonatal forms are most common; serious manifestations usually are present at birth, and young infants may die quickly from hepatic or renal failure. Patients who survive infancy develop liver cirrhosis (congenital hepatic fibrosis).

Medullary Diseases With Cysts

There are two major types of cystic disease affecting the medulla: *medullary sponge kidney,* a relatively common and usually innocuous condition, occasionally associated with nephrolithiasis, which will not be discussed further, and *nephronophthisis-medullary cystic disease complex,* which is almost always associated with renal dysfunction.

Nephronophthisis–medullary cystic disease complex is an underappreciated cause of chronic kidney disease that usually begins in childhood. Four variants are recognized on the basis of the timing of onset: infantile, juvenile, and adolescent nephronophthisis, and medullary cystic disease developing later in adult life. The juvenile form is the most common. Approximately 15% to 20% of children with juvenile nephronophthisis have extrarenal manifestations, which most often appear as retinal abnormalities, including retinitis pigmentosa, and even early-onset blindness in the most severe form. Other abnormalities found in some individuals include oculomotor apraxia, mental retardation, cerebellar malformations, and liver fibrosis. In aggregate, the various forms of nephronophthisis are now thought to be the most common genetic cause of end-stage renal disease in children and young adults.

At least nine gene loci (NHP1 to NHP9) have been identified for the autosomal recessive forms of the nephronophthisis complex. The majority of these genes encode proteins that are components of epithelial cilia, as is the

case with other types of polycystic disease. Two autosomal forms cause disease in adults; these are far less common.

MORPHOLOGY

Pathologic features of medullary cystic disease include **small contracted kidneys.** Numerous small cysts lined by flattened or cuboidal epithelium are present, typically at the corticomedullary junction. Other pathologic changes are nonspecific, but most notably include a chronic tubulointerstitial nephritis with tubular atrophy and thickened tubular basement membranes and progressive interstitial fibrosis.

Clinical Features

The initial manifestations are usually polyuria and polydipsia, a consequence of diminished tubular function. Progression to end-stage renal disease ensues over a 5- to 10-year period. The disease is difficult to diagnose because there are no serologic markers, and the cysts may be too small to be seen with radiologic imaging. Adding to this difficulty, cysts may not be apparent on renal biopsy if the corticomedullary junction is not well sampled. A positive family history and unexplained chronic renal failure in young patients should lead to suspicion of nephronophthisis.

SUMMARY

CYSTIC DISEASES

- *Adult polycystic kidney disease* is a disease of autosomal dominant inheritance caused by mutations in the genes encoding polycystin-1 or polycystin-2. It accounts for about 10% of cases of ESRD; the kidneys may be very large and contain many cysts.
- *Autosomal recessive (childhood) polycystic kidney disease* is caused by mutations in the gene encoding fibrocystin. It is less common than the adult form and strongly associated with liver abnormalities; the kidneys contain numerous small cysts.
- *Nephronophthisis–medullary cystic disease complex* is being increasingly recognized as a cause of chronic kidney disease in children and young adults. Of autosomal recessive inheritance, it is associated with mutations in several genes that encode epithelial cell proteins called *nephrocystins* that may be involved in ciliary function; the kidneys are contracted and contain multiple small cysts.

URINARY OUTFLOW OBSTRUCTION

Renal Stones (Urolithiasis)

Urolithiasis is calculus formation at any level in the urinary collecting system, but most often calculi arise in the kidney. Symptomatic urolithiasis is more common in men than in women. The stones occur frequently; it is estimated that by 70 years of age, 11% of men and 5.6% of women in the United States will have developed a symptomatic kidney stone. A familial tendency toward stone formation has long been recognized.

Table 14.5 Prevalence of Various Types of Renal Stones

Stone	Distribution (%)
Calcium oxalate and/or calcium phosphate Idiopathic hypercalciuria (50%) Hypercalcemia and hypercalciuria (10%) Hyperoxaluria (5%) Enteric (4.5%) Primary (0.5%) Hyperuricosuria (20%) No known metabolic abnormality (15% to 20%)	80
Struvite (Mg, NH_3, PO_4) Renal infection	10
Uric acid Associated with hyperuricemia Associated with hyperuricosuria Idiopathic (50% of uric acid stones)	6–7
Cystine	1–2
Others or unknown	±1–2

Pathogenesis

There are three major types of renal stones:

- About 80% are composed of either calcium oxalate or calcium oxalate mixed with calcium phosphate.
- About 10% are composed of magnesium ammonium phosphate.
- Approximately 6% to 9% are either uric acid or cystine stones.

In all cases, an organic matrix of mucoprotein is present that makes up about 2.5% of the stone by weight.

The cause of stone formation is often obscure, particularly in the case of calcium-containing stones. Probably involved is a confluence of predisposing conditions, including the concentration of the solute, changes in urine pH, and bacterial infections. *The most important cause is increased urinary concentration of the stone's constituents,* so that it exceeds their solubility in urine (supersaturation). As shown in Table 14.5, 50% of patients who develop *calcium stones* have hypercalciuria that is not associated with hypercalcemia. Most patients in this group absorb calcium from the gut in excessive amounts (absorptive hypercalciuria) and promptly excrete it in the urine, and some have a primary renal defect of calcium reabsorption (renal hypercalciuria).

The causes of the other types of renal stones are better understood. *Magnesium ammonium phosphate (struvite) stones* almost always occur in individuals with a persistently alkaline urine resulting from UTIs. In particular, infections with urea-splitting bacteria, such as *Proteus vulgaris* and staphylococci, predispose individuals to urolithiasis. Moreover, bacteria may serve as particulate nidi for the formation of any kind of stone. In avitaminosis A, desquamated cells from the metaplastic epithelium of the collecting system act as nidi.

Gout and diseases involving rapid cell turnover, such as leukemias, lead to high uric acid levels in the urine and the possibility of *uric acid stones.* About one half of individuals with uric acid stones, however, have neither hyperuricemia nor increased urine urate but demonstrate an unexplained tendency to excrete a persistently acidic urine

(with a pH < 5.5). This low pH favors uric acid stone formation, in contrast with the high pH that favors formation of stones containing calcium phosphate. *Cystine stones* are almost invariably associated with a genetically determined defect in the renal transport of certain amino acids, including cystine. Like uric acid stones, cystine stones are more likely to form when the urine is relatively acidic.

MORPHOLOGY

Stones are unilateral in about 80% of patients. Common sites of formation are the renal pelvis and calyces and the bladder. Often, many stones are found in one kidney. They tend to be small (average diameter, 2–3 mm) and may be smooth or jagged. Occasionally, progressive accretion of salts leads to the development of branching structures known as **staghorn calculi,** which create a cast of the renal pelvis and calyceal system. These massive stones usually are composed of magnesium ammonium phosphate.

Clinical Features

Stones may be present without producing symptoms or significant renal damage. This is particularly true with large stones lodged in the renal pelvis. Smaller stones may pass into the ureter, where they may lodge and produce intense pain, known as *renal or ureteral colic,* characterized by paroxysms of flank pain radiating toward the groin. Often at this time there is *gross hematuria.* The clinical significance of stones lies in their capacity to obstruct urine flow or to produce sufficient trauma to cause ulceration and bleeding. In either case, they *predispose the sufferer to bacterial infection.* In most cases, the diagnosis is readily made radiologically.

Hydronephrosis

Hydronephrosis refers to dilation of the renal pelvis and calyces, with accompanying atrophy of the parenchyma, caused by obstruction to the outflow of urine. The obstruction may be sudden or insidious, and it may occur at any level of the urinary tract, from the urethra to the renal pelvis. The most common causes are categorized as follows:

- *Congenital,* such as atresia of the urethra, valve formations in either the ureter or urethra, an aberrant renal artery compressing the ureter, renal ptosis with torsion, or kinking of the ureter
- *Acquired*
  - *Foreign bodies,* such as calculi or sloughed necrotic papillae
  - *Proliferative lesions,* such as benign prostatic hyperplasia, carcinoma of the prostate, bladder tumors (papilloma and carcinoma), contiguous malignant disease (retroperitoneal lymphoma, and carcinoma of the cervix or uterus)
  - *Inflammatory lesions,* such as prostatitis, ureteritis, urethritis, and retroperitoneal fibrosis
  - *Neurogenic,* such as paralysis of the bladder following spinal cord damage
  - *Normal pregnancy,* in which hydronephrosis is mild and reversible

Bilateral hydronephrosis occurs only when the obstruction is below the level of the ureters. If blockage is at the ureters or above, the lesion is unilateral. Sometimes obstruction is complete, allowing no urine to pass; usually it is only partial.

Pathogenesis

Even with complete obstruction, glomerular filtration persists for some time, and the filtrate subsequently diffuses back into the renal interstitium and perirenal spaces, from where it ultimately returns to the lymphatic and venous systems. Because of the continued filtration, the affected calyces and pelvis become dilated, often markedly so. The unusually high pressure thus generated in the renal pelvis, as well as that transmitted back through the collecting ducts, causes compression of the renal vasculature. Both arterial insufficiency and venous stasis result, although the latter probably is more important. The most severe effects are seen in the papillae, because they are subjected to the greatest increases in pressure. Accordingly, the initial functional disturbances are largely tubular, manifested primarily by impaired concentrating ability. Only later does glomerular filtration begin to diminish. Experimental studies indicate that serious irreversible damage occurs in about 3 weeks with complete obstruction, and in 3 months with incomplete obstruction. In addition to functional changes, the obstruction also triggers an interstitial inflammatory reaction, leading eventually to interstitial fibrosis.

MORPHOLOGY

Bilateral hydronephrosis (or unilateral hydronephrosis when the other kidney is already damaged or absent) leads to renal failure, and the onset of uremia tends to abort the natural course of the lesion. With subtotal or intermittent obstruction, the kidney may be massively enlarged (lengths in the range of 20 cm), and the organ may consist almost entirely of the greatly distended pelvicalyceal system. The renal parenchyma itself is compressed and atrophied, with obliteration of the papillae and flattening of the pyramids (Fig. 14.23). On the other hand, when obstruction is sudden and complete, glomerular filtration is compromised relatively early, and as a consequence, renal function may cease while dilation is still comparatively slight. Depending on the level of the obstruction, one or both ureters also may be dilated **(hydroureter).**

On microscopic examination, the early lesions show tubular dilation, followed by atrophy and fibrous replacement of the tubular epithelium with relative sparing of the glomeruli. Eventually, in severe cases the glomeruli also become atrophic and disappear, converting the entire kidney into a thin shell of fibrous tissue. With sudden and complete obstruction, there may be coagulative necrosis of the renal papillae, similar to the changes of papillary necrosis. In uncomplicated cases, the accompanying inflammatory reaction is minimal. Superimposed pyelonephritis, however, is common.

Clinical Features

Bilateral complete obstruction produces anuria. When the obstruction is distal to the bladder, the dominant symptoms are those of bladder distention. Paradoxically, incomplete bilateral obstruction causes polyuria rather

Fig. 14.23 Hydronephrosis of the kidney, with marked dilation of the pelvis and calyces and thinning of renal parenchyma.

than oliguria as a result of defects in tubular concentrating mechanisms, and this may obscure the true nature of the lesion. *Unilateral* hydronephrosis may remain completely silent for long periods unless the other kidney also is dysfunctional. Often the enlarged kidney is discovered on routine physical examination. Sometimes the underlying cause of the hydronephrosis, such as renal calculi or an obstructing tumor, produces symptoms that uncover the hydronephrosis. Removal of obstruction usually permits full return of function within a few weeks; however, with time the changes become irreversible.

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Congenital and developmental abnormalities of the kidney and urinary tract represent the most common cause of end-stage renal disease in individuals younger than 21 years of age and account for 40% to 50% of pediatric renal failure worldwide. The abnormalities can affect the kidney (e.g., dysplasia, agenesis, and hypoplasia), collecting system (e.g., duplicated collecting system, hydronephrosis, and megaureter), bladder (e.g., ureterocele and vesicoureteral reflux), or urethra (e.g., posterior urethral valves). They may present as an isolated feature or as part of a syndrome in association with extrarenal manifestations. Most result from sporadic developmental defects of unknown cause. Others are caused by germline mutations in genes that impact the development of the kidney and especially the ureteric bud. The spectrum of clinical presentations is broad depending on the nature and severity of the underlying abnormalities. We restrict the discussion to a few forms affecting the kidney.

- *Multicystic dysplasia* is the most common form of renal cystic disease in childhood. The term *dysplasia* in this context refers to a developmental rather than a preneoplastic lesion. Because renal dysplasia is often associated with obstruction in the lower urinary tract, increased hydrostatic pressure in the developing kidney is thought to play a role in its development. The kidneys are usually grossly distorted; the cysts range from microscopic to several centimeters in diameter. The histologic hallmarks are ducts and tubules lined by epithelial cells and surrounded by cuffs of cellular mesenchyme.
- *Renal agenesis:* Bilateral agenesis is incompatible with life and usually is encountered in stillborn infants. It is often associated with other congenital disorders (e.g., limb defects, hypoplastic lungs). Unilateral agenesis is uncommon and compatible with normal life if no other abnormalities exist.
- *Hypoplasia* may occur bilaterally, resulting in renal failure in early childhood, but is more commonly encountered as a unilateral defect. The hypoplastic kidney shows no scars and has a reduced number of renal lobes and pyramids, usually six or fewer.

NEOPLASMS

Many types of benign and malignant neoplasms occur in the urinary tract. In general, benign neoplasms such as small cortical papillary adenomas (<0.5 cm in diameter), which are found in up to 40% of adults in autopsies, have limited clinical significance. The most common malignant neoplasm of the kidney is renal cell carcinoma, followed in frequency by nephroblastoma (Wilms tumor) and by primary neoplasms of the calyces and pelvis. Other types of renal cancer are rare and are not discussed here. Neoplasms of the lower urinary tract are about twice as common as renal cell carcinomas. They are discussed in Chapter 18.

Neoplasms of the Kidney

Oncocytoma

Oncocytoma, a benign neoplasm that arises from the intercalated cells of collecting ducts, represents about 10% of renal neoplasms. These neoplasms are associated with genetic changes—loss of chromosomes 1 and Y—that distinguish them from other renal neoplasms. Oncocytomas are characterized by a plethora of mitochondria, providing the basis for their tan color and their finely granular eosinophilic cytoplasm, seen histologically. A central stellate scar, which is another feature of oncocytomas, provides a characteristic appearance on imaging studies.

Renal Cell Carcinoma

Renal cell carcinomas are derived from the renal tubular epithelium, and hence they are located predominantly in the cortex. These neoplasms represent 80% to 85% of all primary malignant neoplasms of the kidney and 2% to 3% of all cancers in adults. These data translate into about 65,000 cases per year in the United States; 40% of patients die of the disease. Carcinomas of the kidney are most common from the sixth to seventh decades, and men are affected about twice as commonly as women. The risk for developing these neoplasms is higher in smokers,

hypertensive or obese patients, and those who have had occupational exposure to cadmium. The risk for developing renal cell cancer is increased 30-fold in individuals with acquired polycystic disease as a complication of chronic dialysis. The role of genetic factors in the causation of these cancers is discussed later.

Renal cell cancers are classified on the basis of morphology and growth patterns. However, recent advances in the understanding of the genetic basis of renal carcinomas have led to a new classification that takes into account the molecular origins of these tumors. The three most common forms, discussed next, are clear cell carcinoma, papillary renal cell carcinoma, and chromophobe renal carcinoma.

Clear Cell Carcinomas

Clear cell carcinomas are the most common type, accounting for 65% of renal cell cancers. Histologically, they are composed of cells with clear cytoplasm. Although most are sporadic, they also occur in familial forms or in association with von Hippel-Lindau (VHL) disease. It is the study of VHL disease that has provided molecular insights into the causation of clear cell carcinomas. VHL disease is inherited as an autosomal dominant trait and is characterized by predisposition to a variety of neoplasms, but particularly to hemangioblastomas of the cerebellum and retina. Hundreds of bilateral renal cysts and bilateral, often multiple, clear cell carcinomas develop in 40% to 60% of affected individuals. Those with VHL disease inherit a germline mutation of the *VHL* gene on chromosomal band 3p25 and lose the second allele by somatic mutation. The *VHL* gene also is involved in the majority of sporadic clear cell carcinomas. Cytogenetic abnormalities giving rise to loss of a segment on chromosome 3p that harbors the *VHL* gene are often seen in sporadic renal cell cancers. The second, nondeleted allele is inactivated by a somatic mutation or hypermethylation in 60% of sporadic cases. Thus, loss or inactivation of both copies of the *VHL* gene seems to be the common underlying molecular abnormality in both sporadic and familial forms of clear cell carcinomas. The VHL protein causes the degradation of hypoxia-induced factors (HIFs), and in the absence of VHL, HIFs are stabilized. HIFs are transcription factors that contribute to carcinogenesis by stimulating the expression of vascular endothelial growth factor (VEGF), an important angiogenic factor, as well as a number of other genes that drive tumor cell growth (Chapter 6). An uncommon familial form of clear cell carcinoma unrelated to VHL disease also is associated with cytogenetic abnormalities involving the short arm of chromosome 3 (3p). In addition, recent deep sequencing of clear cell carcinoma genomes has revealed frequent loss-of-function mutations in genes that encode proteins that regulate histone methylation, suggesting that changes in the "epigenome" have a central role in the genesis of this subtype of renal carcinoma.

Papillary Renal Cell Carcinomas

Papillary renal cell carcinomas account for 10% to 15% of all renal cancers and are defined in part by their papillary growth pattern. These neoplasms are frequently multifocal and bilateral and appear as early-stage tumors. Like clear cell carcinomas, they occur in familial and sporadic forms, but unlike these neoplasms, papillary renal cancers are not associated with abnormalities of chromosome 3. The culprit in most cases of hereditary papillary renal cell cancers is the *MET* proto-oncogene, located on chromosome 7q. The *MET* gene encodes a tyrosine kinase receptor for hepatocyte growth factor. The increased dosage of the *MET* gene due to duplications of chromosome 7 seems to spur abnormal growth in the proximal tubular epithelial cell precursors of papillary carcinomas. In familial cases, genetic analysis shows activating mutations of *MET* in the germ line, along with increased gene dosage in the cancers. Activating mutations of the *MET* gene also are found in a subset of patients with sporadic forms of papillary renal cell carcinoma.

Chromophobe Renal Carcinomas

Chromophobe renal carcinomas are the least common form, representing 5% of all renal cell carcinomas. They arise from intercalated cells of collecting ducts. Their name derives from the observation that the tumor cells stain more darkly (i.e., they are less clear) than cells in clear cell carcinomas. These neoplasms are unique in having multiple losses of entire chromosomes leading to extreme hypoploidy. Because of multiple losses, the "critical hit" has not been determined. In general, chromophobe renal cancers have a favorable prognosis.

MORPHOLOGY

Clear cell cancers (the most common form of renal carcinomas) usually are solitary and large when symptomatic (spherical masses 3 to 15 cm in diameter), but high-resolution radiographic techniques for investigation of unrelated problems sometimes detect smaller lesions incidentally. They may arise anywhere in the cortex. The cut surface of clear cell renal cell carcinomas is **yellow to orange to gray-white, with prominent areas of cystic softening or of hemorrhage,** either fresh or old (Fig. 14.24). The margins of the tumor are well defined. However, at times small processes project into the surrounding parenchyma and small satellite nodules are found, providing clear evidence of the aggressiveness of these lesions. As the tumor enlarges, it may fungate through the walls of the collecting system, extending through the calyces and pelvis as far as the ureter. Even more frequently, the **tumor invades the renal vein** and grows as a solid column within this vessel, sometimes extending in serpentine fashion as far as the inferior vena cava and even into the right side of the heart. Occasionally, direct invasion into the perinephric fat and adrenal gland may be seen.

Depending on the amounts of lipid and glycogen present, **the neoplastic cells of clear cell renal cell carcinoma may appear almost vacuolated or may be solid.** The classic vacuolated (lipid-laden) cells or clear cells are demarcated only by their cell membranes. The nuclei are usually small and round (Fig. 14.25). At the other extreme are granular cells, resembling the tubular epithelium, which have small, round, regular nuclei enclosed within granular pink cytoplasm. Some neoplasms are highly anaplastic, with numerous mitotic figures and markedly enlarged, hyperchromatic, pleomorphic nuclei. Between the extremes of clear cells and solid, granular cells, all intergradations may be found. The cellular arrangement, too, varies widely. The

Fig. 14.24 Renal cell carcinoma: Representative cross-section showing yellowish, spherical neoplasm in one pole of the kidney. Note the tumor in the dilated, thrombosed renal vein.

cells may form abortive tubules or may cluster in cords or disorganized masses. The stroma is usually scant but highly vascularized.

Papillary renal cell carcinomas exhibit various degrees of papilla formation with fibrovascular cores. They tend to be bilateral and multiple. They also may show gross evidence of necrosis, hemorrhage, and cystic degeneration, but they are less vibrantly orange-yellow because of their lower lipid content. The cells may have a clear or, more commonly, pink cytoplasm. **Chromophobe-type renal cell carcinoma** tends to be grossly tan-brown. The cells usually have clear, flocculent cytoplasm with very prominent, distinct cell membranes. The nuclei are surrounded by halos of clear cytoplasm. Ultrastructurally, large numbers of characteristic macrovesicles are seen.

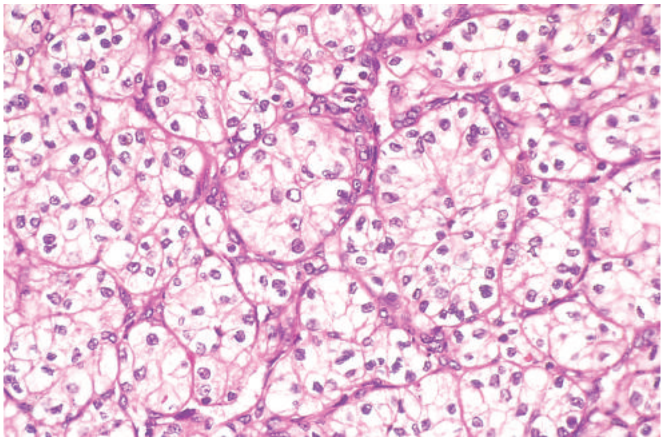

Fig. 14.25 The clear cell pattern of renal cell carcinoma.

Clinical Features

Renal cell carcinomas have several peculiar clinical characteristics that create especially difficult and challenging diagnostic problems. The signs and symptoms vary, but the *most frequent presenting manifestation is hematuria, occurring in more than 50% of cases.* Macroscopic hematuria tends to be intermittent and fleeting, superimposed on a steady microscopic hematuria. Less commonly, the tumor may declare itself simply by virtue of its size, when it has grown large enough to produce flank pain and a *palpable mass*. Because of the widespread use of imaging studies for unrelated conditions, even smaller tumors are detected. Extrarenal effects are *fever* and *polycythemia,* which, because they are nonspecific, may be misinterpreted for some time before their association with the renal tumor is appreciated. Polycythemia affects 5% to 10% of affected individuals and results from production of erythropoietin by the cancer cells. Uncommonly, these tumors produce other hormone-like substances, resulting in hypercalcemia, hypertension, Cushing syndrome, or feminization or masculinization. These, as noted in Chapter 6, are *paraneoplastic syndromes*. In some patients, the primary tumor remains silent and is discovered only after metastases produce symptoms. The common locations for metastases are the lungs and the bones. It must be apparent that renal cell carcinoma manifests in many ways, some quite devious, *but the triad of painless hematuria, a palpable abdominal mass, and dull flank pain is characteristic.*

SUMMARY
RENAL CELL CARCINOMA

Renal cell carcinomas account for 2% to 3% of all cancers in adults and are classified into three main types:

- *Clear cell carcinomas* are the most common and are associated with homozygous loss or inactivation of the VHL tumor suppressor protein; tumors frequently invade the renal vein.
- *Papillary renal cell carcinomas* frequently are associated with increased expression and activating mutations of the *MET* oncogene; they tend to be bilateral and multiple and show variable papilla formation.
- *Chromophobe renal cell carcinomas* are less common; neoplastic cells are not as clear as in the other renal cell carcinomas.

Wilms Tumor

Although Wilms tumor is rare in adults, it is the third most common solid (non-hematologic) cancer in children younger than 10 years of age. These neoplasms contain a variety of cell and tissue components, all derived from mesoderm. Wilms tumor, like retinoblastoma, may arise sporadically or be familial, with the susceptibility to tumorigenesis inherited as an autosomal dominant trait. This neoplasm is discussed in greater detail in Chapter 7 along with other tumors of childhood.

CHAPTER

15 Oral Cavities and Gastrointestinal Tract

CHAPTER OUTLINE

The gastrointestinal tract is a hollow tube consisting of the esophagus, stomach, small intestine, colon, rectum, and anus. Each region has unique, complementary, and highly integrated functions that together serve to regulate the intake, processing, and absorption of ingested nutrients and the disposal of waste products. The intestines also are the principal site at which the immune system interfaces with a diverse array of antigens present in food and gut microbes. Thus, it is not surprising that the small intestine and colon frequently are involved by infectious and inflammatory processes. Finally, the colon is the most common site of gastrointestinal neoplasia in Western populations. In this chapter, we discuss the diseases that affect each section of the gastrointestinal tract. Disorders that typically involve more than one segment, such as Crohn disease, are considered with the most frequently involved region. We begin our discussion with diseases of the oral cavity, since that is where the journey of food begins.

Oral Cavity

Pathologic conditions of the oral cavity can be broadly divided into diseases affecting teeth their support structures, oral mucosa, salivary glands, and jaws. Discussed next are the more common conditions affecting these sites. Odontogenic cysts and tumors (benign and malignant), which are derived from the epithelial and/or mesenchymal tissues associated with tooth development, are also discussed briefly.

DISEASES OF TEETH AND SUPPORTING STRUCTURES

Caries

Dental caries results from focal demineralization of tooth structure (enamel and dentin) caused by acids generated during the fermentation of sugars by bacteria. Worldwide, caries is the main cause of tooth loss before 35 years of age. The prevalence of caries used to be very high in developed countries where there is ready access to processed and refined foods containing large amounts of carbohydrates. However, the rate of caries has dropped markedly in countries such as the United States, where oral hygiene has improved and fluoridation of the drinking water is widespread. Fluoride is incorporated into the crystalline structure of enamel, forming fluoroapatite, which is resistant to degradation by bacterial acids. In contrast, with the globalization of the world's economy, processed foods are being increasingly consumed in developing nations; as a result, the rate of caries is increasing in these regions of the world.

Gingivitis

Inflammation involving the squamous mucosa, or gingiva, and associated soft tissues that surround teeth is defined as *gingivitis.* Poor oral hygiene, which facilitates buildup of dental plaque and calculus between and on the surfaces of teeth, is the most frequent cause of gingivitis. Dental plaque is a sticky biofilm composed of bacteria, salivary proteins, and desquamated epithelial cells. As it accumulates, plaque becomes mineralized to form calculus, or tartar. In chronic gingivitis, this is accompanied by gingival erythema, edema, and bleeding. Gingivitis may occur at any age but is most prevalent and severe in adolescence, where it is present in 40% to 60% of individuals, after which the incidence tapers off. Fortunately, gingivitis can be reversed, primarily by regular brushing and flossing of teeth which reduces accumulation of plaque and calculus.

Periodontitis

Periodontitis is an inflammatory process that affects the supporting structures of the teeth (periodontal ligaments), alveolar bone, and cementum. With progression, periodontitis may result in destruction of periodontal ligament and alveolar bone and eventual tooth loss. Periodontitis is associated with poor oral hygiene that affects the composition of gingival bacteria. Facultative Gram-positive organisms are found at healthy sites, while anaerobic and microaerophilic Gram-negative bacteria colonize plaque within areas of active periodontitis. Although about 300 bacterial species reside within the oral cavity, periodontitis is most closely associated with *Aggregatibacter (Actinobacillus) actinomycetemcomitans, Porphyromonas gingivalis,* and *Prevotella intermedia.*

SUMMARY

DISEASES OF TEETH AND SUPPORTING STRUCTURES

- Caries is the most common cause of tooth loss in individuals younger than 35 years of age. The primary cause is destruction of tooth structure by acid end products of sugar fermentation by bacteria.
- Gingivitis is a common and reversible inflammation of the mucosa surrounding the teeth. It is associated with buildup of dental plaque and calculus.
- Periodontitis is a chronic inflammatory condition that can lead to the destruction of the supporting structures of the teeth with eventual loss of dentition. It is associated with poor oral hygiene and altered oral microbiota.

ORAL INFLAMMATORY LESIONS

Aphthous Ulcers (Canker Sores)

These common superficial mucosal ulcerations affect up to 40% of the population. They are more frequent in the first 2 decades of life, extremely painful, and often recur. Although the cause of aphthous ulcers is unknown, they tend to be familal and may be associated with celiac disease, inflammatory bowel disease, and Behçet disease. Ulcers can be solitary or multiple; typically, they are shallow, with a hyperemic base covered by a thin exudate and rimmed by a narrow zone of erythema (Fig. 15.1). In most cases they resolve spontaneously in 7 to 10 days but can recur.

Herpes Simplex Virus Infections

Herpes simplex virus causes a self-limited primary infection that can be reactivated when there is a compromise in host resistance. Most orofacial herpetic infections are caused by herpes simplex virus type 1 (HSV-1), with the remainder being caused by HSV-2 (genital herpes). With changing sexual practices, oral HSV-2 is becoming increasingly common. Primary infections typically occur in children between 2 and 4 years of age and are often asymptomatic. However, in 10% to 20% of cases the primary infection manifests as acute herpetic gingivostomatitis, with abrupt onset of vesicles and ulcerations throughout the oral cavity. Most adults harbor latent HSV-1, and the virus can be reactivated, resulting in a

Fig. 15.1 Aphthous ulcer. Single ulceration with an erythematous halo surrounding a yellowish fibrinopurulent membrane.

so-called "cold sore" or recurrent herpetic stomatitis. Factors associated with HSV reactivation include trauma, allergies, exposure to ultraviolet light and extremes of temperature, upper-respiratory tract infections, pregnancy, menstruation, and immunosuppression. Recurrent lesions, which occur at the site of primary inoculation or in adjacent mucosa innervated by the same ganglion, typically appear as groups of small (1- to 3-mm) vesicles. The lips (herpes labialis), nasal orifices, buccal mucosa, gingiva, and hard palate are the most common locations. Although lesions typically resolve within 7 to 10 days, they can persist in immunocompromised patients, who may require systemic anti-viral therapy. Morphologically, the lesions resemble those seen in esophageal herpes (see Fig. 15.8 later in the chapter) and genital herpes (Chapter 19). The infected cells become ballooned and have large eosinophilic intranuclear inclusions. Adjacent cells commonly fuse to form large multinucleated polykaryons.

Oral Candidiasis (Thrush)

Candidiasis is the most common fungal infection of the oral cavity. *Candida albicans* is a normal component of the oral flora and only produces disease under unusual circumstances. Predisposing factors include the following:

- Immunosuppression
- The specific strain of *C. albicans*
- The composition of the oral microbial flora (microbiota)

Broad-spectrum antibiotics that alter the normal microbiota can promote oral candidiasis. The three major clinical forms of oral candidiasis are pseudomembranous, erythematous, and hyperplastic. The pseudomembranous form is most common and is known as *thrush.* This condition is characterized by a superficial, curdlike, gray to white inflammatory membrane composed of matted organisms enmeshed in a fibrinosuppurative exudate that can be readily scraped off to reveal an underlying erythematous base. In mildly immunosuppressed or debilitated individuals, such as diabetics, the infection usually remains superficial, but it may spread to deep sites in association with more severe immunosuppression, that may be seen in organ or hematopoietic stem cell transplant recipients, and in patients with neutropenia, chemotherapy-induced immunosuppression, or AIDS.

SUMMARY

ORAL INFLAMMATORY LESIONS

- Aphthous ulcers are painful superficial ulcers of unknown etiology that may in some cases be associated with systemic diseases.
- Herpes simplex virus causes a self-limited infection that presents with vesicles (cold sores, fever blisters) that rupture and heal, without scarring, and often leave latent virus in nerve ganglia. Reactivation can occur.
- Oral candidiasis may occur when the oral microbiota is altered (e.g., after antibiotic use). Invasive disease may occur in immunosuppressed individuals.

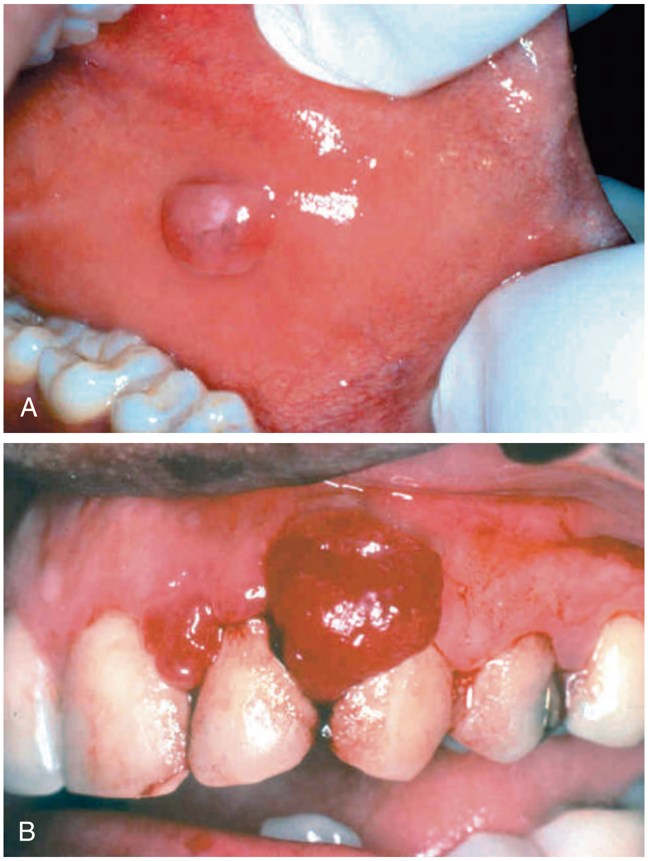

Fig. 15.2 Fibrous proliferations. (A) Fibroma. Smooth pink exophytic nodule on the buccal mucosa. (B) Pyogenic granuloma. Erythematous hemorrhagic exophytic mass arising from the gingival mucosa.

PROLIFERATIVE AND NEOPLASTIC LESIONS OF THE ORAL CAVITY

Fibrous Proliferative Lesions

Fibromas are submucosal nodular fibrous tissue masses that are formed when chronic irritation results in reactive connective tissue hyperplasia (Fig. 15.2A). They occur most often on the buccal mucosa along the bite line. Treatment is complete surgical excision and removal of the source of irritation.

Pyogenic granuloma (Fig. 15.2B) is an inflammatory lesion typically found on the gingiva of children, young adults, and pregnant women (pregnancy tumor). These lesions are richly vascular and typically ulcerated, which gives them a red to purple color. In some cases, growth can be rapid and raise fear of a malignant neoplasm. However, histologic examination demonstrates a proliferation of immature vessels similar to that seen in granulation tissue. Pyogenic granulomas may regress, mature into dense fibrous masses, or develop into a peripheral ossifying fibroma. Complete surgical excision is definitive treatment.

Leukoplakia and Erythroplakia

Leukoplakia is defined by the World Health Organization as "a white patch or plaque that cannot be scraped

off and cannot be characterized clinically or pathologically as any other disease." This description is reserved for lesions that arise in the oral cavity in the absence of any known cause (Fig. 15.3A). Accordingly, white patches caused by obvious irritation or entities such as lichen planus and candidiasis are not considered leukoplakia. Approximately 3% of the world's population has leukoplakic lesions, of which 5% to 25% are dysplastic and at risk for progression to squamous cell carcinoma. Thus, until proved otherwise by means of histologic evaluation, all leukoplakias must be considered precancerous. A related but less common entity, *erythroplakia,* is a red, velvety, sometimes eroded lesion that is flat or slightly depressed relative to the surrounding mucosa. Erythroplakia is associated with a much greater risk for malignant transformation than leukoplakia. While leukoplakia and erythroplakia may be seen in adults at any age, they typically affect individuals between 40 and 70 years of age, with a 2:1 male predominance. Although the etiology is multifactorial, tobacco use (cigarettes, pipes, cigars, and chewing tobacco) is the most common risk factor for leukoplakia and erythroplakia.

MORPHOLOGY

On histologic examination leukoplakia and erythroplakia show a spectrum of epithelial changes ranging from hyperkeratosis overlying a thickened, acanthotic but orderly mucosal epithelium to lesions with markedly dysplastic changes sometimes merging into carcinoma in situ (Fig. 15.3B). The most severe dysplastic changes are associated with erythroplakia, and more than 50% of these cases undergo malignant transformation. With increasing dysplasia and anaplasia, a subjacent inflammatory cell infiltrate of lymphocytes and macrophages is often present.

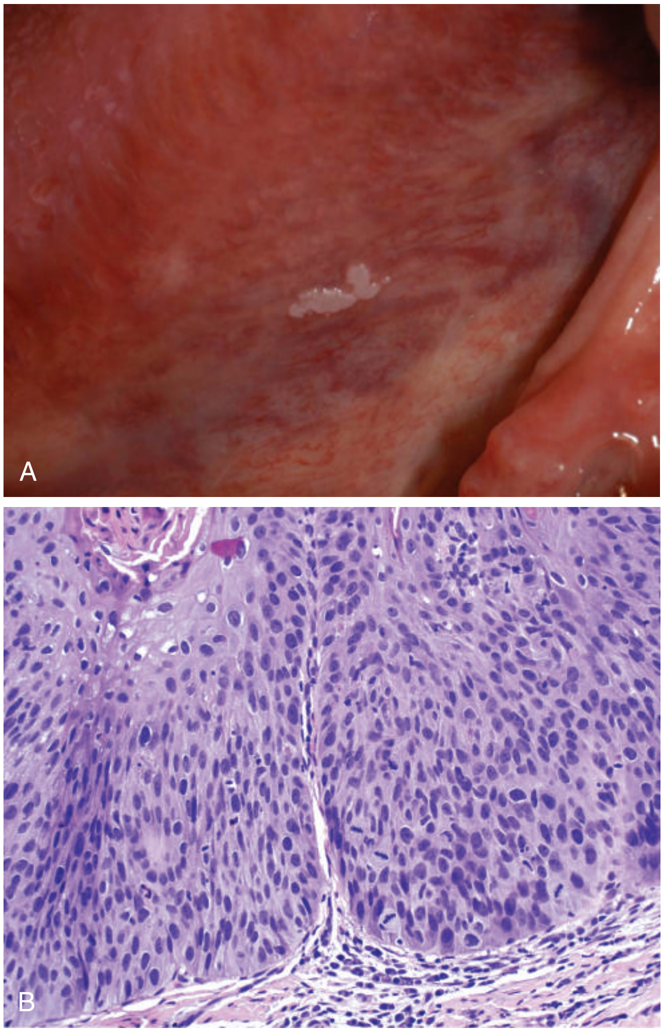

Fig. 15.3 Leukoplakia. (A) Gross appearance of leukoplakia is highly variable. In this example, the lesion is smooth with well-demarcated borders and minimal elevation. (B) Histologic appearance of leukoplakia showing dysplasia, characterized by nuclear and cellular pleomorphism and loss of normal maturation.

Squamous Cell Carcinoma

Approximately 95% of cancers of the oral cavity are squamous cell carcinomas, with the remainder largely consisting of adenocarcinomas of salivary glands. Squamous cell carcinoma, an aggressive epithelial malignancy, is the sixth most common neoplasm in the world today. Despite numerous advances in treatment, the overall long-term survival rate has remained less than 50% for the past 50 years. This dismal outlook is due to several factors, in large part because oral cancer often is diagnosed at an advanced stage.

Multiple primary tumors may be present at initial diagnosis but more often are detected later, at an estimated rate of 3% to 7% per year; patients who survive 5 years after diagnosis of the initial tumor have up to a 35% chance of developing at least one new primary tumor within that interval. The development of these secondary tumors can be particularly devastating for individuals whose initial lesions were small. Therefore, surveillance and early detection of new premalignant lesions are critical for the long-term survival of patients with oral squamous cell carcinoma.

The elevated risk for development of additional primary tumors in these patients has led to the concept of "field cancerization." This hypothesis suggests that multiple primary tumors develop independently as a result of years of chronic mucosal exposure to carcinogens such as alcohol or tobacco (described next).

Pathogenesis

Squamous cancers of the oropharynx arise through two distinct pathogenic pathways, one involving exposure to carcinogens, and the other related to infection with high risk variants of human papilloma virus (HPV). Carcinogen exposure mainly stems from chronic alcohol and tobacco (both smoked and chewed) use. In India and Southeast Asia, chewing of betel quid and paan are important predisposing factors. Betel quid is a "witch's brew" containing araca nut, slaked lime, and tobacco, all wrapped in betel nut leaf. It is likely that these tumors arise by a pathway similar to that characterized for tobacco use–associated tumors in the West. Deep sequencing of these cancers has revealed frequent mutations that bear a molecular signature consistent with exposure to carcinogens in tobacco. These mutations frequently involve *TP53* and

genes that regulate cell proliferation, such as *RAS*. The HPV-related tumors tend to occur in the tonsillar crypts or the base of the tongue and harbor oncogenic "high-risk" subtypes, particularly HPV-16. These tumors carry far fewer mutations than those associated with tobacco exposure and often overexpress p16, a cyclin-dependent kinase inhibitor.

It is conservatively predicted that the incidence of HPV-associated oropharyngeal squamous cell carcinoma will surpass that of cervical cancer by 2020, in part because the anatomic sites of origin—tonsillar crypts, base of tongue, and oropharynx—are not readily accessible or amenable to cytologic screening (unlike the cervix). The prognosis for patients with HPV-positive tumors is better than for those with HPV-negative tumors. The HPV vaccine, which is protective against cervical cancer, offers hope to limit the increasing frequency of HPV-associated oropharyngeal squamous cell carcinoma.

The incidence of oral cavity squamous cell carcinoma (particularly in the tongue) has been on the rise in individuals younger than 40 years of age who have no known risk factors. The pathogenesis in this group of patients, who are nonsmokers and are not infected with HPV, is unknown

MORPHOLOGY

Squamous cell carcinoma may arise anywhere in the oral cavity. However, the most common locations are the ventral surface of the tongue, floor of the mouth, lower lip, soft palate, and gingiva (Fig. 15.4A). In early stages, these cancers may appear as raised, firm, pearly plaques or as irregular, roughened, or verrucous mucosal thickenings. Either pattern may be superimposed on a background of leukoplakia or erythroplakia. As these lesions enlarge, they typically form ulcerated and protruding masses that have irregular and indurated or rolled borders. Histopathologic analysis has shown that squamous cell carcinoma develops from dysplastic precursor lesions. Histologic patterns range from well-differentiated keratinizing neoplasms (Fig. 15.4B) to anaplastic, sometimes sarcomatoid tumors. However, the degree of histologic differentiation, as determined by the relative degree of keratinization, does not necessarily correlate with biologic behavior. Typically, oral squamous cell carcinoma infiltrates locally before it metastasizes. The cervical lymph nodes are the most common sites of regional metastasis; frequent sites of distant metastases include the mediastinal lymph nodes, lungs, and liver.

SUMMARY

LESIONS OF THE ORAL CAVITY

- Fibromas and pyogenic granulomas are common reactive lesions of the oral mucosa.
- Leukoplakia and eryhtroplakia are mucosal plaques that may undergo malignant transformation.
- The risk for malignant transformation is greater in erythroplakia (relative to leukoplakia).
- A majority of oral cavity cancers are squamous cell carcinomas.
- Oral squamous cell carcinomas are classically linked to tobacco and alcohol use, but the incidence of HPV-associated lesions is rising.

Fig. 15.4 Oral squamous cell carcinoma. (A) Gross appearance demonstrating ulceration and induration of the oral mucosa. (B) Histologic appearance demonstrating numerous nests and islands of malignant keratinocytes invading the underlying connective tissue stroma.

DISEASES OF SALIVARY GLANDS

There are three major salivary glands—parotid, submandibular, and sublingual—as well as innumerable minor salivary glands distributed throughout the oral mucosa. Inflammatory or neoplastic disease may develop within any of these.

Xerostomia

Xerostomia is defined as a dry mouth resulting from a decrease in the production of saliva. Its incidence varies among populations but has been reported in more than 20% of individuals older than 70 years of age. It is a major feature of the autoimmune disorder Sjögren syndrome, in which it usually is accompanied by dry eyes (Chapter 5). A lack of salivary secretions is also a major complication of radiation therapy. However, xerostomia is most frequently observed as a side effect of many common classes of medications including anti-cholinergic, anti-depressant/anti-psychotic, diuretic, anti-hypertensive, sedative, muscle relaxant, analgesic, and anti-histaminic agents. The oral

cavity may reveal only dry mucosa and/or atrophy of the papillae of the tongue, with fissuring and ulcerations, or, in Sjögren syndrome, concomitant inflammatory enlargement of the salivary glands. Complications of xerostomia include increased rates of dental caries and candidiasis, as well as difficulty in swallowing and speaking.

Sialadenitis

Inflammation of the salivary glands, referred to as *sialadenitis*, may be induced by trauma, viral or bacterial infection, or autoimmune disease. The most common form of viral sialadenitis is *mumps,* which may produce enlargement of all salivary glands but predominantly involves the parotids. Mumps produces interstitial inflammation marked by a mononuclear inflammatory infiltrate. While mumps in children is most often a self-limited benign condition, in adults it can cause pancreatitis or orchitis; the latter sometimes causes sterility.

The *mucocele* is the most common inflammatory lesion of the salivay glands and results from either blockage or rupture of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma. Mucocele occurs most often in toddlers, young adults, and older adults, and typically manifests as a fluctuant swelling of the lower lip that may change in size, particularly in association with meals (Fig. 15.5A). Histologic examination demonstrates a cystlike space lined by granulation tissue or fibrous connective tissue that is filled with mucin and inflammatory cells, particularly macrophages (Fig. 15.5B). Complete excision of the cyst and the minor salivary gland constitutes definitive treatment.

Bacterial sialadenitis is a common infection that most often involves the major salivary glands, particularly the submandibular glands. The most frequent pathogens are *Staphylococcus aureus* and *Streptococcus viridans.* Duct obstruction by stones (sialolithiasis) is a common antecedent to infection; it may also be induced by impacted food debris or by edema consequent to injury. Dehydration and decreased secretory function can also predispose to bacterial invasion. Systemic dehydration, with decreased salivary secretions, may predispose to suppurative bacterial parotitis in older adult patients following major thoracic or abdominal surgery. Such obstruction and bacterial invasion lead to nonspecific inflammation of the affected glands that may be largely interstitial or, when induced by staphylococci or other pyogens, may be associated with suppurative necrosis and abscess formation.

Autoimmune sialadenitis, better known as Sjögren syndrome, is discussed in Chapter 5.

Neoplasms

Despite their relatively simple morphology, the salivary glands give rise to at least 30 histologically distinct tumors (Table 15.1). A small number of these neoplasms account for more than 90% of tumors. Overall, salivary gland tumors are relatively uncommon and represent less than 2% of all human tumors. Approximately 65% to 80% arise within the parotid, 10% in the submandibular gland, and the remainder in the minor salivary glands, including the sublingual glands. Approximately 15% to 30% of tumors

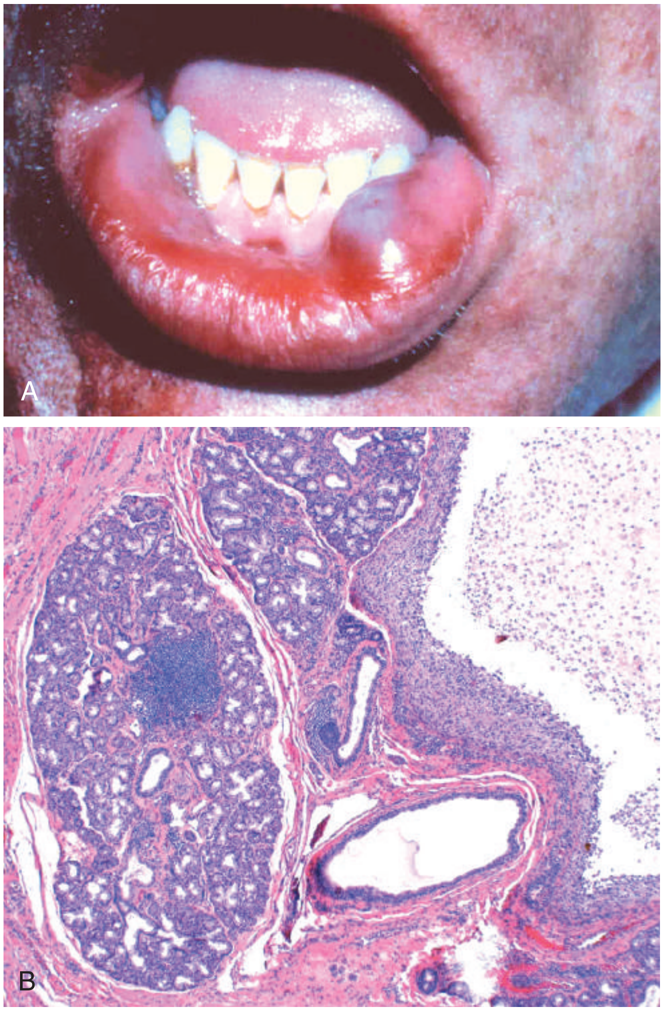

Fig. 15.5 Mucocele. (A) Fluctuant fluid-filled lesion on the lower lip subsequent to trauma. (B) Cystlike cavity *(right)* filled with mucinous material and lined by organizing granulation tissue. The normal gland acini are seen on the left.

in the parotid glands are malignant. By contrast, approximately 40% of submandibular, 50% of minor salivary gland, and 70% to 90% of sublingual tumors are cancerous. Thus, the likelihood that a salivary gland tumor is malignant is inversely proportional, roughly, to the size of the gland.

Salivary gland tumors usually occur in adults, with a slight female predominance, but about 5% occur in

Table 15.1 Histopathologic Classification and Prevalence of the Most Common Benign and Malignant Salivary Gland Tumors

Benign	Malignant
Pleomorphic adenoma (50%)	Mucoepidermoid carcinoma (15%)
Warthin tumor (5%)	Acinic cell carcinoma (6%)
Oncocytoma (2%)	Adenocarcinoma NOS (6%)
Cystadenoma (2%)	Adenoid cystic carcinoma (4%)
Basal cell adenoma (2%)	Malignant mixed tumor (3%)

NOS, Not otherwise specified.
Data from Ellis GL, Auclair PL, Gnepp DR: *Surgical pathology of the salivary glands, Vol 25: Major problems in pathology.* Philadelphia, 1991, Saunders.

children younger than 16 years of age. Whatever the histologic pattern, parotid gland neoplasms produce swelling in front of and below the ear. Benign tumors may be present for months to several years before coming to clinical attention, while cancers more often come to attention promptly, probably because of their more rapid growth. However, there are no reliable criteria to differentiate benign from malignant lesions on clinical grounds, and histopathologic evaluation is essential.

Pleomorphic Adenoma

Pleomorphic adenomas are benign tumors that consist of a mixture of ductal (epithelial) and myoepithelial cells, so they exhibit both epithelial and mesenchymal differentiation. Epithelial elements are dispersed throughout the matrix, which may contain variable mixtures of myxoid, hyaline, chondroid (cartilaginous), and even osseous tissue. In some pleomorphic adenomas, the epithelial elements predominate; in others, they are present only in widely dispersed foci. This histologic diversity has given rise to the alternative, albeit less preferred, name *mixed tumor.*

Pleomorphic adenomas represent about 60% of tumors in the parotid, are less common in the submandibular glands, and are relatively rare in the minor salivary glands. They present as slow-growing, painless, mobile discrete masses. They recur if incompletely excised. Recurrence rates approach 25% after simple enucleation of the tumor, but are only 4% after wider resection. In both settings, recurrence stems from a failure to recognize minute extensions of tumor into surrounding soft tissues.

Carcinoma arising in a pleomorphic adenoma is referred to variously as a *carcinoma ex pleomorphic adenoma* or *malignant mixed tumor.* The incidence of malignant transformation increases with time from 2% of tumors present for less than 5 years to almost 10% for those present for more than 15 years. The cancer usually takes the form of an adenocarcinoma or undifferentiated carcinoma. Unfortunately, these are among the most aggressive malignant neoplasms of salivary glands, with mortality rates of 30% to 50% at 5 years.

MORPHOLOGY

Pleomorphic adenomas typically manifest as rounded, well-demarcated masses rarely exceeding 6 cm in the greatest dimension. Although they are encapsulated, in some locations (particularly the palate), the capsule is not fully developed, and expansile growth produces protrusions into the surrounding tissues. The cut surface is gray-white and typically contains myxoid and blue translucent chondroid (cartilage-like) areas. The most striking histologic feature is their characteristic heterogeneity. Epithelial elements resembling ductal or myoepithelial cells are arranged in ducts, acini, irregular tubules, strands, or even sheets. These typically are dispersed within a mesenchyme-like background of loose myxoid tissue containing islands of chondroid and, rarely, foci of bone (Fig. 15.6). Sometimes the epithelial cells form well-developed ducts lined by cuboidal to columnar cells with an underlying layer of deeply chromatic, small myoepithelial cells. In other instances there may be strands or sheets of myoepithelial cells. Islands of well-differentiated squamous epithelium also may be present. In most cases, no epithelial dysplasia or mitotic activity is evident. No difference in biologic behavior has been observed between the tumors composed largely of epithelial elements and those composed largely of mesenchymal elements.

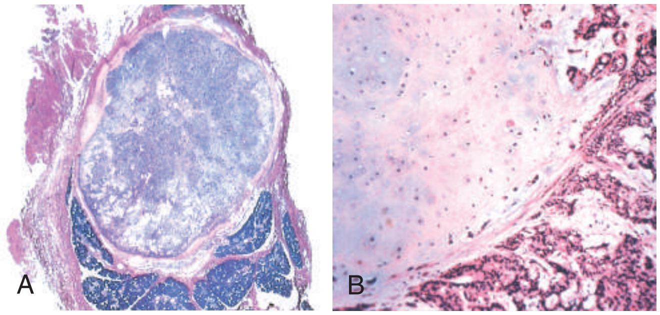

Fig. 15.6 Pleomorphic adenoma. (A) Low-power view showing a well-demarcated tumor with adjacent, deeply staining, normal salivary gland parenchyma. (B) High-power view showing epithelial cells as well as myoepithelial cells within chondroid matrix material.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas are composed of variable mixtures of squamous cells, mucus-secreting cells, and intermediate cells. These neoplasms represent about 15% of all salivary gland tumors, and while they occur mainly (60%–70%) in the parotids, they account for a large fraction of salivary gland neoplasms in the other glands, particularly the minor salivary glands. Overall, mucoepidermoid carcinoma is the most common form of primary malignant tumor of the salivary glands.

MORPHOLOGY

Mucoepidermoid carcinomas can grow as large as 8 cm in diameter and, although they are apparently circumscribed, they lack well-defined capsules and often are infiltrative. The cut surface is pale gray to white and frequently demonstrates small, mucinous cysts. On histologic examination, these tumors contain cords, sheets, or cysts lined by squamous, mucous, or intermediate cells. The latter is a hybrid cell type with both squamous features and mucus-filled vacuoles, which are most easily detected with mucin stains. Cytologically, tumor cells may be benign-appearing or highly anaplastic and unmistakably malignant.

Clinical course and prognosis depend on histologic grade. Low-grade tumors may invade locally and recur in about 15% of cases but metastasize only rarely and afford a 5-year survival rate of over 90%. By contrast, high-grade neoplasms and, to a lesser extent, intermediate-grade tumors are invasive and difficult to excise. As a result, they recur in 25% to 30% of cases, and about 30% metastasize to distant sites. The 5-year survival rate is only 50%.

SUMMARY

DISEASES OF SALIVARY GLANDS

- Sialadenitis (inflammation of the salivary glands) can be caused by trauma, infection (such as mumps), or an autoimmune reaction.

- Pleomorphic adenoma is a slow-growing neoplasm composed of a heterogeneous mixture of epithelial and mesenchymal cells. It is typically benign.
- Mucoepidermoid carcinoma is a malignant neoplasm of variable biologic aggressiveness that is composed of a mixture of squamous and mucous cells.

ODONTOGENIC CYSTS AND TUMORS

Odontogenic cysts usually are derived from remnants of odontogenic epithelium present within the jaws. In contrast to the rest of the skeleton, epithelium-lined cysts are quite common in the jaws. These cysts are subclassified as either inflammatory or developmental. Only the most common lesions are considered here, starting with developmental cysts.

The *dentigerous cyst* originates around the crown of an unerupted tooth and is thought to be the result of degeneration of the dental follicle (primordial tissue that makes the enamel surface of teeth). They are lined by a thin, stratified squamous epithelium that typically is associated with a dense chronic inflammatory infiltrate in the underlying connective tissue. Complete removal is curative.

Odontogenic keratocysts can occur at any age but are most frequent in individuals between 10 and 40 years of age, have a male predominance, and typically are located within the posterior mandible. Differentiation of the odontogenic keratocyst from other odontogenic cysts is important because it is locally aggressive and has a high recurrence rate. On histologic examination, the cyst lining consists of a thin layer of parakeratinized or orthokeratinized stratified squamous epithelium with a prominent basal cell layer and a corrugated luminal epithelial surface. Treatment requires aggressive and complete removal; recurrence rates of up to 60% are associated with inadequate resection.

In contrast with the developmental cysts just described, the *periapical cyst* has an inflammatory etiology. These extremely common lesions occur at the tooth apex as a result of long-standing pulpitis, which may be caused by advanced caries or trauma. Necrosis of the pulpal tissue, which can traverse the length of the root and exit the apex of the tooth into the surrounding alveolar bone, can lead to a periapical abscess. Over time, granulation tissue (with or without an epithelial lining) may develop. Periapical inflammatory lesions persist as a result of bacterial infection or necrotic tissue in the area. Successful treatment, therefore, necessitates the complete removal of the offending material followed by restoration or extraction of the tooth.

Odontogenic tumors are a complex group of lesions with diverse histologic appearances and clinical behaviors. Some are true neoplasms, either benign or malignant, while others are thought to be hamartomas. Odontogenic tumors are derived from odontogenic epithelium, ectomesenchyme, or both. The two most common and clinically significant tumors are ameloblastoma and odontoma.

Ameloblastomas arise from odontogenic epithelium. They are typically cystic, slow-growing and, despite being locally invasive, have an indolent course. The cysts are lined by palisading columnar epithelium that overlies a loose stroma with stellate cells. Odontoma, the most common type of odontogenic tumor, arises from epithelium but shows extensive deposition of enamel and dentin. Odontomas are cured by local excision.

SUMMARY
ODONTOGENIC CYSTS AND TUMORS

- The jaws are a common site of epithelium-lined cysts derived from odontogenic remnants.
- The odontogenic keratocyst is locally aggressive, with a high recurrence rate.
- The periapical cyst is a reactive, inflammatory lesion associated with caries or dental trauma.
- The most common odontogenic tumors are ameloblastoma and odontoma.

Esophagus

The esophagus develops from the cranial portion of the foregut. It is a hollow, highly distensible muscular tube that extends from the epiglottis to the gastroesophageal junction, located just above the diaphragm. Acquired diseases of the esophagus run the gamut from lethal cancers to the persistent "heartburn" of gastroesophageal reflux that may be chronic and incapacitating or merely an occasional annoyance.

OBSTRUCTIVE AND VASCULAR DISEASES

Mechanical Obstruction

Atresia, fistulas, and duplications may occur in any part of the gastrointestinal tract. When they involve the esophagus, they are discovered shortly after birth, usually because of regurgitation during feeding. Prompt surgical repair is required. Absence, or agenesis, of the esophagus is extremely rare. Atresia, in which a thin, noncanalized cord replaces a segment of esophagus, is more common. It occurs most frequently at or near the tracheal bifurcation and usually is associated with a fistula connecting the upper or lower esophageal pouches to a bronchus or the trachea. This abnormal connection can result in aspiration, suffocation, pneumonia, or severe fluid and electrolyte imbalances.

Esophageal stenosis may be congenital or more commonly acquired. When acquired the narrowing generally is caused by fibrous thickening of the submucosa and atrophy of the muscularis propria. Stenosis due to inflammation and scarring may be caused by chronic gastroesophageal reflux,

irradiation, ingestion of caustic agents, or other forms of severe injury. Stenosis-associated dysphagia usually is progressive; difficulty eating solids typically occurs long before problems with liquids.

Functional Obstruction

Efficient delivery of food and fluids to the stomach requires coordinated waves of peristaltic contractions. *Esophageal dysmotility* interferes with this process and can take several forms, all of which are characterized by discoordinated contraction or spasm of the muscularis. Because it increases esophageal wall stress, spasm also can cause small diverticula to form. Esophageal dysmotility can be separated into several forms depending on the character of the contractile abnormalities.

Achalasia is characterized by the triad of incomplete lower esophageal sphincter (LES) relaxation, increased LES tone, and esophageal aperistalsis. Primary achalasia is caused by failure of distal esophageal inhibitory neurons and is, by definition, idiopathic. Degenerative changes in neural innervation, either intrinsic to the esophagus or within the extraesophageal vagus nerve or the dorsal motor nucleus of the vagus, may lead to secondary achalasia. This occurs in Chagas disease, in which *Trypanosoma cruzi* infection causes destruction of the myenteric plexus, failure of LES relaxation, and esophageal dilatation. Duodenal, colonic, and ureteric myenteric plexuses also can be affected in Chagas disease. Achalasia-like disease may be caused by diabetic autonomic neuropathy, infiltrative disorders such as malignancy, amyloidosis, or sarcoidosis, and lesions of dorsal motor nuclei, which may be produced by polio or surgical ablation.

Ectopia

Ectopic tissues (developmental rests) are common in the gastrointestinal tract. The most frequent site of ectopic gastric mucosa is the upper third of the esophagus, where it is referred to as an *inlet patch.* Although the presence of such tissue generally is asymptomatic, acid released by gastric mucosa within the esophagus can result in dysphagia, esophagitis, Barrett esophagus, or, rarely, adenocarcinoma. *Gastric heterotopia,* small patches of ectopic gastric mucosa in the small bowel, particularly within a Meckel diverticulum, or colon, may present with occult blood loss due to local injury caused by acid secretion.

Esophageal Varices

Instead of returning directly to the heart, venous blood from the gastrointestinal tract is delivered to the liver via the portal vein before reaching the inferior vena cava. This circulatory pattern is responsible for the first-pass effect, in which drugs and other materials absorbed in the intestines are processed by the liver before entering the systemic circulation. **Diseases that impede portal blood flow cause portal hypertension, which can lead to the development of esophageal varices, an important cause of massive and frequently life-threatening bleeding.**

Pathogenesis

One of the few sites where the splanchnic and systemic venous circulations can communicate is the esophagus. Portal hypertension induces development of collateral channels that allow portal blood to shunt into the caval system. However, these collateral veins enlarge the subepithelial and submucosal venous plexi within the distal esophagus. These vessels, termed *varices,* develop in 50% of cirrhotic patients, most commonly in association with alcoholic liver disease. Worldwide, hepatic schistosomiasis is the second most common cause of varices. A more detailed consideration of portal hypertension is given in Chapter 16.

MORPHOLOGY

Varices can be detected by angiography, but are most commonly detected during endoscopy (Fig. 15.7A and B) and appear as tortuous dilated veins within the submucosa of the distal esophagus and proximal stomach (see Fig. 15.7C and D). The overlying mucosa can be intact or ulcerated and necrotic, particularly if rupture has occurred.

Clinical Features

Varices often are asymptomatic, but their rupture can lead to massive hematemesis and death. Variceal rupture therefore constitutes a medical emergency. Despite intervention, as many as half of the patients die from the first bleeding episode, either as a direct consequence of hemorrhage or due to hepatic coma triggered by the protein load that results from intraluminal bleeding as well as hypovolemic shock. Among those who survive, additional episodes of hemorrhage, each potentially fatal, occur in as many as 20% of cases.

ESOPHAGITIS

Esophageal Lacerations, Mucosal Injury, and Infections

The most common esophageal lacerations are *Mallory-Weiss tears*, which are often induced by severe retching or vomiting. Normally, a reflex relaxation of the gastroesophageal musculature precedes the anti-peristaltic contractile wave associated with vomiting. This relaxation may fail during prolonged vomiting, with the result that refluxing gastric contents cause the esophageal wall to stretch and tear. Patients usually present with hematemesis.

The roughly linear lacerations of Mallory-Weiss syndrome are longitudinally oriented and usually cross the gastroesophageal junction (Fig. 15.8A). These superficial tears generally heal quickly without surgical intervention. By contrast, severe, transmural esophageal tears *(Boerhaave syndrome)* result in mediastinitis, are catastrophic, and require prompt surgical intervention.

Chemical and Infectious Esophagitis

The stratified squamous mucosa of the esophagus may be damaged by a variety of irritants including alcohol, corrosive acids or alkalis, excessively hot fluids, and heavy

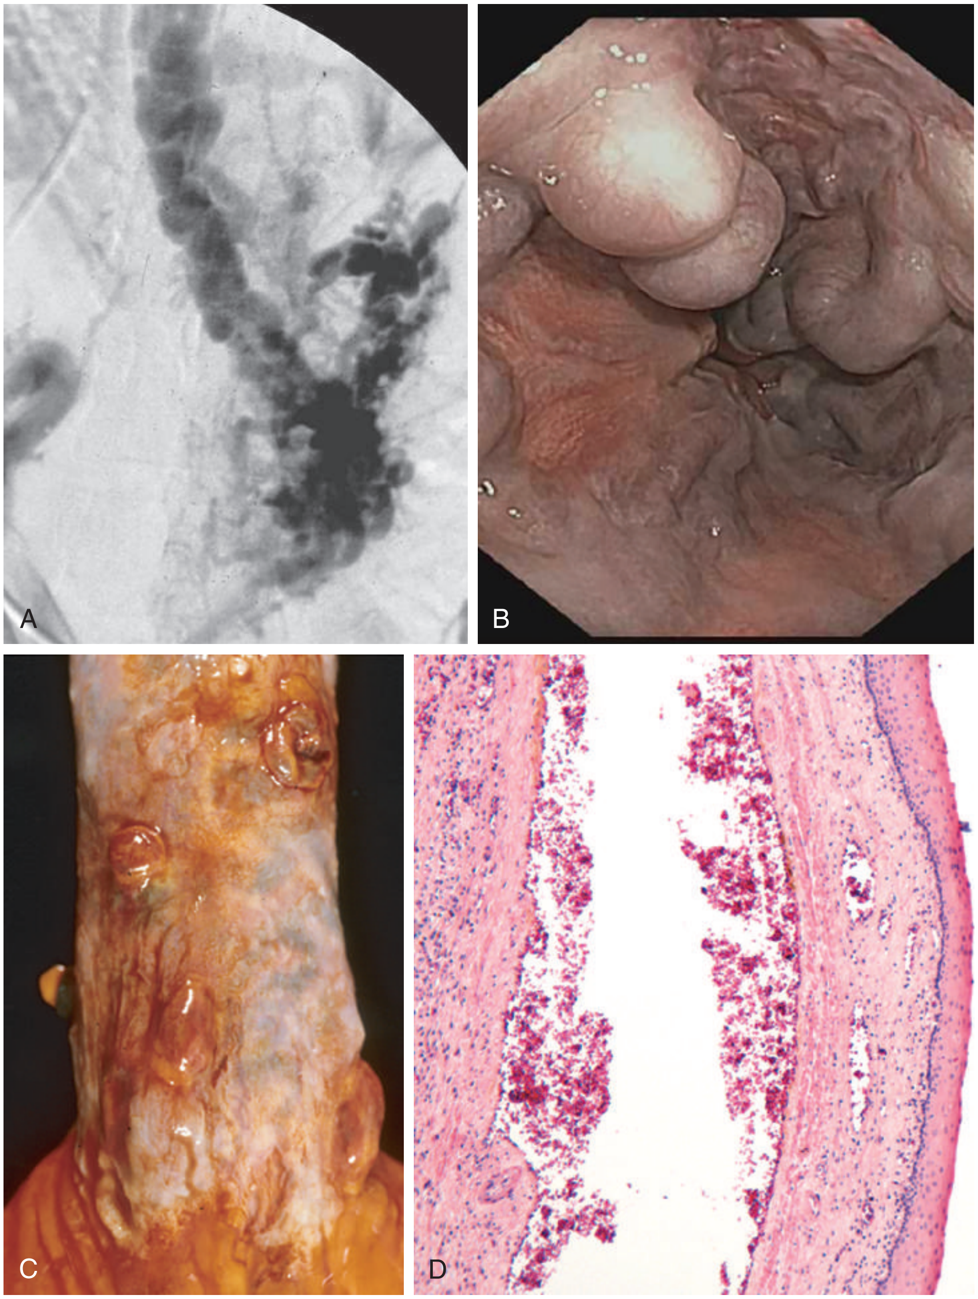

Fig. 15.7 Esophageal varices. (A) Angiogram showing several tortuous esophageal varices. (B) Although the angiogram is striking, endoscopy is more commonly used to identify varices. (C) Collapsed varices are present in this postmortem specimen corresponding to the angiogram in (A). The polypoid areas are sites of variceal hemorrhage that were ligated with bands. (D) Dilated varices beneath intact squamous mucosa.

smoking. Medicinal pills, most commonly doxycycline and bisphosphonates, may adhere to the esophageal lining and dissolve in the esophagus rather than passing immediately into the stomach, resulting in pill-induced esophagitis. Esophagitis due to chemical injury generally causes only self-limited pain, particularly odynophagia (pain with swallowing). Hemorrhage, stricture, or perforation may occur in severe cases. Iatrogenic esophageal injury may be caused by cytotoxic chemotherapy, radiation therapy, or graft-versus-host disease. The morphologic changes are nonspecific, consisting of ulceration and acute inflammation. Irradiation causes blood vessel damage adding an element of ischemic injury.

Infectious esophagitis may occur in otherwise healthy individuals but is most frequent in those who are debilitated or immunosuppressed. In these patients, esophageal infection by herpes simplex viruses, cytomegalovirus (CMV), or fungal organisms is common. Among fungi, Candida is the most common pathogen, although mucormycosis and aspergillosis may also occur. The esophagus may also be involved in desquamative skin diseases such as bullous pemphigoid and epidermolysis bullosa and, rarely, Crohn disease.

Infection by fungi or bacteria can be primary or complicate a preexisting ulcer. Nonpathogenic oral bacteria frequently are found in ulcer beds, while pathogenic organisms, which

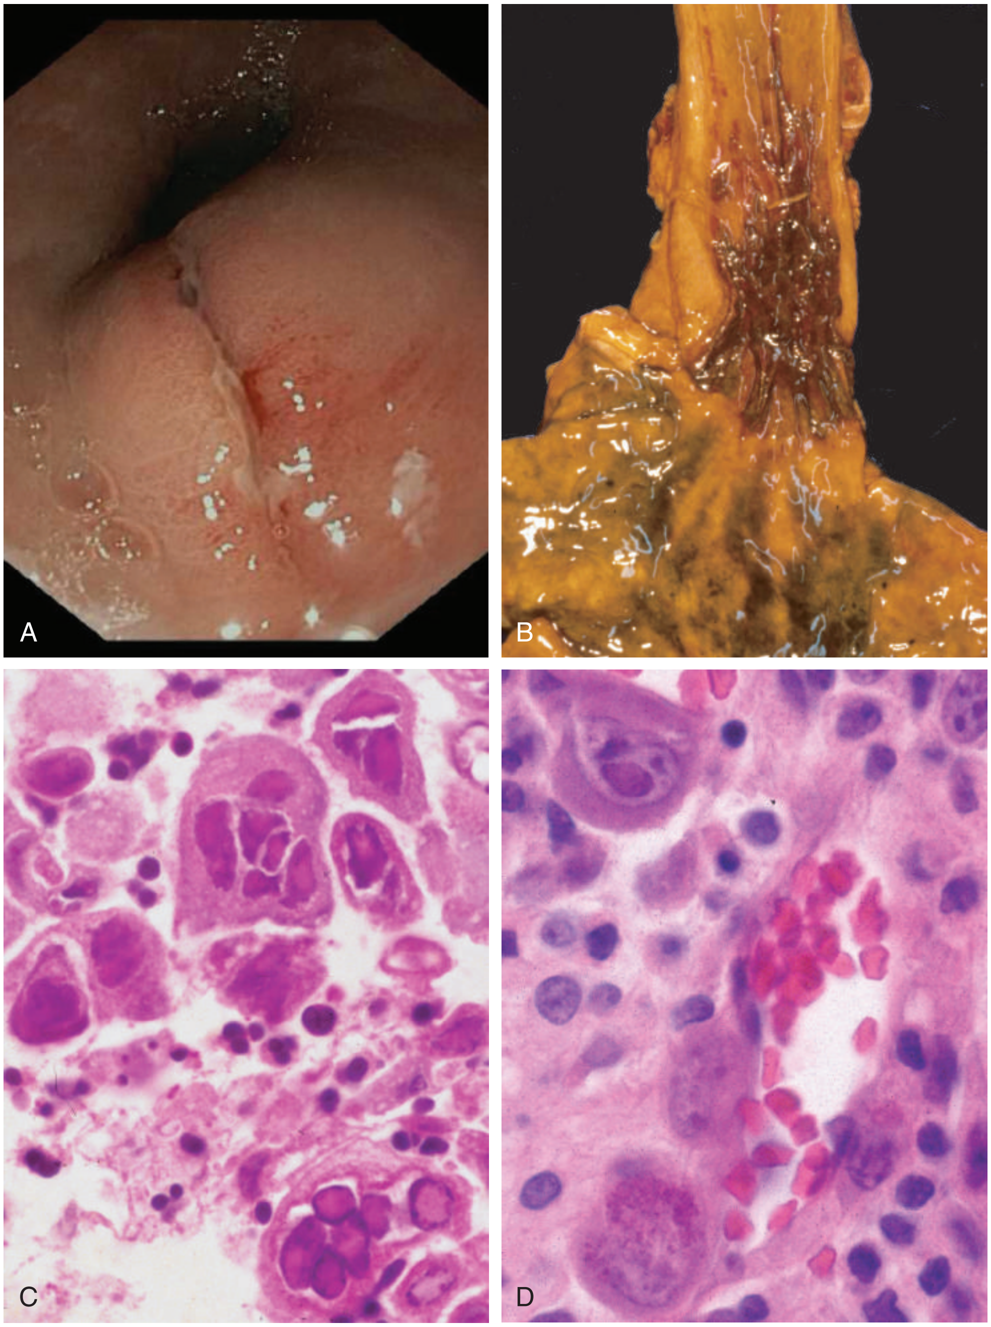

Fig. 15.8 Traumatic and viral esophagitis. (A) Endoscopic view of a longitudinally-oriented Mallory-Weiss tear. These superficial lacerations can range from millimeters to several centimeters in length. (B) Postmortem specimen with multiple herpetic ulcers in the distal esophagus. (C) Multinucleate squamous cells containing herpesvirus nuclear inclusions. (D) Cytomegalovirus-infected endothelial cells with nuclear and cytoplasmic inclusions. *(Endoscopic image courtesy of Dr. Ira Hanan, The University of Chicago, Chicago, Illinois.)*

account for about 10% of infectious esophagitis cases, may invade the lamina propria and cause necrosis of overlying mucosa. Candidiasis in its most advanced form is characterized by adherent, gray-white pseudomembranes composed of densely matted fungal hyphae and inflammatory cells covering the esophageal mucosa.

The endoscopic appearance often provides a clue to the identity of the infectious agent in viral esophagitis. Herpesviruses typically cause punched-out ulcers (Fig. 15.8B), and histopathologic analysis demonstrates nuclear viral inclusions within a rim of degenerating epithelial cells at the ulcer edge (Fig. 15.8C). By contrast, CMV causes shallower ulcerations. Biopsy of these lesions show the characteristic nuclear and cytoplasmic inclusions within capillary endothelium and stromal cells (Fig. 15.8D). Immunohistochemical staining for viral antigens can be a useful ancillary diagnostic tool.

Reflux Esophagitis

Reflux of gastric contents into the lower esophagus is the most frequent cause of esophagitis and the most

common gastrointestinal ailment with which patients present in the out patient setting in the United States. The associated clinical condition is termed *gastroesophageal reflux disease (GERD).* The stratified squamous epithelium of the esophagus is resistant to abrasion from foods but is sensitive to acid. The submucosal glands of the proximal and distal esophagus contribute to mucosal protection by secreting mucin and bicarbonate. More important, high lower esophageal sphincter tone protects against reflux of acidic gastric contents, which are under positive pressure.

Pathogenesis

Reflux of gastric juices is central to the development of mucosal injury in GERD. In severe cases, duodenal bile reflux may exacerbate the damage. Conditions that decrease lower esophageal sphincter tone or increase abdominal pressure contribute to GERD and include alcohol and tobacco use, obesity, central nervous system depressants, pregnancy, hiatal hernia (discussed later), delayed gastric emptying, and increased gastric volume. In many cases, no definitive cause is identified.

MORPHOLOGY

Simple hyperemia, evident to the endoscopist as redness, may be the only alteration. In mild GERD the mucosal histology is often unremarkable. With more significant disease, eosinophils are recruited into the squamous mucosa, followed by neutrophils, which usually are associated with more severe injury (Fig. 15.9A). Basal zone hyperplasia exceeding 20% of the total epithelial thickness and elongation of lamina propria papillae, such that they extend into the upper third of the epithelium, also may be present.

Clinical Features

GERD is most common in those over 40 years of age but also occurs in infants and children. The most frequently reported symptoms are heartburn, dysphagia, and, less often, noticeable regurgitation of sour-tasting gastric contents. Rarely, chronic GERD is punctuated by attacks of severe chest pain that may be mistaken for heart disease. Treatment with proton pump inhibitors reduces gastric acidity and typically provides symptomatic relief. While the severity of symptoms is not closely related to the degree of histologic damage, the latter tends to increase with disease duration. Complications of reflux esophagitis include esophageal ulceration, hematemesis, melena, stricture development, and Barrett esophagus, a precursor lesion to esophageal carcinoma.

Hiatal hernia is characterized by separation of the diaphragmatic crura and protrusion of the stomach into the thorax through the resulting gap. Congenital hiatal hernias are recognized in infants and children, but many are acquired in later life. Hiatal hernia is symptomatic in fewer than 10% of adults; symptoms when present resemble GERD since hiatal hernia can cause LES incompetence.

Eosinophilic Esophagitis

Eosinophilic esophagitis is a chronic immunologically mediated disorder that is being increasingly recognized. Symptoms include food impaction and dysphagia in adults and feeding intolerance or GERD-like symptoms in children. The cardinal histologic feature is epithelial infiltration by large numbers of eosinophils, particularly superficially (Fig. 15.9B) and at sites far from the gastroesophageal junction. Their abundance can help to differentiate eosinophilic esophagitis from GERD, Crohn disease, and other causes of esophagitis. Endoscopically evident rings in the upper and

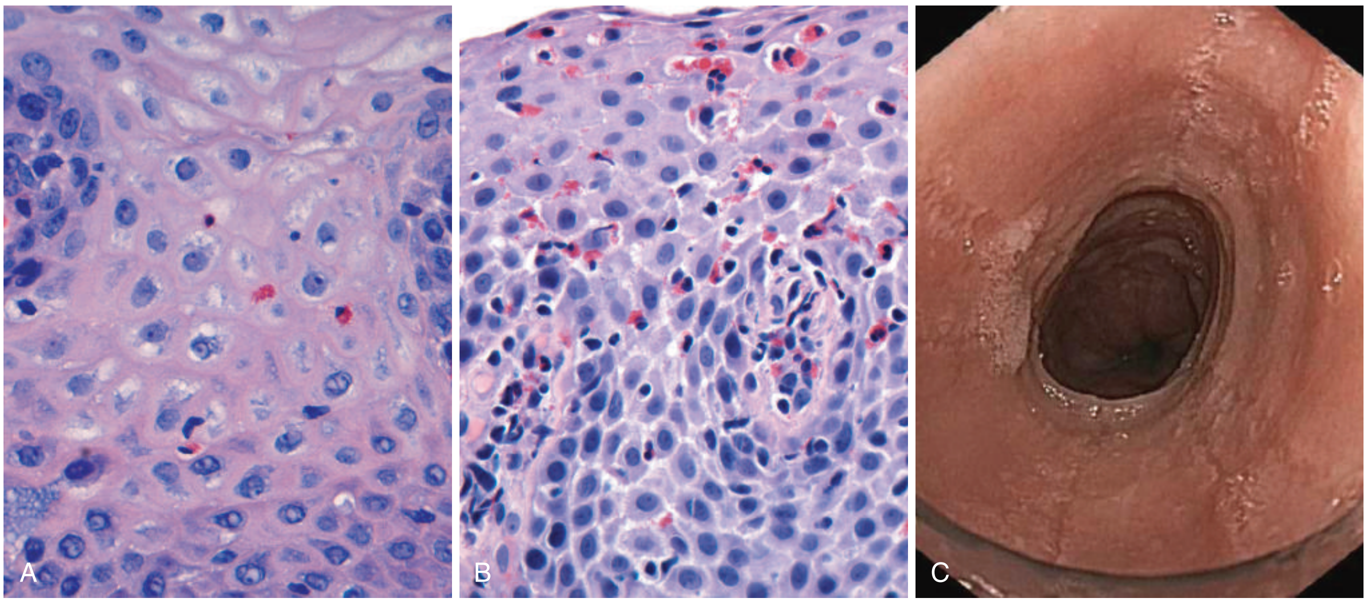

Fig. 15.9 Esophagitis. (A) Reflux esophagitis with scattered intraepithelial eosinophils. (B) Eosinophilic esophagitis with numerous intraepithelial eosinophils. (C) Endoscopy reveals circumferential rings in the proximal esophagus of this patient with eosinophilic esophagitis. *(Endoscopic image courtesy of Dr. Ira Hanan, The University of Chicago, Chicago, Illinois.)*

mid portions of the esophagus (Fig. 15.9C), may also help to distinguish eosinophilic esophagitis from GERD. Patients with eosinophilic esophagitis are typically refractory to high-dose proton pump inhibitor treatment. *Most patients are atopic, and many have atopic dermatitis, allergic rhinitis, asthma, or modest peripheral eosinophilia.* Treatments include dietary restrictions to prevent exposure to food allergens, such as cow milk and soy products, and topical or systemic corticosteroids.

Barrett Esophagus

Barrett esophagus is a complication of chronic GERD that is characterized by intestinal metaplasia within the esophageal squamous mucosa. The incidence of Barrett esophagus is rising; it is estimated to occur in as many as 10% of individuals with symptomatic GERD. White males are affected most often and typically present between 40 and 60 years of age. The greatest concern in Barrett esophagus is that *it confers an increased risk for development of esophageal adenocarcinoma*. Molecular studies suggest that Barrett epithelium may be more similar genetically to adenocarcinoma than to normal esophageal epithelium, consistent with the view that Barrett esophagus is a direct precursor of cancer. In keeping with this, epithelial *dysplasia*, considered to be a preinvasive lesion, develops in 0.2% to 1% of individuals with Barrett esophagus each year; its incidence increases with duration of symptoms and increasing patient age. Although the vast majority of esophageal adenocarcinomas are associated with Barrett esophagus, it should be noted that most individuals with Barrett esophagus do not develop esophageal cancer.

MORPHOLOGY

Barrett esophagus is recognized endoscopically as tongues or patches of red, velvety mucosa extending upward from the gastroesophageal junction (Fig. 15.10A). This metaplastic mucosa alternates with residual smooth, pale squamous (esophageal) mucosa proximally and interfaces with light-brown columnar (gastric) mucosa distally (Fig. 15.10B and C). High-resolution endoscopes have increased the sensitivity of Barrett esophagus detection.

Most experts require both endoscopic evidence of abnormal mucosa above the gastroesophageal junction and histologically documented gastric or intestinal metaplasia for diagnosis of Barrett esophagus. The defining feature of intestinal metaplasia, and a feature of Barrett esophagus, is the presence of goblet cells, which have distinct mucous vacuoles that stain pale blue by H&E and impart the shape of a wine goblet to the remaining cytoplasm (Fig. 15.10C). Dysplasia is classified as low-grade or high-grade on the basis of morphologic criteria. Intramucosal carcinoma is characterized by invasion of neoplastic epithelial cells into the lamina propria.

Clinical Features

Diagnosis of Barrett esophagus is usually prompted by GERD symptoms and requires endoscopy and biopsy. The best course of management is a matter of debate, but most clinicians recommend periodic surveillance endoscopy with biopsy to screen for dysplasia. Dysplasia is often treated and more advanced lesions, including high-grade dysplasia and intramucosal carcinoma, always require

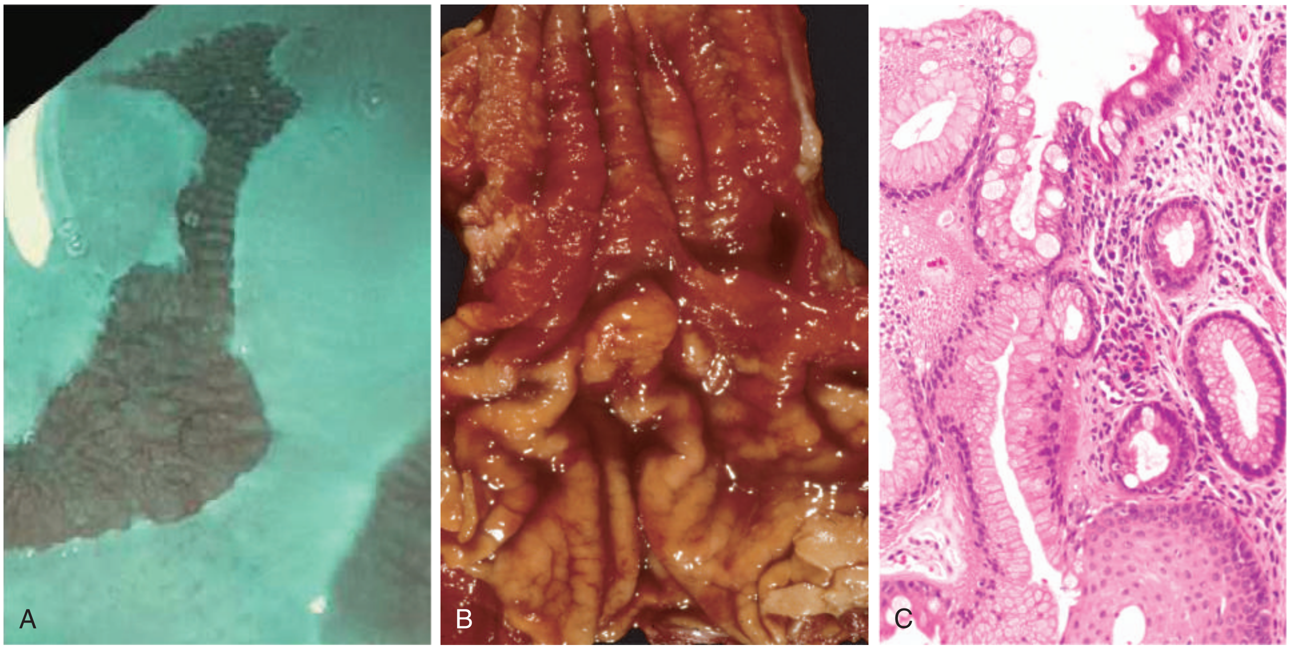

Fig. 15.10 Barrett esophagus. (A) Narrow band imaging of Barrett esophagus during endoscopy. Note the tan islands of ectopic metaplasia within bluish squamous mucosa. (B) Gross image of Barrett esophagus (compare to Fig. 15.7C). Only a few areas of pale squamous mucosa remain within the predominantly metaplastic, reddish mucosa of the distal esophagus. (C) Histologic appearance of the gastroesophageal junction in Barrett esophagus. Note the transition between esophageal squamous mucosa *(lower right)* and metaplastic mucosa containing goblet cells *(upper)*. *(Endoscopic image courtesy of Dr. Ira Hanan, The University of Chicago, Chicago, Illinois.)*

therapeutic intervention. Available modalities include surgical resection *(esophagectomy);* newer approaches include photodynamic therapy, radiofrequency ablation, and endoscopic mucosectomy.

ESOPHAGEAL TUMORS

Two morphologic variants account for a majority of esophageal cancers: adenocarcinoma and squamous cell carcinoma. Worldwide, squamous cell carcinoma is more common, but adenocarcinoma is on the rise. Other rare tumors are not discussed here.

Adenocarcinoma

Esophageal adenocarcinoma typically arises in a background of Barrett esophagus and long-standing GERD. Risk for development of adenocarcinoma is greater in patients with documented dysplasia and in those who use tobacco, are obese, or who have had previous radiation therapy. In the United States, esophageal adenocarcinoma occurs most frequently in whites and shows a strong gender bias, being seven times more common in men than in women. However, the incidence varies by a factor of 60-fold worldwide, with rates being highest in Western countries, including the United States, the United Kingdom, Canada, Australia, and the Netherlands, and lowest in Korea, Thailand, Japan, and Ecuador. In countries where esophageal adenocarcinoma is more common, the incidence has increased markedly since 1970, more rapidly than for almost any other cancer. As a result, esophageal adenocarcinoma, which represented less than 5% of esophageal cancers before 1970, now accounts for half of all esophageal cancers in some Western countries, including the United States.

Pathogenesis

Molecular studies suggest that the progression of Barrett esophagus to adenocarcinoma occurs over an extended period through the stepwise acquisition of genetic and epigenetic changes. This model is supported by the observation that epithelial clones identified in nondysplastic Barrett metaplasia persist and accumulate mutations during progression to dysplasia and invasive carcinoma. Chromosomal abnormalities and *TP53* mutation are often present in the early stages of esophageal adenocarcinoma. Additional genetic changes and inflammation are thought to contribute to tumor progression.

MORPHOLOGY

Esophageal adenocarcinoma usually occurs in the distal third of the esophagus and may invade the adjacent gastric cardia (Fig. 15.11A). While early lesions may appear as flat or raised patches in otherwise intact mucosa, later tumors may form large exophytic masses, infiltrate diffusely, or ulcerate and invade deeply. On microscopic examination, Barrett esophagus frequently is present adjacent to the tumor. Tumors typically produce mucin and form glands (Fig. 15.11B).

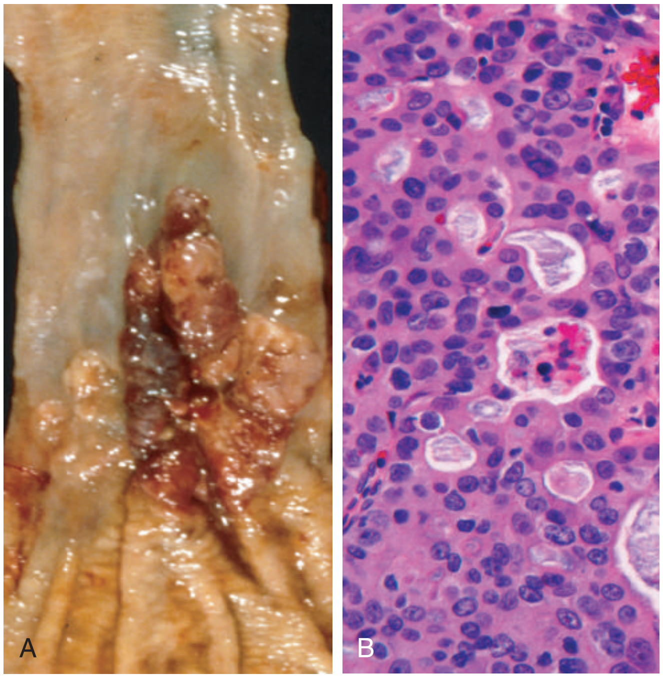

Fig. 15.11 Esophageal adenocarcinoma. (A) Adenocarcinoma usually occurs distally and, as in this case, often involves the gastric cardia. (B) Esophageal adenocarcinoma growing as back-to-back glands.

Clinical Features

Patients most commonly present with pain or difficulty in swallowing, progressive weight loss, chest pain, or vomiting. By the time signs and symptoms appear, the tumor usually has invaded submucosal lymphatic vessels. As a result of the advanced stage at diagnosis, the overall 5-year survival rate is less than 25%. By contrast, 5-year survival approximates 80% in the few patients with adenocarcinoma limited to the mucosa or submucosa.

Squamous Cell Carcinoma

In the United States, esophageal squamous cell carcinoma typically occurs in adults older than 45 years of age and affects males four times more frequently than females. Risk factors include alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, Plummer-Vinson syndrome, frequent consumption of very hot beverages, and previous radiation therapy to the mediastinum. It is nearly six times more common in African Americans than in whites—a striking risk disparity that cannot be accounted for by differences in rates of alcohol and tobacco use. The incidence of esophageal squamous cell carcinoma can vary by more than 100-fold between and within countries, being more common in rural and underdeveloped areas. The countries with highest incidences are Iran, central China, Hong Kong, Argentina, Brazil, and South Africa.

Pathogenesis

A majority of esophageal squamous cell carcinomas in Europe and the United States are at least partially

related to the use of alcohol and tobacco, the effects of which synergize to increase risk. However, esophageal squamous cell carcinoma also is common in some regions where alcohol and tobacco use are uncommon due to religious or societal norms. In these areas, nutritional deficiencies, as well as exposure to polycyclic hydrocarbons, nitrosamines, and other mutagenic compounds, such as those found in fungus-contaminated foods, are suspected to be the risk factors. HPV infection also has been implicated in esophageal squamous cell carcinoma in high-risk but not in low-risk regions. The molecular pathogenesis of esophageal squamous cell carcinoma remains incompletely defined.

MORPHOLOGY

In contrast to the distal location of most adenocarcinomas, half of squamous cell carcinomas occur in the middle third of the esophagus (Fig. 15.12A). Squamous cell carcinoma begins as an in situ lesion in the form of **squamous dysplasia.** Early lesions appear as small, gray-white plaquelike thickenings. Over months to years, they grow into tumor masses that may be polypoid and protrude into and obstruct the lumen. Other tumors are either ulcerated or diffusely infiltrative lesions that spread within the esophageal wall, where they can cause thickening, rigidity, and luminal narrowing. These cancers may invade surrounding structures including the respiratory tree, causing pneumonia; the aorta, causing catastrophic exsanguination; or the mediastinum and pericardium.

Most squamous cell carcinomas are moderately to well-differentiated (Fig. 15.12B). Regardless of the histology symptomatic tumors have often invaded the esophageal wall at time of diagnosis. The rich submucosal lymphatic network promotes circumferential and longitudinal spread, and intramural tumor nodules may be present several centimeters away from the main mass. The sites of lymph node metastases vary with tumor location: Cancers in the upper third of the esophagus favor cervical lymph nodes; those in the middle third favor mediastinal, paratracheal, and tracheobronchial nodes; and those in the lower third spread to gastric and celiac nodes.

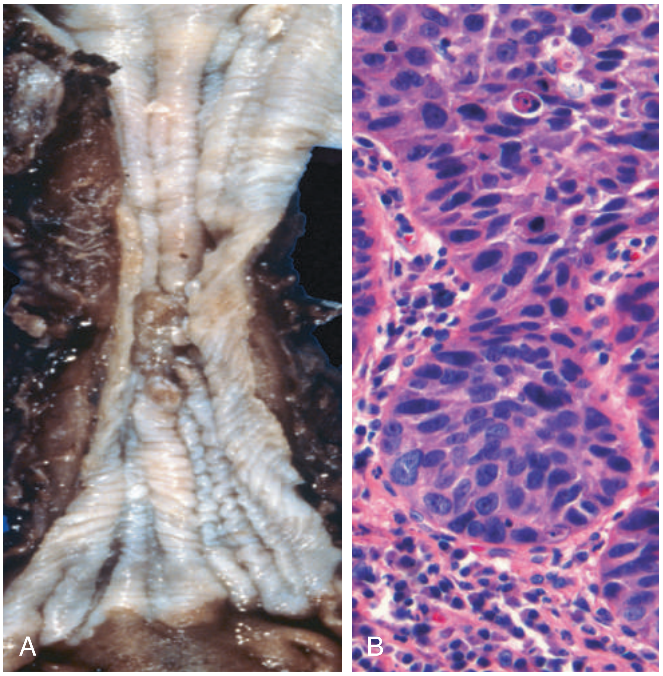

Fig. 15.12 Esophageal squamous cell carcinoma. (A) Squamous cell carcinoma most frequently is found in the mid-esophagus, where it commonly causes strictures. (B) Squamous cell carcinoma composed of nests of malignant cells that partially recapitulate the stratified organization of squamous epithelium.

Clinical Features

Clinical manifestations of squamous cell carcinoma of the esophagus begin insidiously and include dysphagia, odynophagia (pain on swallowing), and obstruction. As with other forms of esophageal obstruction, patients may unwittingly adjust to the progressively increasing obstruction by altering their diet from solid to liquid foods. Extreme weight loss and debilitation may occur as consequences of both impaired nutrition and tumor-associated cachexia. As with adenocarcinoma, hemorrhage and sepsis may accompany tumor ulceration. Occasionally, squamous cell carcinomas of the upper and mid esophagus present with symptoms caused by aspiration of food via a tracheoesophageal fistula.

Increased use of endoscopic screening has led to earlier diagnosis of esophageal squamous cell carcinoma. Early detection is critical, because 5-year survival rates are 75% for patients with superficial esophageal carcinoma but much lower for patients with more advanced tumors. The overall 5-year survival rate remains a dismal 9%.

SUMMARY

DISEASES OF THE ESOPHAGUS

- *Esophageal obstruction* may occur as a result of mechanical or functional anomalies. Mechanical causes include developmental defects, fibrotic strictures, and tumors.
- *Achalasia,* characterized by incomplete LES relaxation, increased LES tone, and esophageal aperistalsis, is a common form of functional esophageal obstruction.
- *Esophagitis* can result from chemical or infectious mucosal injury. Infections are most frequent in immunocompromised individuals.
- The most common cause of esophagitis is *gastroesophageal reflux disease (GERD),* which must be differentiated from *eosinophilic esophagitis.*
- *Barrett esophagus,* which may develop in patients with chronic GERD, is associated with increased risk for development of esophageal adenocarcinoma.
- *Esophageal squamous cell carcinoma* is associated with alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, and Plummer-Vinson syndrome.

Stomach

Disorders of the stomach are a frequent cause of clinical disease, with inflammatory and neoplastic lesions being particularly common. In the United States, symptoms related to gastric acidity account for nearly one third of all health care spending on gastrointestinal disease. In addition, despite a decreasing incidence in certain locales, including the United States, gastric cancer remains a leading cause of death worldwide.

The stomach is divided into four major anatomic regions: the cardia, fundus, body, and antrum. The cardia is lined mainly by mucin-secreting *foveolar cells* that form shallow glands. The antral glands are similar but also contain endocrine cells, such as *G cells,* that release gastrin to stimulate luminal acid secretion by *parietal cells* within the gastric fundus and body. The well-developed glands of the body and fundus also contain *chief cells* that produce and secrete digestive enzymes such as pepsin.

GASTROPATHY AND ACUTE GASTRITIS

Gastritis results from mucosal injury. When neutrophils are present, the lesion is referred to as *acute gastritis*. When cell injury and regeneration are present but inflammatory cells are rare or absent, the term *gastropathy* is applied. Agents that cause gastropathy include nonsteroidal anti-inflammatory drugs, alcohol, bile, and stress-induced injury. Acute mucosal erosion or hemorrhage, such as Curling ulcers or lesions following disruption of gastric blood flow, for example, in portal hypertension, can also cause gastropathy that typically progresses to gastritis. The term *hypertrophic gastropathy* is applied to a specific group of diseases exemplified by Ménétrier disease and Zollinger-Ellison syndrome (discussed later).

Both gastropathy and acute gastritis may be asymptomatic or cause variable degrees of epigastric pain, nausea, and vomiting. In more severe cases, there may be mucosal erosion, ulceration, hemorrhage, hematemesis, melena, or, rarely, massive blood loss.

Pathogenesis

The gastric lumen is strongly acidic, with a pH close to 1—more than 1 million times more acidic than the blood. This harsh environment contributes to digestion but also has the potential to damage the mucosa. Multiple mechanisms have evolved to protect the gastric mucosa (Fig. 15.13). Mucin secreted by surface foveolar cells forms a thin layer of mucus that prevents large food particles from directly touching the epithelium. The mucus layer also promotes formation of an "unstirred" layer of fluid over the epithelium that protects the mucosa; it has a neutral pH as a result of secretion of bicarbonate ions by surface epithelial cells. Finally, the rich blood supply of the gastric mucosa efficiently buffers and removes protons that back-diffuse into the lamina propria. Gastropathy, acute

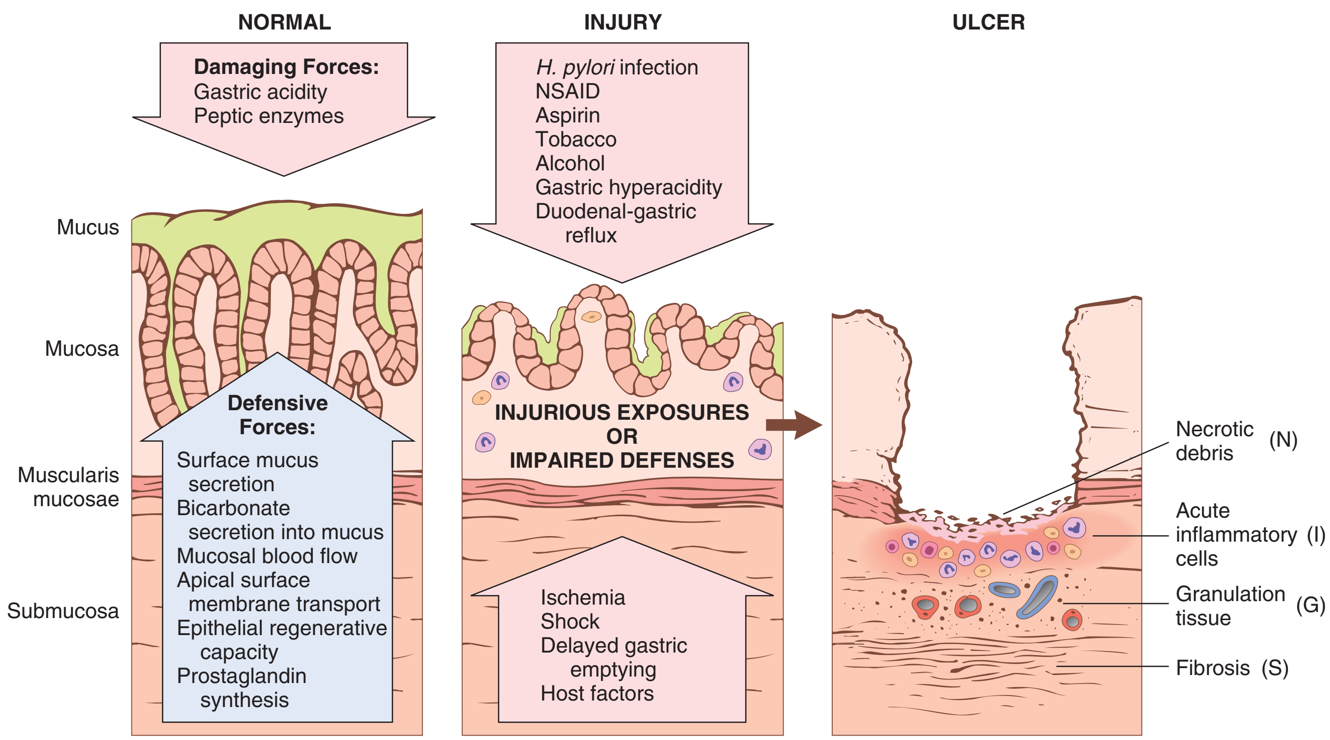

Fig. 15.13 Mechanisms of gastric injury and protection. This diagram illustrates the progression from mild forms of injury to ulceration that may occur with acute or chronic gastritis. Ulcers include layers of necrotic debris *(N)*, inflammation *(I)*, and granulation tissue *(G)*; scarring *(S)*, which develops over time, is present only in chronic lesions.

gastritis, and chronic gastritis can occur after disruption of any of these protective mechanisms. The main causes include:

- Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit cyclooxygenase (COX)-dependent synthesis of prostaglandins E2 and I2, which stimulate nearly all of the above defense mechanisms including mucus and bicarbonate secretion, mucosal blood flow, and epithelial restitution. Although COX-1 plays a larger role than COX-2, both isoenzymes contribute to mucosal protection. Thus, while the risk for development of NSAID-induced gastric injury is greatest with nonselective inhibitors, such as aspirin, ibuprofen, and naproxen, selective COX-2 inhibition, for example, by celecoxib, can also result in gastropathy or gastritis.
- The gastric injury that occurs in uremic patients and those infected with urease-secreting *H. pylori* may be due to inhibition of gastric bicarbonate transporters by ammonium ions.
- Reduced mucin and bicarbonate secretion have been suggested as factors that explain the increased susceptibility of older adults to gastritis.
- Hypoxemia and decreased oxygen delivery may account for an increased incidence of gastropathy and acute gastritis at high altitudes.
- Ingestion of harsh chemicals, particularly acids or bases, either accidentally or in a suicide attempt, leads to severe gastric mucosal damage as a result of direct injury to epithelial and stromal cells. Direct cellular damage also contributes to gastritis induced by excessive alcohol consumption, NSAID use, and radiation therapy. Agents that inhibit DNA synthesis or the mitotic apparatus, including those used in cancer chemotherapy, may cause generalized mucosal damage due to insufficient epithelial renewal.

MORPHOLOGY

Histologically, gastropathy and mild acute gastritis may be difficult to recognize, since the lamina propria shows only moderate edema and slight vascular congestion. The surface epithelium is intact, but hyperplasia of foveolar mucus cells is typically present. Neutrophils, lymphocytes, and plasma cells are not prominent.

The presence of neutrophils above the basement membrane in contact with epithelial cells is abnormal in all parts of the gastrointestinal tract and signifies active inflammation, or, at this site, gastritis (rather than gastropathy). The term *active inflammation* is preferred over acute inflammation throughout the luminal gastrointestinal tract, since active inflammation may be present in both acute and chronic disease states. With more severe mucosal damage, erosions and hemorrhage develop. Hemorrhage may manifest as dark punctae in an otherwise hyperemic mucosa. Concurrent presence of erosion and hemorrhage is termed **acute erosive hemorrhagic gastritis.**

Stress-Related Mucosal Disease

Stress-related gastric injury occurs in patients with severe trauma, extensive burns, intracranial disease, major surgery, serious medical disease, and other forms of severe physiologic stress. More than 75% of critically ill patients develop endoscopically visible gastric lesions during the first 3 days of their illness. In some cases, the associated ulcers are given specific names based on location and clinical associations. Examples are as follows:

- *Stress ulcers* affecting critically ill patients with shock, sepsis, or severe trauma.
- *Curling ulcers* occur in the proximal duodenum and are associated with severe burns or trauma.
- *Cushing ulcers* arise in the stomach, duodenum, or esophagus of those with intracranial disease and have a high incidence of perforation.

Pathogenesis

The pathogenesis of stress-related gastric mucosal injury is most often due to local ischemia. This may be caused by systemic hypotension or reduced blood flow resulting from stress-induced splanchnic vasoconstriction. Upregulation and increased release of the vasoconstrictor endothelin-1 also contributes to ischemic gastric mucosal injury, while increased COX-2 expression appears to be protective. Cushing ulcers are thought to be caused by direct stimulation of vagal nuclei resulting acid hypersecretion. Systemic acidosis may also contribute to mucosal injury by lowering the intracellular pH of mucosal cells.

MORPHOLOGY

Stress-related gastric mucosal injury ranges from shallow erosions caused by superficial epithelial damage to deeper lesions that penetrate the depth of the mucosa. Acute ulcers are rounded and typically less than 1 cm in diameter. The ulcer base frequently is stained brown to black by acid-digested extravasated red cells. Unlike peptic ulcers, which arise in the setting of chronic injury, acute stress ulcers are found anywhere in the stomach and are often multiple. They are sharply demarcated, with essentially normal adjacent mucosa, although there may be suffusion of blood into the mucosa and submucosa and some inflammatory reaction. The scarring and thickening of blood vessels that characterize chronic peptic ulcers are absent. Healing with complete reepithelialization occurs days or weeks after the injurious factors are removed.

Clinical Features

Most critically ill patients admitted to hospital intensive care units have histologic evidence of gastric mucosal damage. Ulcers are associated with nausea, vomiting, melena, and coffee-ground hematemesis. Bleeding from superficial gastric erosions or ulcers that may require transfusion develop in 1% to 4% of these patients. Other complications, including perforation, also may occur. Prophylaxis with proton pump inhibitors may blunt the impact of stress ulceration, but the most important determinant of outcome is the severity of the underlying condition.

CHRONIC GASTRITIS

The most common cause of chronic gastritis is infection with the bacillus *Helicobacter pylori. Autoimmune*

gastritis, typically associated with gastric atrophy, represents less than 10% of cases of chronic gastritis but is the most common cause in patients without *H. pylori* infection. Chronic NSAID use is a third important cause of gastritis in some populations, as discussed later. Less common causes include radiation injury and chronic bile reflux.

The signs and symptoms associated with chronic gastritis typically are less severe but more persistent than those of acute gastritis. Nausea and upper-abdominal discomfort may occur, sometimes with vomiting, but hematemesis is uncommon.

Helicobacter pylori Gastritis

The discovery of the association of *H. pylori* with peptic ulcer disease revolutionized the understanding of chronic gastritis. These spiral-shaped or curved bacilli are present in gastric biopsy specimens from almost all patients with duodenal ulcers and a majority of those with gastric ulcers or chronic gastritis. Acute *H. pylori* infection is subclinical in most cases; rather, it is the chronic gastritis that ultimately brings the afflicted person to medical attention. *H. pylori* infection most often presents as an *antral gastritis with increased acid production.* The increased acid production may give rise to peptic ulcer disease of the duodenum or stomach.

While in most cases *H. pylori* gastritis is limited to the antrum, in some individuals it progresses to involve the gastric body and fundus, resulting in reduced parietal cell mass and acid secretion. Reduced acid output results in hypergastrinemia, as in autoimmune atrophic gastritis. In addition, extension of the gastritis to the gastric body and fundus results in intestinal metaplasia and increased risk of gastric cancer.

Epidemiology

In the United States, *H. pylori* infection is associated with poverty, household crowding, limited education, residence in areas with poor sanitation, and birth outside of the United States. Infection is typically acquired in childhood and may then persist for life. Improved sanitation in many areas likely explains why *H. pylori* infection rates among younger individuals today are markedly lower than they were in similarly aged individuals 30 years ago. In the United States, the prevalence of *H. pylori* infection is also higher in African Americans and Mexican Americans. Worldwide, colonization rates vary from less than 10% to more than 80% as a function of age, geography, and social factors.

Pathogenesis

H. pylori organisms have adapted to the ecologic niche provided by gastric mucus. Although *H. pylori* may invade the gastric mucosa, the contribution of invasion to disease pathogenesis is not known. Four features are linked to *H. pylori* virulence:

- *Flagella,* which allow the bacteria to be motile in viscous mucus
- *Urease,* which generates ammonia from endogenous urea, thereby elevating local gastric pH around the organisms and protecting the bacteria from the acidic pH of the stomach
- *Adhesins,* which enhance bacterial adherence to surface foveolar cells
- *Toxins,* such as that encoded by cytotoxin-associated gene A *(CagA),* that may be involved in ulcer or cancer development

These factors allow *H. pylori* to create an imbalance between gastroduodenal mucosal defenses and damaging forces that overcome those defenses.

MORPHOLOGY

Gastric biopsy specimens generally demonstrate *H. pylori* in infected individuals (Fig. 15.14A). The organism is concentrated within mucus overlying epithelial cells in the surface and neck regions. The inflammatory reaction includes a variable number of neutrophils within the lamina propria, including some that cross the basement membrane to assume an intraepithelial location (Fig. 15.14B) and accumulate in the lumen of gastric pits to create pit abscesses. The superficial lamina propria includes large numbers of plasma cells, often in clusters or sheets, as well as increased numbers of lymphocytes and macrophages. When intense, inflammatory infiltrates may create thickened rugal folds, mimicking infiltrative lesions. Lymphoid aggregates, some with germinal centers, are frequently present (Fig. 15.14C) and represent an induced form of **mucosa-associated lymphoid tissue** (MALT) that has the potential to transform into lymphoma. **Intestinal metaplasia,** characterized by the presence of goblet cells and columnar absorptive cells (Fig. 15.14D), also may be present and is associated with increased risk of gastric adenocarcinoma. *H. pylori* shows tropism for gastric foveolar epithelium and generally is not found in areas of intestinal metaplasia, acid-producing mucosa of the gastric body, or duodenal epithelium. Antral biopsies are therefore preferred for evaluation of *H. pylori* gastritis.

Clinical Features

In addition to histologic identification of the organism, several diagnostic tests have been developed including a noninvasive serologic test for anti–*H. pylori* antibodies, a stool test for the organism, and the urea breath test, based on the generation of ammonia by bacterial urease. Gastric biopsy specimens also can be analyzed by the rapid urease test, bacterial culture, or polymerase chain reaction (PCR) assay for bacterial DNA. Effective treatments include combinations of antibiotics and proton pump inhibitors. Patients with *H. pylori* gastritis usually improve after treatment, although relapses can follow incomplete eradication or reinfection.

Autoimmune Gastritis

Autoimmune gastritis accounts for less than 10% of cases of chronic gastritis. In contrast *H. pylori*-associated gastritis, autoimmune gastritis typically spares the antrum and induces marked *hypergastrinemia* (Table 15.2). Autoimmune gastritis is characterized by the following:

- Antibodies to parietal cells and intrinsic factor that can be detected in serum and gastric secretions
- Reduced serum pepsinogen I levels
- Antral endocrine cell hyperplasia

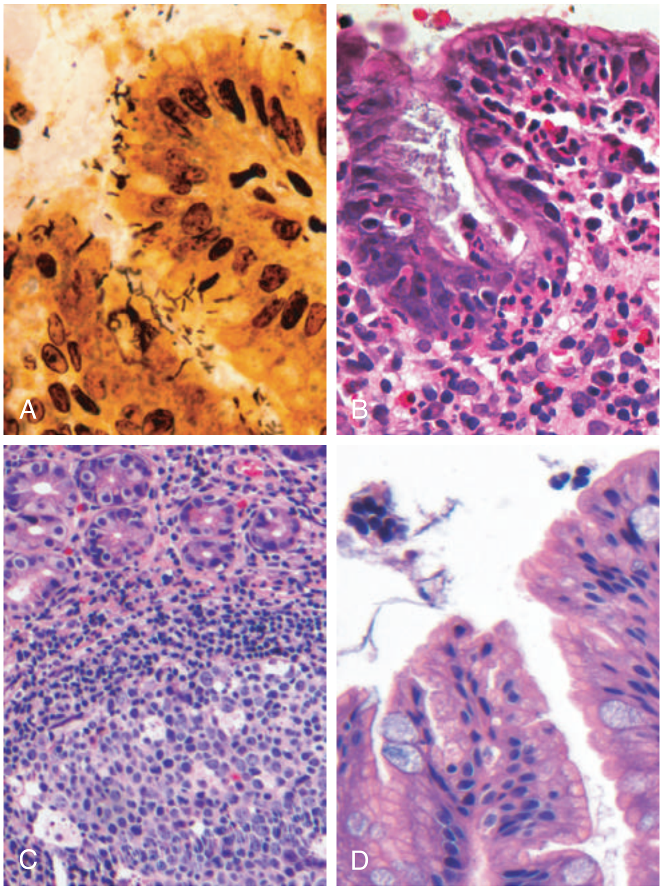

Fig. 15.14 Chronic gastritis. (A) Spiral-shaped *Helicobacter pylori* bacilli are highlighted in this Warthin-Starry silver stain. Organisms are abundant within surface mucus. (B) Intraepithelial and lamina propria neutrophils are prominent. (C) Lymphoid aggregates with germinal centers and abundant subepithelial plasma cells within the superficial lamina propria are characteristic of *H. pylori* gastritis. (D) Intestinal metaplasia, recognizable as the presence of goblet cells admixed with gastric foveolar epithelium, can develop and is a risk factor for development of gastric adenocarcinoma.

- Vitamin B_{12} deficiency leading to pernicious anemia and neurologic changes
- Impaired gastric acid secretion *(achlorhydria)*

Pathogenesis

Autoimmune gastritis is associated with immune-mediated loss of parietal cells and subsequent reductions in acid and intrinsic factor secretion. Deficient acid secretion stimulates gastrin release, resulting in hypergastrinemia and hyperplasia of antral gastrin-producing G cells. Lack of intrinsic factor disables ileal vitamin B_{12} absorption, leading to B_{12} deficiency and a particular form of megaloblastic anemia called pernicious anemia (Chapter 12). Reduced serum concentration of pepsinogen I reflects chief cell loss. Although *H. pylori* can cause hypochlorhydria, it is not associated with achlorhydria or pernicious anemia, because the parietal and chief cell damage is not as severe as in autoimmune gastritis.

MORPHOLOGY

Autoimmune gastritis is characterized by diffuse **damage of the oxyntic** (acid-producing) **mucosa** within the body and fundus. Damage to the antrum and cardia typically is absent or mild. With **diffuse atrophy,** the oxyntic mucosa of the body and fundus appears markedly thinned, and rugal folds are lost. Neutrophils may be present, but the inflammatory infiltrate more commonly is composed of lymphocytes, macrophages, and plasma cells; in contrast with ***H. pylori* gastritis,** the inflammatory reaction most often is deep and centered on the gastric glands. **Parietal and chief cell loss** can be extensive, and **intestinal metaplasia** may develop.

Clinical Features

Antibodies to parietal cells and intrinsic factor are present early in the disease, but B_{12} deficiency and pernicious anemia develop in only a minority of patients. The median age at diagnosis is 60 years, and there is a slight female predominance. Autoimmune gastritis often is associated with other autoimmune diseases but is not linked to specific human leukocyte antigen (HLA) alleles.

COMPLICATIONS OF CHRONIC GASTRITIS

There are three important complications of chronic gastritis: Peptic ulcer disease, mucosal atrophy and intestinal metaplasia, and dysplasia. Each of these is discussed shortly.

Peptic Ulcer Disease

Peptic ulcer disease (PUD) most often is associated with *H. pylori* infection or NSAID use. The imbalances of

Table 15.2 Characteristics of *Helicobacter pylori*–Associated and Autoimmune Gastritis

Feature	*H. pylori*–Associated	Autoimmune
Location	Antrum	Body
Inflammatory infiltrate	Neutrophils, subepithelial plasma cells	Lymphocytes, macrophages
Acid production	Increased to slightly decreased	Decreased
Gastrin	Normal to markedly increased	Markedly increased
Other lesions	Hyperplastic/inflammatory polyps	Neuroendocrine hyperplasia
Serology	Antibodies to *H. pylori*	Antibodies to parietal cells (H^+,K^+-ATPase, intrinsic factor)
Sequelae	Peptic ulcer, adenocarcinoma, lymphoma	Atrophy, pernicious anemia, adenocarcinoma, carcinoid tumor
Associations	Low socioeconomic status, poverty, residence in rural areas	Autoimmune disease; thyroiditis, diabetes mellitus, Graves disease

mucosal defenses and damaging forces that cause chronic gastritis (see Fig. 15.13) are also responsible for PUD. In the United States, NSAID use is becoming the most common cause of gastric ulcers as *H. pylori* infection rates are falling and low-dose aspirin use in the aging population is increasing. PUD may occur in any portion of the gastrointestinal tract exposed to acidic gastric juices but is most common in the gastric antrum and first portion of the duodenum. Peptic (acid-induced) injury may occur in the esophagus as a result of acid reflux (GERD) or acid secretion by ectopic gastric mucosa. Peptic injury in the small intestine may also be associated with gastric heterotopia, including that within a Meckel diverticulum.

Epidemiology

PUD is common and is a frequent cause of physician visits worldwide. It leads to treatment of over 3 million individuals, 190,000 hospitalizations, and 5000 deaths in the United States each year. The lifetime risk for developing an ulcer is approximately 10% for males and 4% for females.

Pathogenesis

H. pylori infection and NSAID use are the primary underlying causes of PUD. More than 70% of PUD cases are associated with *H. pylori* infection and in these individuals PUD generally develops on a background of chronic gastritis. Because only 5% to 10% of *H. pylori*–infected individuals develop ulcers, it is probable that host factors as well as variation among *H. pylori* strains also contribute to the pathogenesis.

Gastric acid is fundamental to the pathogenesis of PUD. Hyperacidity may be caused by *H. pylori* infection, parietal cell hyperplasia, and excessive secretory responses. Insufficient inhibition of stimulatory mechanisms such as gastrin release may also contribute. For example, *Zollinger-Ellison syndrome*, characterized by multiple peptic ulcerations in the stomach, duodenum, and even jejunum, is caused by uncontrolled release of gastrin by a tumor and the resulting massive acid production. Cofactors in peptic ulcerogenesis include chronic NSAID use, as noted; cigarette smoking, which impairs mucosal blood flow and healing; and high-dose corticosteroids, which suppress prostaglandin synthesis and impair healing. Peptic ulcers are more frequent in individuals with alcoholic cirrhosis, chronic obstructive pulmonary disease, chronic renal failure, and hyperparathyroidism. In the latter two conditions, hypercalcemia stimulates gastrin production and thereby increases acid secretion.

MORPHOLOGY

Peptic ulcers are four times more common in the proximal duodenum than in the stomach. Duodenal ulcers usually occur within a few centimeters of the pyloric valve and involve the anterior duodenal wall. Gastric peptic ulcers are predominantly located near the interface of the body and antrum.

Peptic ulcers are solitary in more than 80% of patients. Lesions less than 0.3 cm in diameter tend to be shallow, whereas those over 0.6 cm are likely to be deeper. The classic peptic ulcer is a round to oval, **sharply punched-out defect** (Fig. 15.15A and B). The base of peptic ulcers is smooth and clean as a result of peptic digestion of exudate and on histologic examination is composed of richly vascular granulation tissue (Fig. 15.15C). Ongoing bleeding within the ulcer base may cause life-threatening hemorrhage. **Perforation** is a complication that demands emergent surgical intervention.

Clinical Features

Peptic ulcers are chronic, recurring lesions that occur most often in middle-aged to older adults without obvious precipitating conditions, other than chronic gastritis. A majority of peptic ulcers come to clinical attention after patient complaints of *epigastric burning or aching pain,* although a significant fraction manifest with complications such as *iron deficiency anemia, frank hemorrhage,* or *perforation.* The pain tends to occur 1 to 3 hours after meals during the day, is worse at night, and is relieved by alkali or food. Nausea,

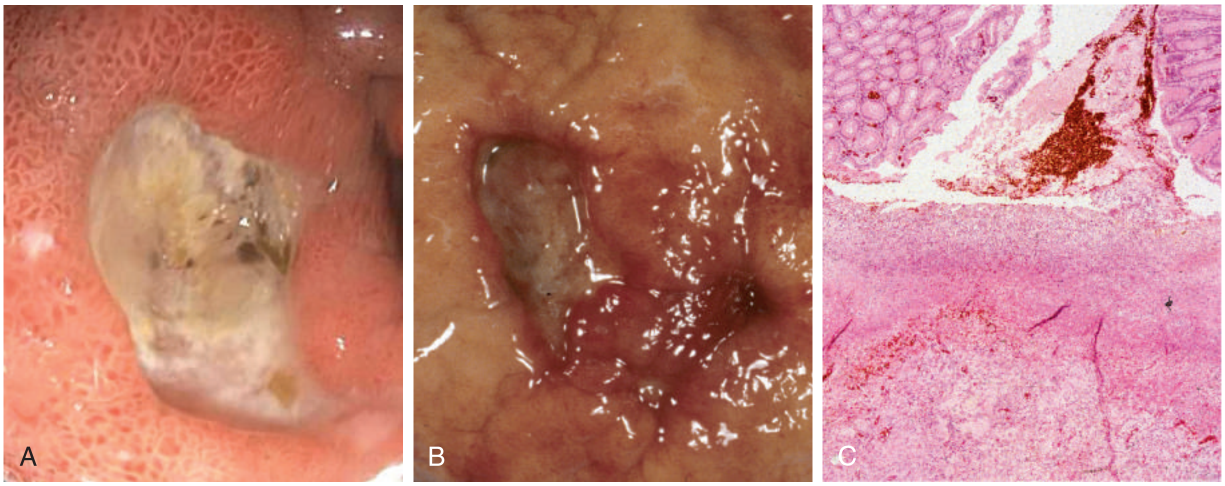

Fig. 15.15 Peptic ulcer disease. (A) Endoscopic view of typical antral ulcer associated with NSAID use. (B) Gross view of a similar ulcer that was resected due to gastric perforation, presenting as free air under the diaphragm. Note the clean edges. (C) The necrotic ulcer base is composed of granulation tissue overlaid by degraded blood. *(Endoscopic image courtesy of Dr. Ira Hanan, The University of Chicago, Chicago, Illinois.)*

vomiting, bloating, and belching may be present. Healing may occur with or without therapy, but the tendency to develop subsequent ulcers remains.

PUD causes much more morbidity than mortality. A variety of surgical approaches were formerly used to treat PUD, but current therapies are aimed at *H. pylori* eradication with antibiotics and neutralization of gastric acid, usually through use of proton pump inhibitors. These efforts have markedly reduced the need for surgical management, which is reserved primarily for treatment of ulcers with uncontrollable bleeding or perforation.

Mucosal Atrophy and Intestinal Metaplasia

Long-standing chronic gastritis may be associated with intestinal metaplasia, recognized by the presence of goblet cells. This is strongly associated with increased risk for development of gastric adenocarcinoma. In addition, the achlorhydria of gastric mucosal atrophy, which is commonly associated with intestinal metaplasia, permits overgrowth of bacteria that produce carcinogenic nitrosamines. Intestinal metaplasia caused by chronic *H. pylori* gastritis may regress after eradication of the organism.

Dysplasia

Chronic gastritis exposes the epithelium to inflammation-related free radical damage and proliferative stimuli. Over time, this can lead to the accumulation of genetic alterations that result in carcinoma. Preinvasive in situ lesions can be recognized histologically as dysplasia, which is marked by variations in epithelial size, shape, and orientation along with coarse chromatin texture, hyperchromasia, and nuclear enlargement. These overlap with and are sometimes difficult to distinguish from injury-associated regenerative changes.

SUMMARY

ACUTE AND CHRONIC GASTRITIS

- Gastritis is a mucosal inflammatory process. When inflammatory cells are absent or rare, the term *gastropathy* can be applied.
- The spectrum of acute gastritis ranges from asymptomatic disease to mild epigastric pain, nausea, and vomiting. Causative factors include any agent or disease that interferes with gastric mucosal protection. Acute gastritis can progress to gastric ulceration.
- The most common cause of chronic gastritis is *H. pylori* infection; most remaining cases are caused by NSAIDs, alcohol, or *autoimmune gastritis*.
- *H. pylori* gastritis typically affects the antrum and is associated with increased gastric acid production.
- *H. pylori* gastritis induces mucosa-associated lymphoid tissue (MALT) that can give rise to B-cell lymphomas (MALTomas).
- *Autoimmune gastritis* causes atrophy of the gastric body oxyntic glands, which results in decreased gastric acid production, antral G-cell hyperplasia, achlorhydria, and vitamin B_{12} deficiency. Anti–parietal cell and anti–intrinsic factor antibodies are typically present.
- *Intestinal metaplasia* develops in both forms of chronic gastritis and is a risk factor for development of gastric dysplasia and adenocarcinoma.
- Peptic ulcer disease can be caused by *H. pylori* chronic gastritis and the resultant hyperchlorhydria or NSAID use. Ulcers can develop in the stomach or duodenum and usually heal after suppression of gastric acid production, discontinuation of NSAID use, or, if present, *H. pylori* eradication.

GASTRIC POLYPS AND TUMORS

Gastric Polyps

Polyps are nodules or masses that project above the level of the surrounding mucosa. They are identified in up to 5% of upper gastrointestinal tract endoscopies. Polyps may develop as a result of epithelial or stromal cell hyperplasia, inflammation, ectopia, or neoplasia. Although many different types of polyps can occur in the stomach, only hyperplastic and inflammatory polyps, fundic gland polyps, and adenomas are considered here.

Inflammatory and Hyperplastic Polyps

Up to 75% of all gastric polyps are *inflammatory* or *hyperplastic polyps.* In the stomach, inflammatory and hyperplastic polyps represent opposite ends of the morphologic spectrum of a single entity; the distinction is based solely on the degree of inflammation. They most commonly affect individuals between 50 and 60 years of age, usually arising in a background of chronic gastritis that initiates the injury and reactive hyperplasia that cause polyp growth. If associated with *H. pylori* gastritis, polyps may regress after bacterial eradication.

The frequency with which dysplasia, a precancerous in situ lesion, develops in these polyps correlates with size; there is a significant increase in risk with polyps larger than 1.5 cm.

Fundic Gland Polyps

Fundic gland polyps occur sporadically and in individuals with familial adenomatous polyposis (FAP) Polyps associated with FAP (but not sporadic) may show dysplasia, but they almost never progress to become malignant. The incidence of sporadic lesions has increased markedly as a result of the widespread use of proton pump inhibitors. This likely results from increased gastrin secretion, in response to reduced acidity, and glandular hyperplasia driven by gastrin. Fundic gland polyps are nearly always asymptomatic, and are usually an incidental finding. These well-circumscribed polyps occur in the gastric body and fundus, often are multiple, and are composed of cystically dilated, irregular glands lined by flattened parietal and chief cells.

Gastric Adenoma

Gastric adenomas represent up to 10% of all gastric polyps. Their incidence increases with age and varies among different populations in parallel with that of gastric

adenocarcinoma. Patients usually are between 50 and 60 years of age, and males are affected three times more often than females. Adenomas almost always occur on a background of chronic gastritis with atrophy and intestinal metaplasia. All gastrointestinal adenomas exhibit epithelial dysplasia, which can be classified as low- or high-grade. The risk for development of adenocarcinoma in gastric adenomas is related to the size of the lesion and is particularly elevated with lesions greater than 2 cm in diameter. Overall, the malignant potential of gastric adenomas is far greater than that of their colonic counterparts. Carcinoma may be present in up to 30% of gastric adenomas.

Gastric Adenocarcinoma

Adenocarcinoma is the most common malignancy of the stomach, comprising more than 90% of all gastric cancers. Early symptoms resemble those of chronic gastritis, including dyspepsia, dysphagia, and nausea. As a result, the cancer is often diagnosed at advanced stages when clinical manifestations such as weight loss, anorexia, altered bowel habits, anemia, and hemorrhage trigger diagnostic evaluation.

Epidemiology

Gastric cancer rates vary markedly with geography. The incidence is up to 20 times higher in Japan, Chile, Costa Rica, and Eastern Europe than in North America, northern Europe, Africa, and Southeast Asia. Mass endoscopic screening programs have been successful in regions of high incidence, such as Japan, where 35% of newly detected cases are *early gastric cancer* (i.e., tumors limited to the mucosa and submucosa). Unfortunately, mass screening programs are not cost-effective in regions in which the incidence is low, and less than 20% of cases are detected at an early stage in North America and northern Europe.

Gastric cancer is more common in lower socioeconomic groups and in individuals with *multifocal mucosal atrophy and intestinal metaplasia.* PUD does not impart an increased risk for development of gastric cancer, but patients who have had partial gastrectomies for PUD have a slightly higher risk for developing cancer in the residual gastric stump as a result of hypochlorhydria, bile reflux, and chronic gastritis.

In the United States, *gastric cancer rates have dropped by more than 85% during the 20th century.* Similar declines have been reported in many other Western countries, reflecting the importance of environmental and dietary factors. Despite this decrease in overall gastric adenocarcinoma incidence, *cancer of the gastric cardia is on the rise.* This trend probably is related to increased rates of Barrett esophagus and may reflect the growing prevalence of obesity and chronic GERD.

Pathogenesis

Gastric cancers are genetically heterogeneous, but certain molecular alterations are common. We will consider these first to be followed by the role of *H. pylori*–induced chronic inflammation and the association of a subset of gastric cancers with EBV infection.

- *Mutations.* While the majority of gastric cancers are not hereditary, mutations identified in familial gastric cancer have provided important insights into the mechanisms of carcinogenesis in sporadic cases. Germ line mutations in *CDH1,* which encodes E-cadherin, a protein that contributes to epithelial intercellular adhesion, are associated with familial gastric cancers, usually of the diffuse type. By comparison, mutations in *CDH1* are present in about 50% of sporadic diffuse gastric tumors, while E-cadherin expression is drastically decreased in the rest, often by methylation of the *CDH1* promoter. *Thus, the loss of E-cadherin function seems to be a key step in the development of diffuse gastric cancer.*

  In contrast to *CDH1,* patients with FAP who have germ line mutations in *adenomatous polyposis coli (APC) genes* have an increased risk for development of intestinal-type gastric cancer. Sporadic intestinal-type gastric cancer is associated with several genetic abnormalities including acquired mutations of β-catenin, a protein that binds to both E-cadherin and APC protein; microsatellite instability; and hypermethylation of genes including *TGFβRII, BAX, IGFRII,* and *p16/INK4a. TP53* mutations are present in a majority of sporadic gastric cancers of both histologic types.
- *H. pylori.* Chronic gastritis, most commonly due to *H. pylori* infection, promotes the development and progression of cancers that may be induced by diverse genetic alterations (Chapter 6). As is the case with many forms of chronic inflammation, *H. pylori*–induced chronic gastritis is associated with increased production of proinflammatory proteins, such as interleukin-1β (IL-1β) and tumor necrosis factor (TNF). It is therefore not surprising that polymorphisms of genes that encode such factors and enhance production of these cytokines confer increased risk for development of chronic gastritis-associated gastric cancer in those with coexisting *H. pylori* infection.
- *Epstein-Barr virus (EBV).* While *H. pylori* is most commonly associated with gastric cancer, approximately 10% of gastric adenocarcinomas are associated with Epstein-Barr virus (EBV) infection. Although the precise role of EBV in the development of gastric adenocarcinomas remains to be defined, it is notable that EBV episomes in these tumors frequently are clonal, suggesting that infection preceded neoplastic transformation. Further, *TP53* mutations are uncommon in EBV-positive gastric tumors, suggesting that the molecular pathogenesis of these cancers is distinct from that of other gastric adenocarcinomas. Morphologically, EBV-positive tumors tend to occur in the proximal stomach and most commonly have a diffuse morphology with a marked lymphocytic infiltrate.

MORPHOLOGY

Gastric adenocarcinomas are classified according to their location in the stomach as well as gross and histologic morphology. The **Lauren classification** that separates gastric cancers into **intestinal** and **diffuse** types correlates with distinct patterns of molecular alterations, as discussed earlier. Intestinal-type cancers tend to be bulky (Fig. 15.16A) and are composed of glandular structures similar to esophageal and colonic

adenocarcinoma. Intestinal-type adenocarcinomas typically grow along broad cohesive fronts to form either an exophytic mass or an ulcerated tumor. The neoplastic cells often contain apical mucin vacuoles, and abundant mucin may be present in gland lumina.

Diffuse gastric cancers display an infiltrative growth pattern (Fig. 15.16B) and are composed of discohesive cells with large mucin vacuoles that expand the cytoplasm and push the nucleus to the periphery, creating a **signet ring cell** morphology (Fig. 15.16C). These cells permeate the mucosa and stomach wall individually or in small clusters. A mass may be difficult to appreciate in diffuse gastric cancer, but these infiltrative tumors often evoke a **desmoplastic** reaction that stiffens the gastric wall and may cause diffuse rugal flattening and a rigid, thickened wall that imparts a "leather bottle" appearance termed ***linitis plastica.***

Clinical Features

Intestinal-type gastric cancer predominates in high-risk areas and develops from precursor lesions such as dysplasia and adenomas. The mean age at presentation is 55 years, and the male-to-female ratio is 2:1. By contrast, the incidence of diffuse gastric cancer is relatively uniform across countries, there are no identified precursor lesions, and the disease occurs at similar frequencies in males and females. Of note, *the decrease in gastric cancer incidence applies only to the intestinal type,* which is most closely associated with atrophic gastritis and intestinal metaplasia. As a result, the incidences of intestinal and diffuse types of gastric cancers are now similar in some regions.

The depth of invasion and the extent of nodal and distant metastasis at the time of diagnosis remain the most powerful prognostic indicators for gastric cancer. Local invasion into the duodenum, pancreas, and retroperitoneum is also characteristic. When possible, surgical resection remains the preferred treatment for gastric adenocarcinoma. After surgical resection, the 5-year survival rate for early gastric cancer can exceed 90%, even if lymph node metastases are present. By contrast, the 5-year survival rate for advanced gastric cancer remains below 20%, in large part because current chemotherapy regimens are have limited impact. This is changing slowly with individualized therapies. For example, patients whose tumors over-express the epidermal growth factor receptor HER2 benefit from agents that inhibit HER2 signaling. Nevertheless, most gastric cancers are discovered at advanced stage in the United States, and the overall 5-year survival rate is less than 30%.

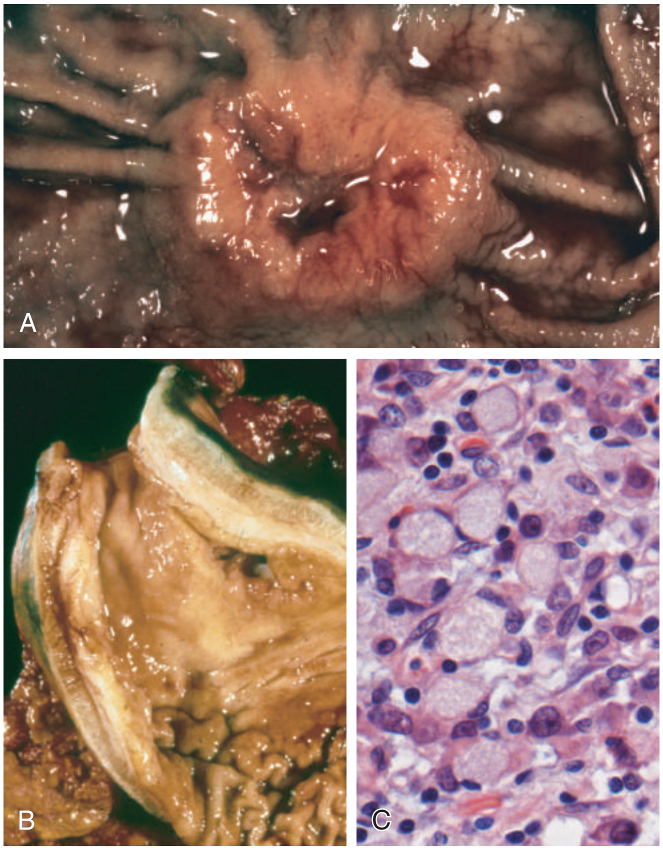

Fig. 15.16 Gastric adenocarcinoma. (A) Intestinal-type adenocarcinoma consisting of an elevated mass with heaped-up borders and central ulceration. Compare with the peptic ulcer in Fig. 15.15A. (B) Linitis plastica. The gastric wall is markedly thickened, and rugal folds are partially lost. (C) Signet ring cells with large cytoplasmic mucin vacuoles and peripherally displaced, crescent-shaped nuclei.

Lymphoma

Although extranodal lymphomas can arise in virtually any tissue, they do so most commonly in the gastrointestinal tract, particularly the stomach. In allogeneic hematopoietic stem cell and organ transplant recipients, the bowel also is the most frequent site for Epstein-Barr virus–positive B cell lymphoproliferations. Nearly 5% of all gastric malignancies are primary lymphomas, the most common of which are indolent extranodal marginal zone B-cell lymphomas. In the gut, these tumors often are referred to as lymphomas of *MALT,* or *MALTomas.* This entity and the second most common primary lymphoma of the gut, diffuse large B cell lymphoma, are discussed in Chapter 12.

Neuroendocrine (Carcinoid) Tumor

Neuroendocrine tumors, also referred to as *carcinoid tumors,* arise from neuroendocrine organs (e.g., the endocrine pancreas) and neuroendocrine-differentiated gastrointestinal epithelia (e.g., G cells). A majority of these tumors are found in the gastrointestinal tract, and more than 40% occur in the small intestine. The tracheobronchial tree and lungs are the next most commonly involved sites. Gastric neuroendocrine tumors may be associated with endocrine cell hyperplasia, chronic atrophic gastritis, and Zollinger-Ellison syndrome. These tumors were called "carcinoid" because they are slower growing than carcinomas. The most current WHO classification describes these as low- or intermediate-grade neuroendocrine tumors. High-grade neuroendocrine tumors, termed *neuroendocrine carcinoma,* resemble small cell carcinoma of the lung (Chapter 13) and, in the gastrointestinal tract, are most common in the jejunum.

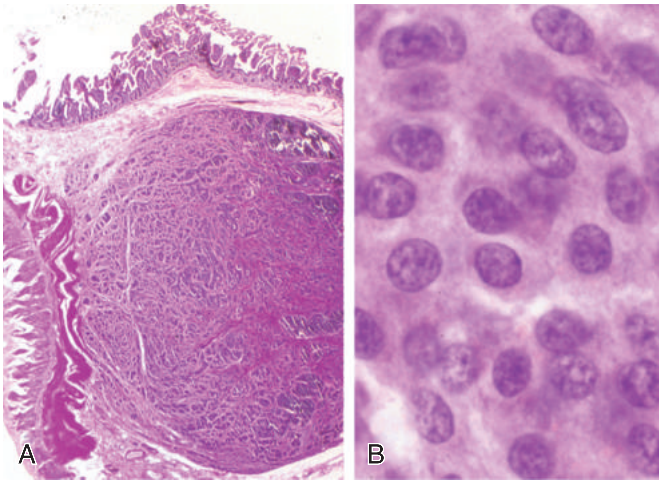

Fig. 15.17 Gastrointestinal carcinoid tumor (neuroendocrine tumor). (A) Carcinoid tumors often form a submucosal nodule composed of tumor cells embedded in dense fibrous tissue. (B) High magnification shows the bland cytology that typifies neuroendocrine tumors. The chromatin texture, with fine and coarse clumps, frequently assumes a "salt-and-pepper" pattern. Despite their innocuous appearance, tumors can be aggressive.

MORPHOLOGY

Neuroendocrine tumors are intramural or submucosal masses that create small polypoid lesions (Fig. 15.17A). The tumors are yellow or tan in appearance and elicit an intense desmoplastic reaction that may cause kinking of the bowel and obstruction. On histologic examination, neuroendocrine tumors are composed of islands, trabeculae, strands, glands, or sheets of uniform cells with scant, pink granular cytoplasm and a round-to-oval stippled nucleus (Fig. 15.17B).

Clinical Features

The peak incidence of neuroendocrine tumors is in the sixth decade, but they may appear at any age. Symptoms are determined by the hormones produced. For example, the *carcinoid syndrome* is caused by vasoactive substances secreted by the tumor that cause cutaneous flushing, sweating, bronchospasm, colicky abdominal pain, diarrhea, and right-sided cardiac valvular fibrosis. When tumors are confined to the intestine, the vasoactive substances released are metabolized to inactive forms by the liver—a "first-pass" effect similar to that seen with oral drugs. Thus, carcinoid syndrome occurs in less than 10% of patients and is *strongly associated with metastatic disease.*

The most important prognostic factor for gastrointestinal neuroendocrine tumors is location:

- *Foregut neuroendocrine (carcinoid) tumors* found within the stomach, duodenum proximal to the ligament of Treitz, and esophagus, rarely metastasize and are generally cured by resection. Rare duodenal gastrin-producing neuroendocrine tumors, also termed *gastrinomas,* may present with symptoms related to increased acid production, including pain and/or bleeding from gastroduodenal ulcers, refractory gastroesophageal reflux, and diarrhea due to inactivation of pancreatic enzymes by excessive gastric acid.
- *Midgut neuroendocrine (carcinoid) tumors* arise in the jejunum and ileum, are often multiple and tend to be aggressive. In these tumors, depth of local invasion, size, and the presence of necrosis and mitoses are associated with poor outcome.
- *Hindgut neuroendocrine (carcinoid)* tumors arising in the appendix and colorectum are typically discovered incidentally. Those in the appendix occur at any age and are almost uniformly pursue a benign course. Rectal tumors tend to produce polypeptide hormones and may manifest with abdominal pain and weight loss. Because they are usually discovered when small, metastasis of rectal neuroendocrine tumors is uncommon.

Gastrointestinal Stromal Tumor

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of the abdomen, and more than half of these tumors occur in the stomach. A wide variety of other mesenchymal neoplasms may arise in the stomach. Many are named according to the cell type they most resemble; for example, smooth muscle tumors are called *leiomyomas* or *leiomyosarcomas,* nerve sheath tumors are termed *schwannomas,* and those resembling glomus bodies in the nail beds and at other sites are termed *glomus tumors.* These tumors are all rare and are not discussed here.

Pathogenesis

The most common genetic change underlying the pathogenesis of GISTs is gain-of-function mutations of the gene encoding the tyrosine kinase KIT, the receptor for stem cell factor. These are present in 75% to 85% of all GISTs. An additional 8% of GISTs have mutations that activate a related tyrosine kinase, platelet-derived growth factor receptor A (PDGFRA). The term *stromal* reflects historical confusion about the origin of this tumor, which is now recognized to arise from the interstitial cells of Cajal, or pacemaker cells, of the gastrointestinal muscularis propria. For unknown reasons, GISTs bearing *PDGFRA* mutations are overrepresented in the stomach. *KIT* and *PDGFRA* gene mutations are mutually exclusive, reflecting their activities within the same signal transduction pathway. Germ line mutations in these same genes are present in rare familial GISTs, in which patients develop multiple GISTs and may also have diffuse hyperplasia of Cajal cells.

Both sporadic and germ line mutations result in constitutively active KIT or PDGFRA receptor tyrosine kinases and produce intracellular signals that promote tumor cell proliferation and survival (Chapter 6). In GISTs without *KIT* or *PDGFRA* mutations, genes encoding components of the mitochondrial succinate dehydrogenase (SDH) complex are most commonly affected. These mutations result in loss of SDH function and confer increased risk for both GIST and paraganglioma. One mutant allele is often inherited, with the second copy of the gene being either mutated or otherwise lost in the tumor. The loss of SDH causes a number of metabolic changes, including increased production of reactive oxygen species, activation of hypoxia induced factor (HIF), and increased dependency

on glycolysis for ATP production, but how these alterations lead to transformation is uncertain.

MORPHOLOGY

Primary gastric GISTs usually form a solitary, well-circumscribed, fleshy, submucosal mass. Metastases may form multiple small serosal nodules or fewer large nodules in the liver; spread outside of the abdomen is uncommon. GISTs can be composed of thin, elongated **spindle cells** or plumper **epithelioid cells.** The most useful diagnostic marker is KIT, which is immunohistochemically detectable in 95% of these tumors.

Clinical Features

The peak incidence of gastric GIST is around 60 years of age, with less than 10% occurring in individuals younger than 40 years of age. Overall, GISTs are slightly more common in males. Small GISTs may come to clinical attention incidentally during work-up of other GI symptoms, which are common. Larger GISTs may present with symptoms related to mass effects or mucosal ulceration, such as intestinal obstruction or gastrointestinal bleeding. Complete surgical resection is the primary treatment for localized gastric GIST. The prognosis correlates with tumor size, mitotic index, and location, *with gastric GISTs being somewhat less aggressive than those arising in the small intestine.* Recurrence or metastasis is rare for gastric GISTs less than 5 cm in diameter but common for mitotically active tumors larger than 10 cm. Tumors that are unresectable or metastatic often respond, sometimes for years, to tyrosine kinase inhibitors that are active against KIT and PDGFRA, such as imatinib. Unfortunately, as in chronic myeloid leukemia (Chapter 12), resistance to imatinib eventually arises due to outgrowth of subclones with additional mutations in KIT or PDGFRA. In some instances, these tumors respond to other tyrosine kinase inhibitors that retain activity against KIT and PDGFRA.

SUMMARY

GASTRIC POLYPS AND TUMORS

- *Inflammatory and hyperplastic gastric polyps* are reactive lesions associated with chronic gastritis. Risk for development of dysplasia increases with polyp size.
- *Gastric adenomas* develop in a background of chronic gastritis and are particularly associated with intestinal metaplasia and mucosal (glandular) atrophy. Adenocarcinoma frequently arises in gastric adenomas, which therefore require complete excision and surveillance to detect recurrence.
- *Gastric adenocarcinomas* are classified according to location and gross and histologic morphology. Those with an intestinal histologic pattern tend to form bulky tumors and may be ulcerated, whereas those composed of mucus-filled signet ring cells typically display a diffuse infiltrative growth pattern that may thicken the gastric wall (linitis plastica) without forming a discrete mass.
- *H. pylori* infection is the most common etiologic agent for gastric adenocarcinoma, but other associations, including chronic atrophic gastritis and EBV infection, suggest several possible pathways of neoplastic transformation.
- *Primary gastric lymphomas* most often are derived from the mucosa-associated lymphoid tissue whose development is induced by chronic gastritis.
- Low- or intermediate-grade *neuroendocrine (carcinoid) tumors* arise from the diffuse components of the endocrine system and are most common in the gastrointestinal tract, particularly the small intestine. Tumors of the small intestine tend to be most aggressive, while those of the appendix are almost always benign.
- *Gastrointestinal stromal tumor (GIST)*, the most common mesenchymal tumor of the abdomen, occurs most often in the stomach. GISTs arise from benign pacemaker cells, also known as the *interstitial cells of Cajal.* A majority of tumors have activating mutations in either the c-KIT or the PDGFRA tyrosine kinases and respond to kinase inhibitors.

Small and Large Intestines

The small intestine and colon are the sites of a wide variety of diseases, many of which affect nutrient and water transport. Perturbation of these processes may cause malabsorption and diarrhea. The intestines are also the principal site where the immune system interfaces with a diverse array of antigens present in food and gut microbes. Recent advances have defined the composition and diversity of the gut microbiome, which is largely unculturable, using molecular approaches. One common trend is the association of reduced microbial diversity in disease. The gut microbiome is also exquisitely sensitive to diet, which may partly explain the association between food allergy and other diet-induced diseases and altered composition of the microbiome. Thus, it is not surprising that the small intestine and colon frequently are involved by infectious and inflammatory processes. The colon is the most common site of gastrointestinal neoplasia in Western populations.

INTESTINAL OBSTRUCTION

Obstruction of the gastrointestinal tract may occur at any level, but the small intestine is most often involved because of its relatively narrow lumen. Collectively, *hernias, intestinal adhesions, intussusception,* and *volvulus* account for 80% of mechanical obstructions (Fig. 15.18), while tumors and infarction account for most of the remainder. The clinical manifestations of intestinal obstruction include abdominal pain and distention, vomiting, and constipation. Surgical intervention is usually required in cases involving

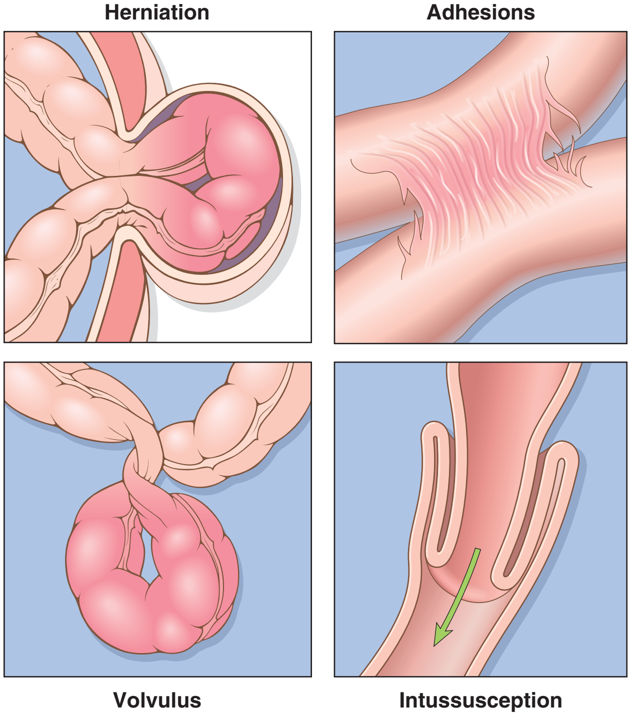

Fig. 15.18 Intestinal obstruction. The four major mechanical causes of intestinal obstruction are (1) herniation of a segment in the umbilical or inguinal regions, (2) adhesion between loops of intestine, (3) volvulus, and (4) intussusception.

mechanical obstruction or severe infarction. Volvulus and adhesions between bowel loops are well illustrated in Fig. 15.18. Brief comments are made next about the other causes of obstruction.

Intussusception

Intussusception occurs when a segment of the intestine, constricted by a wave of peristalsis, telescopes into the immediately distal segment. Once trapped, the invaginated segment is propelled by peristalsis and pulls the mesentery along. Untreated intussusception may progress to intestinal obstruction, compression of mesenteric vessels, and infarction. *Intussusception is the most common cause of intestinal obstruction in children younger than 2 years of age.* There usually is no underlying anatomic defect and the child is otherwise healthy. Other cases are associated with viral infection and rotavirus vaccines and may be related to reactive hyperplasia of Peyer patches, which can act as the leading edge of the intussusception. Contrast enemas are diagnostically useful and also are effective in correcting idiopathic intussusception in infants and young children. However, surgical intervention is necessary when an intraluminal mass or tumor serves as the initiating point of traction, as is typical in older children and in adults.

Hirschsprung Disease

***Hirschsprung disease* occurs in approximately 1 of 5000 live births and stems from a congenital defect in colonic innervation.** It may be isolated or occur in combination with other developmental abnormalities. It is more common in males but tends to be more severe in females. Siblings are at increased risk for development of Hirschsprung disease.

Patients typically present as neonates with failure to pass meconium in the immediate postnatal period followed by obstructive constipation. The major threats to life are enterocolitis, fluid and electrolyte disturbances, perforation, and peritonitis. Surgical resection of the aganglionic segment with anastomosis of the normal colon to the rectum is effective, although it may take years for patients to attain normal bowel function and continence.

Pathogenesis

The enteric neuronal plexus develops from neural crest cells that migrate into the bowel wall during embryogenesis. Hirschsprung disease, also known as *congenital aganglionic megacolon,* results when the normal migration of neural crest cells from cecum to rectum is disrupted. This produces a distal intestinal segment that lacks both the Meissner submucosal plexus and the Auerbach myenteric plexus ("aganglionosis"), and thus fails to develop coordinated peristaltic contractions. **Mutations in the receptor tyrosine kinase RET account for a majority of familial cases** and approximately 15% of sporadic cases. Mutations in other genes, including disease-modifying genes, as well as environmental factors must also be involved.

MORPHOLOGY

Hirschsprung disease always affects the rectum, but the length of the additional involved segments varies. Most cases are limited to the rectum and sigmoid colon, but severe disease can involve the entire colon. The aganglionic region may have a grossly normal or contracted appearance, while the normally innervated proximal colon may undergo progressive dilation as a result of functional distal obstruction (Fig. 15.19). Diagnosis is made by demonstrating the absence of ganglion cells in the affected segment.

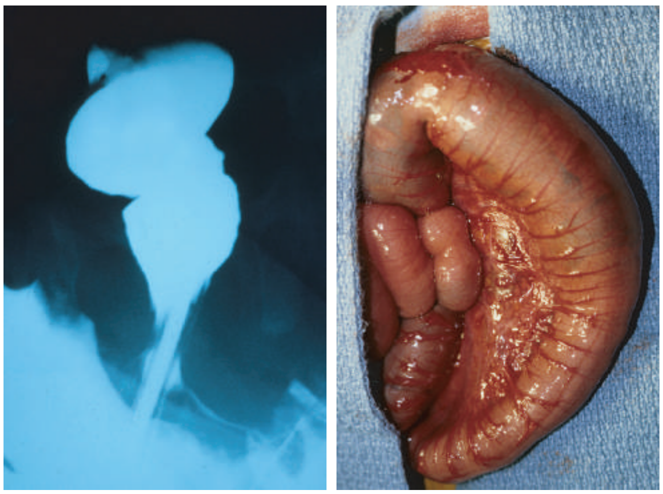

Fig. 15.19 Hirschsprung disease. (A) Preoperative barium enema study showing constricted rectum *(bottom)* and dilated sigmoid colon. Ganglion cells were absent in the rectum, but present in the sigmoid colon. (B) Corresponding intraoperative appearance of the dilated sigmoid colon. *(Courtesy of Dr. Aliya Husain, The University of Chicago, Chicago, Illinois.)*

Abdominal Hernia

Any weakness or defect in the wall of the peritoneal cavity may permit protrusion of a serosa-lined pouch of peritoneum called a *hernia sac.* Acquired hernias most commonly occur anteriorly, through the inguinal and femoral canals or umbilicus, or at sites of surgical scars. These are of concern because of visceral protrusion *(external herniation).* This is particularly true of inguinal hernias, which tend to have narrow orifices and large sacs. Small bowel loops herniate most often, but portions of omentum or large bowel also protrude, and any of these may become entrapped. Pressure at the neck of the pouch may impair venous drainage, leading to stasis and edema. These changes increase the bulk of the herniated loop, leading to permanent entrapment, or *incarceration,* and over time, arterial and venous compromise, or *strangulation,* can result in infarction.

SUMMARY

INTESTINAL OBSTRUCTION

- *Intussusception* is the most common cause of intestinal obstruction in children younger than 2 years of age and can usually be treated by barium enema or air enema.
- *Hirschsprung disease* is the result of defective neural crest cell migration from cecum to rectum. It gives rise to functional obstruction.
- *Abdominal herniation* may occur through any weakness or defect in the wall of the peritoneal cavity, including inguinal and femoral canals, umbilicus, and sites of surgical scarring.

VASCULAR DISORDERS OF BOWEL

The largest portion of the gastrointestinal tract is supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. As they approach the intestinal wall, the superior and inferior mesenteric arteries fan out to form the mesenteric arcades. Interconnections between arcades, as well as collateral supplies from the proximal celiac and distal pudendal and iliac circulations make it possible for the small intestine and colon to tolerate slowly progressive loss of the blood supply from one artery. By contrast, acute compromise of any major vessel can lead to infarction of several meters of intestine.

Ischemic Bowel Disease

Ischemic damage to the bowel can range from mucosal infarction, extending no deeper than the muscularis mucosa; to mural infarction of mucosa and submucosa; to transmural infarction involving all three layers of the wall. While mucosal or mural infarctions often are secondary to acute or chronic hypoperfusion, transmural infarction is generally caused by acute vascular obstruction. Important causes of acute arterial obstruction include severe atherosclerosis (which is often prominent at the origin of mesenteric vessels), aortic aneurysm, hypercoagulable states, oral contraceptive use, and embolization of cardiac vegetations or aortic atheromas. Intestinal hypoperfusion can also be associated with cardiac failure, shock, dehydration, or vasoconstrictive drugs. Systemic vasculitides also may damage intestinal arteries. While mesenteric venous thrombosis can lead to ischemic disease, it is uncommon. Other causes include invasive neoplasms, cirrhosis, portal hypertension, trauma, or abdominal masses that compress the portal drainage.

Pathogenesis

The severity of vascular compromise, time frame during which it develops, and vessels affected are the major variables that determine severity of ischemic bowel disease. Intestinal responses to ischemia occur in two phases. The initial hypoxic injury occurs at the onset of vascular compromise and, although some damage occurs, intestinal epithelial cells are relatively resistant to transient hypoxia. The second phase, reperfusion injury, is initiated by restoration of the blood supply and associated with the greatest damage. While the underlying mechanisms of reperfusion injury are incompletely understood, they involve free radical production, neutrophil infiltration, and inflammatory mediators such as complement and cytokines. Two aspects of intestinal vascular anatomy also contribute to the distribution of ischemic damage:

- *Watershed zones* refers to intestinal segments at the end of their respective arterial supplies that are particularly susceptible to ischemia. These zones include the splenic flexure, where the superior and inferior mesenteric arterial circulations terminate, and, to a lesser extent, the sigmoid colon and rectum where inferior mesenteric, pudendal, and iliac arterial circulations end. Generalized hypotension or hypoxemia can therefore cause localized injury at these sites, and ischemic disease should be considered in the differential diagnosis for focal colitis of the splenic flexure or rectosigmoid colon.
- *Patterns of intestinal microvessls.* Intestinal capillaries run alongside the glands, from crypt to surface, before making a hairpin turn at the surface to empty into the postcapillary venules. This configuration leaves the surface epithelium particularly vulnerable to ischemic injury. Thus, surface epithelial atrophy, or even necrosis and epithelial sloughing, with normal or hyperproliferative crypts constitutes a morphologic signature of ischemic intestinal disease.

MORPHOLOGY

Despite the increased susceptibility of watershed zones, **mucosal and mural infarction** may involve any level of the gut from stomach to anus. Involvement is frequently segmental and patchy, and the mucosa is hemorrhagic and often ulcerated. The bowel wall is thickened by edema that may involve the mucosa or extend into the submucosa and muscularis propria. With severe disease, pathologic changes include extensive mucosal and submucosal hemorrhage and necrosis, but serosal hemorrhage and serositis generally are absent. Damage is more pronounced in acute arterial thrombosis and **transmural infarction.** Blood-tinged mucus or blood accumulates within the lumen.

Coagulative necrosis of the muscularis propria occurs within 1 to 4 days and may be associated with purulent serositis and perforation.

Microscopic examination of ischemic intestine demonstrates **atrophy or sloughing of surface epithelium** (Fig. 15.20A). By contrast, crypts may be hyperproliferative. Inflammatory infiltrates are initially absent in acute ischemia, but neutrophils are recruited within hours of reperfusion. Chronic ischemia is accompanied by fibrous scarring of the lamina propria (Fig. 15.20B) and, uncommonly, stricture formation. In acute phases of ischemic damage, bacterial superinfection and enterotoxin release may induce pseudomembrane formation that can resemble *Clostridium difficile*–associated pseudomembranous colitis (discussed later).

Clinical Features

Ischemic bowel disease tends to occur in older adults with coexisting cardiac or vascular disease. Acute transmural infarction typically manifests with sudden, severe abdominal pain and tenderness, sometimes accompanied by nausea, vomiting, bloody diarrhea, or grossly melanotic stool. This presentation may progress to shock and vascular collapse within hours as a result of blood loss. Peristaltic sounds diminish or disappear, and muscular spasm creates boardlike rigidity of the abdominal wall. Because these physical signs overlap with those of other abdominal emergencies, including acute appendicitis, perforated ulcer, and acute cholecystitis, the diagnosis of intestinal infarction may be delayed or missed, with disastrous consequences. As the mucosal barrier breaks down, bacteria enter the circulation and sepsis can develop; the mortality rate in these cases may exceed 50%.

The overall progression of ischemic enteritis depends on the underlying cause and severity of injury:

- *Mucosal and mural infarctions* by themselves may not be fatal. However, these may progress to more extensive, transmural infarction if the vascular supply is not restored by correction of the insult or, in chronic disease, by development of adequate collateral supplies.
- *Chronic ischemia* may masquerade as inflammatory bowel disease, with episodes of bloody diarrhea interspersed with periods of healing.

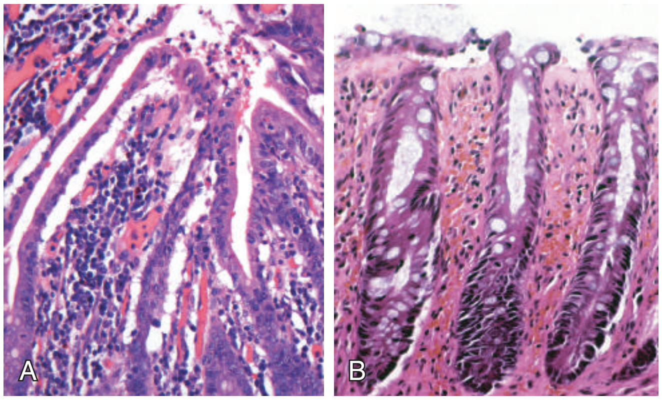

Fig. 15.20 Ischemia. (A) Characteristic attenuated and partially detached villous epithelium in acute jejunal ischemia. Note the hyperchromatic nuclei of proliferating crypt cells. (B) Chronic colonic ischemia with atrophic surface epithelium and fibrotic lamina propria.

- *Cytomegalovirus (CMV) infection* causes ischemic gastrointestinal disease as a consequence of the viral tropism for and infection of endothelial cells. CMV infection can be a complication of immunosuppressive therapy (Chapter 9).
- *Radiation enterocolitis* occurs when the gastrointestinal tract is irradiated. In addition to epithelial damage, radiation-induced vascular injury may be significant and produce changes that are similar to ischemic disease.
- *Necrotizing enterocolitis* is an idiopathic disorder of the small and large intestines that can result in transmural necrosis. It is the most common acquired gastrointestinal emergency of neonates, particularly those who are premature or of low birth weight. Its occurrence is often associated with initiation of oral feeding (Chapter 7). Although pathogenesis of necrotizing enterocolitis is not defined, ischemic injury is thought to contribute.
- *Angiodysplasia,* characterized by malformed submucosal and mucosal blood vessels, occurs most often in the cecum or right colon, and usually presents after the sixth decade of life. Although it affects less than 1% of the adult population, *angiodysplasia accounts for 20% of major episodes of lower intestinal bleeding.*

Hemorrhoids

Hemorrhoids are dilated anal and perianal collateral vessels that connect the portal and caval venous systems to relieve elevated venous pressure within the hemorrhoid plexus. Thus, although hemorrhoids are less serious than esophageal varices, the pathogenesis of these lesions is similar. They are common, affecting about 5% of the general population. Common predisposing factors include constipation and associated straining, which increase intraabdominal and venous pressures, venous stasis of pregnancy, and portal hypertension.

Collateral vessels within the inferior hemorrhoidal plexus are located below the anorectal line and are termed **external hemorrhoids,** while those that result from dilation of the superior hemorrhoidal plexus within the distal rectum are referred to as **internal hemorrhoids.** On histologic examination, hemorrhoids consist of thin-walled, dilated, submucosal vessels beneath anal or rectal mucosa. These vessels are subject to trauma, which leads to rectal bleeding. In addition, they can become thrombosed and inflamed.

Hemorrhoids often manifest with pain and rectal bleeding, particularly bright red blood seen on toilet tissue. Hemorrhoids also may develop as a result of portal hypertension, where the implications are more ominous. Hemorrhoidal bleeding generally is not a medical emergency; treatment options include sclerotherapy, rubber band ligation, and infrared coagulation. In severe cases, hemorrhoids may be removed surgically by *hemorrhoidectomy.*

SUMMARY

VASCULAR DISORDERS OF BOWEL

- Intestinal ischemia can occur as a result of either *arterial or venous obstruction.*
- Ischemic bowel disease resulting from hypoperfusion is most common at the splenic flexure, sigmoid colon, and rectum;

these are *watershed zones* where two arterial circulations terminate.
- Systemic vasculitides and infectious diseases (e.g., CMV infection) can cause vascular disease that is not confined to the gastrointestinal tract.
- Angiodysplasia is a common cause of lower gastrointestinal bleeding in older adults.
- Hemorrhoids are collateral vessels that form in response to venous hypertension.

DIARRHEAL DISEASE

Diarrhea is defined as an increase in stool mass, frequency, or fluidity, typically to amounts greater than 200 grams per day. In severe cases, stool volume can exceed 14 L per day and, without fluid resuscitation, result in death. Worldwide, diarrheal diseases account for greater than 700,000 deaths of children under 5 years of age, making them the second leading cause of death in this age group. Painful, bloody, small-volume diarrhea is known as *dysentery.* Diarrhea is a common symptom of many intestinal diseases, including those due to infection, inflammation, ischemia, malabsorption, and nutritional deficiency. It can be classified into four major categories:

- *Secretory diarrhea* is characterized by isotonic stool and persists during fasting.
- *Osmotic diarrhea,* such as that occurring with lactase deficiency, is due to osmotic forces exerted by unabsorbed luminal solutes. The diarrheal fluid is at least 50 mOsm more concentrated than plasma, and the condition abates with fasting.
- *Malabsorptive diarrhea* caused by inadequate nutrient absorption is associated with steatorrhea and is relieved by fasting.
- *Exudative diarrhea* is due to inflammatory disease and characterized by purulent, bloody stools that continue during fasting.

We begin our discussion with malabsorptive diarrhea. Other disorders associated with secretory and exudative types of diarrhea (e.g., cholera and inflammatory bowel disease, respectively) are addressed in separate sections.

Malabsorptive Diarrhea

Malabsorption manifests most commonly as *chronic diarrhea* and is characterized by defective absorption of fats, fat- and water-soluble vitamins, proteins, carbohydrates, electrolytes, minerals, and water. Chronic malabsorption causes weight loss, anorexia, abdominal distention, borborygmi, and muscle wasting. A hallmark of malabsorption is *steatorrhea,* characterized by excessive fecal fat and bulky, frothy, greasy, yellow, or clay-colored stools. *The chronic malabsorptive disorders most commonly encountered in Western countries are pancreatic insufficiency, celiac disease, and Crohn disease.* Environmental enteric dysfunction, or environmental enteropathy, which has a malabsorptive component, is pervasive in some communities within developing countries.

Malabsorption results from disturbance in at least one of the four phases of nutrient absorption:

- *Intraluminal digestion,* in which proteins, carbohydrates, and fats are broken down into absorbable forms
- *Terminal digestion,* which involves the hydrolysis of carbohydrates and peptides by disaccharidases and peptidases, respectively, in the brush border of the small-intestinal mucosa
- *Transepithelial transport,* in which nutrients, fluid, and electrolytes are transported across and processed within the small-intestinal epithelium
- *Lymphatic transport* of absorbed lipids

In many malabsorptive disorders, a defect in one of these processes predominates, but more than one usually contributes (Table 15.3). As a result, malabsorption syndromes resemble each other more than they differ. Signs and symptoms include diarrhea (from nutrient

Table 15.3 Defects in Malabsorptive and Diarrheal Disease

+, Indicates that the process can be abnormal in the disease indicated. Other processes are not typically affected.

malabsorption and excessive intestinal secretion), flatus, abdominal pain, and weight loss. Inadequate absorption of vitamins and minerals can result in anemia and mucositis due to pyridoxine, folate, or vitamin B_{12} deficiency; bleeding due to vitamin K deficiency; osteopenia and tetany due to calcium, magnesium, or vitamin D deficiency; or neuropathy due to vitamin A or B_{12} deficiency. A variety of endocrine and skin disturbances may also occur. Mycobacterial infection, which can be lead to lymphatic transport defects, is discussed with infectious causes of diarrhea in the next section.

Cystic Fibrosis

Cystic fibrosis is discussed in greater detail elsewhere (Chapter 7). Only the malabsorption associated with cystic fibrosis is considered here. Owing to mutations of the epithelial cystic fibrosis transmembrane conductance regulator *(CFTR)*, individuals with cystic fibrosis have defects in intestinal and pancreatic ductal ion transport. This abnormality interferes with bicarbonate, sodium, and water secretion, ultimately resulting in inadequate luminal hydration. The viscous luminal contents may result in meconium ileus, which is present in up to 10% of newborns with cystic fibrosis. In the pancreas the ducts are plugged by thick mucus. This leads to obstruction, low-grade chronic autodigestion of the pancreas, and eventual *exocrine pancreatic insufficiency in more than 80% of patients.* The result is failure of the intraluminal phase of nutrient absorption, which can be effectively treated in most patients with oral enzyme supplementation.

Celiac Disease

***Celiac disease*, also known as *celiac sprue* or *gluten-sensitive enteropathy*, is an immune-mediated enteropathy triggered by the ingestion of gluten-containing cereals, such as wheat, rye, or barley, in genetically predisposed individuals.** In countries whose populations consist predominantly of whites of European ancestry, celiac disease is a common disorder, with an estimated prevalence of 0.5% to 1%. The primary treatment for celiac disease is a *gluten-free diet*, which results in symptomatic improvement for most patients.

Pathogenesis

Celiac disease is an intestinal immune reaction to gluten, the major storage protein of wheat and similar grains. Gluten is digested by luminal and brush border enzymes into amino acids and peptides, including a 33–amino acid gliadin peptide that is resistant to degradation by gastric, pancreatic, and small-intestinal proteases (Fig. 15.21). Gliadin is deamidated by tissue transglutaminase and is then able to interact with HLA-DQ2 or HLA-DQ8 on antigen-presenting cells and be presented to CD4+ T cells. These T cells in lamina propria produce cytokines that likely contribute to the tissue damage and characteristic mucosal histopathology. An antibody response follows: This includes production of antibodies against tissue transglutaminase, deamidated gliadin, and, perhaps as a result of cross-reactive epitopes, anti-endomysial antibodies, which can be diagnostically useful. They may also be used to monitor disease, as titers typically fall after 3 to 6 months of gluten-free diet. However, whether these antibodies contribute to celiac disease pathogenesis or are merely markers of immune activation remains controversial. In addition to CD4+ cells, there is an accumulation of CD8+ cells that are not specific for gliadin but may play an ancillary role in causing tissue damage. It is thought that deamidated gliadin peptides induce epithelial cells to produce the cytokine IL-15, which in turn triggers activation and proliferation of CD8+ intraepithelial lymphocytes that become cytotoxic and kill

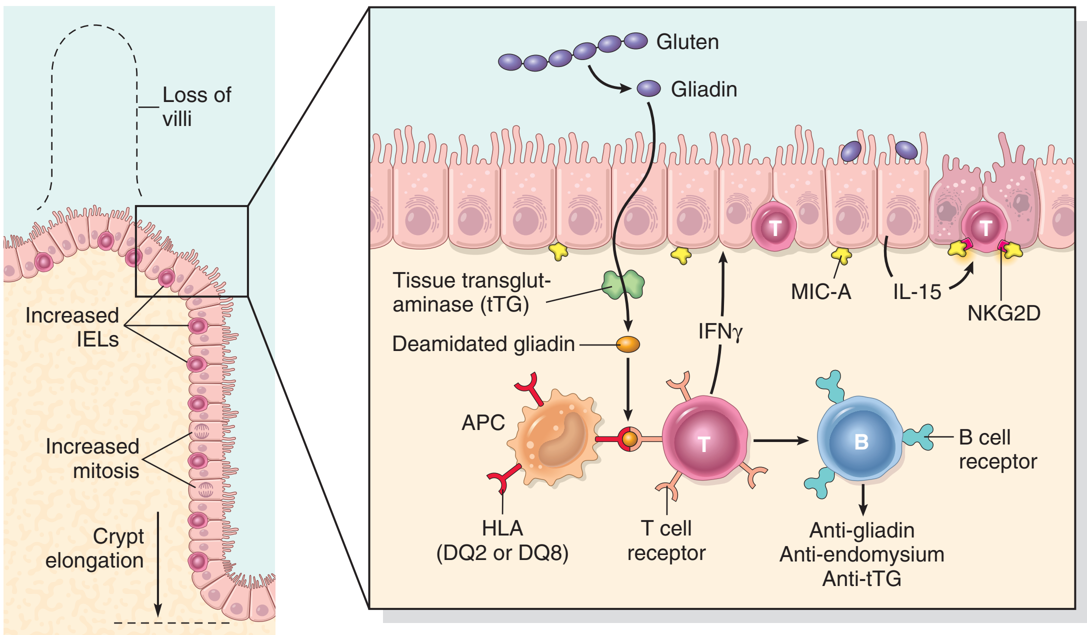

Fig. 15.21 The morphologic alterations that may be present in celiac disease, including varying degrees of villous atrophy, increased numbers of intraepithelial lymphocytes (IELs), and epithelial proliferation with crypt elongation *(left)*. A model for the pathogenesis of celiac disease *(right)*. Note that both innate and adaptive immune mechanisms are involved in the tissue responses to gliadin. CD4 T cells (producing IFNγ) are shown in lamina propria and CD8 T cells, expressing NKG2D receptor, in between epithelial cells.

enterocytes that have been induced by various stressors to express surface MIC-A. This molecule is recognized by the NKG2D receptor on activated CD8+ T cells. The damage caused by these immune mechanisms may increase the movement of gliadin peptides across the epithelium, which are then deamidated by tissue transglutaminase, thus perpetuating the cycle of disease.

While nearly all individuals eat grain and are exposed to gluten and gliadin, most do not develop celiac disease. Thus, host factors determine whether disease develops. Among these, HLA proteins seem to be critical, since almost all individuals with celiac disease carry the class II HLA-DQ2 or HLA-DQ8 alleles. There is also an association of celiac disease with other immune diseases including type 1 diabetes, thyroiditis, and Sjögren syndrome.

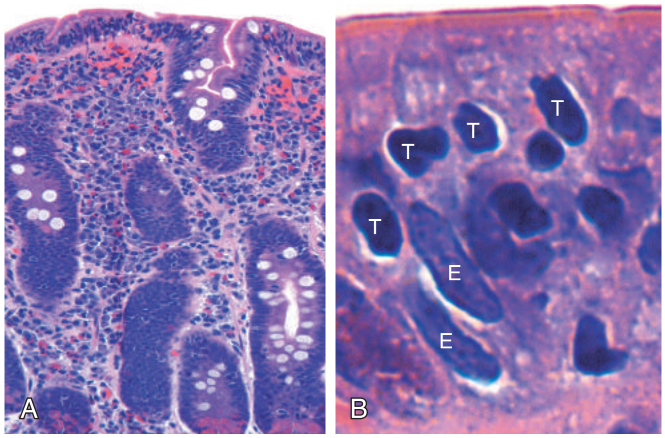

Fig. 15.22 Celiac disease. (A) Advanced cases of celiac disease show complete loss of villi, or total villous atrophy. Note the dense plasma cell infiltrates in the lamina propria. (B) Infiltration of the surface epithelium by T lymphocytes, which can be recognized by their densely stained nuclei (labeled *T*). Compare with elongated, pale-staining epithelial nuclei (labeled *E*).

MORPHOLOGY

Biopsy specimens from the second portion of the duodenum or proximal jejunum, which are exposed to the highest concentrations of dietary gluten, are generally diagnostic in celiac disease. The histopathology is characterized by increased numbers of T lymphocytes, with **intraepithelial lymphocytosis, crypt hyperplasia**, and **villous atrophy** (Fig. 15.22). This loss of mucosal and brush-border surface area due to villous atrophy probably accounts for the malabsorption. In addition, increased rates of epithelial turnover, reflected in increased crypt mitotic activity, may limit the ability of absorptive enterocytes to fully differentiate and express proteins necessary for terminal digestion and transepithelial transport. Other histologic features of celiac disease can include increased numbers of plasma cells, mast cells, and eosinophils, especially within the upper part of the lamina propria. It should be noted that intraepithelial lymphocytosis and villous atrophy can be present in other disorders, including viral enteritis. The combination of histologic and serologic findings is, therefore, most specific for diagnosis of celiac disease.

Clinical Features

Pediatric celiac disease, which affects male and female children equally, may manifest with *classic symptoms,* typically between 6 and 24 months of age (after introduction of gluten to the diet) with irritability, abdominal distention, anorexia, diarrhea, failure to thrive, weight loss, or muscle wasting. Children with *nonclassic symptoms* tend to present at older ages with complaints of abdominal pain, nausea, vomiting, bloating, or constipation. A characteristic pruritic, blistering skin lesion, *dermatitis herpetiformis,* is also present in as many as 10% of patients, and the incidence of *lymphocytic gastritis* and *lymphocytic colitis* is increased as well.

In adults, celiac disease manifests most commonly between 30 and 60 years of age. However, many cases escape clinical attention for extended periods because of atypical presentations. Some patients have silent celiac disease, defined as positive serology and villous atrophy without symptoms, or latent celiac disease, in which positive serology is accompanied neither by villous atrophy nor symptoms. Symptomatic adult celiac disease is often associated with anemia (due to iron deficiency and, less commonly, B_{12} and folate deficiency), diarrhea, bloating, and fatigue.

Noninvasive serologic tests are generally performed before biopsy. The most sensitive tests are the presence of IgA antibodies to tissue transglutaminase or IgA or IgG antibodies to deamidated gliadin. Anti-endomysial antibodies are highly specific but less sensitive than other antibodies.

Patients with celiac disease exhibit a higher than normal rate of malignancy. The most common celiac disease–associated cancer is *enteropathy-associated T cell lymphoma,* an aggressive tumor of intraepithelial T lymphocytes. *Small-intestinal adenocarcinoma* also is more frequent in individuals with celiac disease. Thus, when symptoms such as abdominal pain, diarrhea, and weight loss develop despite a strict gluten-free diet, cancer or *refractory sprue,* in which the response to a gluten-free diet is lost, must be considered. It is, however, important to recognize that failure to adhere to a gluten-free diet is the most common cause of recurrent symptoms, and that most individuals with celiac disease do well with dietary restrictions and die of unrelated causes.

Environmental Enteric Dysfunction

The term *environmental enteric dysfunction, or environmental enteropathy,* refers to a syndrome of stunted growth and impaired intestinal function that is common in developing countries, including many parts of sub-Saharan Africa, such as Zambia; aboriginal populations within northern Australia; and some groups within South America and Asia, such as residents of impoverished communities within Brazil, Guatemala, India, and Pakistan. The impact of environmental enteric dysfunction, which was previously grouped under headings of *tropical enteropathy* or *tropical sprue,* cannot be overstated, as it is estimated to affect over 150 million children worldwide. Although malnutrition most likely contributes to the pathogenesis of this disorder, neither supplementary feeding nor vitamin and mineral supplementation are able to fully reverse the syndrome. Repeated bouts of diarrhea suffered within the first 2 or 3 years of life are most closely linked to environmental enteropathy, but no single

infectious agent has been established as causal in these diarrheal episodes. Intestinal biopsy specimens have been examined in only a small number of cases, and the reported histopathology has some overlap with severe celiac disease as well as infectious enteritis.

Lactase (Disaccharidase) Deficiency

Lactase deficiency gives rise to osmotic diarrhea because, in its absence, osmotically active lactose remains in the lumen. The disaccharidases, including lactase, are located in the apical brush border membrane of villous absorptive epithelial cells. Because the defect is biochemical, biopsies are generally unremarkable. Lactase deficiency is of two types:

- *Congenital lactase deficiency* is an autosomal recessive disorder caused by mutations in the gene encoding lactase. The disease is rare and manifests as explosive diarrhea with watery, frothy stools and abdominal distention after milk ingestion. Symptoms abate when exposure to milk and milk products is terminated.
- *Acquired lactase deficiency* is caused by downregulation of lactase gene expression and is particularly common among Native Americans, African Americans, and Chinese populations. Downregulation of lactase occurs in the gut after childhood, perhaps reflecting the fact that, before farming of dairy animals, lactase was unnecessary after children stopped drinking mother's milk. Onset of acquired lactase deficiency is sometimes associated with enteric viral or bacterial infections.

Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive disease characterized by an inability to secrete triglyceride-rich lipoproteins. Although rare, it is an example of a transepithelial transport defect leading to malabsorption. Mutation in the *microsomal triglyceride transfer protein* renders enterocytes unable to export lipoproteins and free fatty acids. As a result, monoglycerides and triglycerides accumulate within the epithelial cells. Abetalipoproteinemia manifests in infancy, and the clinical picture is dominated by failure to thrive, diarrhea, and steatorrhea. Failure to absorb essential fatty acids leads to deficiencies of fat-soluble vitamins, and lipid defects in plasma membranes often produce acanthocytic red blood cells (spur cells) in peripheral blood smears.

Microscopic Colitis

Microscopic colitis encompasses two entities, *collagenous colitis* and *lymphocytic colitis.* Both of these idiopathic diseases manifest with chronic, nonbloody, watery diarrhea without weight loss. Findings on radiologic and endoscopic studies typically are normal. Collagenous colitis, which occurs primarily in middle-aged and older women, is characterized by the presence of a dense subepithelial collagen layer, increased numbers of intraepithelial lymphocytes, and a mixed inflammatory infiltrate within the lamina propria. Lymphocytic colitis is histologically similar, but the subepithelial collagen layer is of normal thickness and the increase in intraepithelial, predominantly T lymphocytes, may be greater. Lymphocytic colitis is associated with celiac disease and autoimmune diseases, including thyroiditis, arthritis, and autoimmune or lymphocytic gastritis.

Graft-Versus-Host Disease

Graft-versus-host disease occurs after allogeneic hematopoietic stem cell transplantation. The small bowel and colon are involved in most cases. Although graft-versus-host disease is caused by donor T cell–mediated damage to the recipient's epithelial cells, the lymphocytic infiltrate in the lamina propria is typically sparse, suggesting that cytokines secreted by T cells may be the major mediators of tissue injury. Epithelial apoptosis, particularly of crypt cells, is the most common histologic finding. Intestinal graft-versus-host disease often manifests as watery diarrhea.

SUMMARY

MALABSORPTIVE DIARRHEA

- Diarrhea can be characterized as *secretory*, *osmotic*, *malabsorptive*, or *exudative*.
- The malabsorption associated with cystic fibrosis is the result of *pancreatic insufficiency* (i.e., inadequate pancreatic digestive enzymes) and *deficient luminal breakdown* of nutrients.
- *Celiac disease* is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains. The malabsorptive diarrhea in celiac disease is due to *loss of brush border surface area* and, possibly, deficient enterocyte maturation.
- *Lactase deficiency* causes an *osmotic diarrhea* owing to the inability to break down or absorb lactose.
- *Abetalipoproteinemia* is characterized by an inability to secrete triglyceride-rich lipoproteins due to an inherited transepithelial transport defect.
- The two forms of microscopic colitis, *collagenous colitis* and *lymphocytic colitis*, both cause chronic watery diarrhea. The intestines are grossly normal, and the diseases are identified by their histologic features.

Infectious Enterocolitis

This global problem is responsible for more than 1 million deaths annually and greater than 10% of all deaths in patients younger than 5 years of age worldwide. Enterocolitis presents with a broad range of signs and symptoms, including diarrhea, abdominal pain, urgency, perianal discomfort, incontinence, and hemorrhage. Bacterial infections, such as enterotoxigenic *Escherichia coli,* are frequently responsible, but the most common pathogens vary with age, nutrition, and host immune status, as well as environment (Table 15.4). For example, epidemics of cholera are common in areas with poor sanitation, as a result of inadequate public health measures, or as a consequence of natural disaster (e.g., the Haitian earthquake of 2010) or war. Pediatric infectious diarrhea, which may result in severe dehydration and metabolic acidosis, is commonly caused by enteric viruses. A summary of the epidemiology and clinical features of selected causes of bacterial enterocolitis is presented in Table 15.4. Representative bacterial, viral, and parasitic enterocolitides are discussed next.

Cholera

Vibrio cholerae organisms are comma-shaped, gram-negative bacteria that cause cholera, a disease that has

Table 15.4 Features of Bacterial Enterocolitides

Infection Type	Geography	Reservoir	Transmission	Epidemiology	Affected GI Sites	Symptoms	Complications
Cholera	India, Africa	Shellfish	Fecal-oral, water	Sporadic, endemic, epidemic	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
Campylobacter spp.	Developed countries	Chickens, sheep, pigs, cattle	Poultry, milk, other foods	Sporadic; children, travelers	Colon	Watery or bloody diarrhea	Arthritis, Guillain-Barré syndrome
Shigellosis	Worldwide, endemic in developing countries	Humans	Fecal-oral, food, water	Children, migrant workers, travelers, nursing homes	Left colon, ileum	Bloody diarrhea	Reactive arthritis, urethritis, conjunctivitis, hemolytic-uremic syndrome
Salmonellosis	Worldwide	Poultry, farm animals, reptiles	Meat, poultry, eggs, milk	Children, older adults	Colon, small intestine	Watery or bloody diarrhea	Sepsis, abscess
Enteric (typhoid) fever	India, Mexico, Philippines	Humans	Fecal-oral, water	Children. adolescents, travelers	Small intestine	Bloody diarrhea, fever	Chronic infection, carrier state, encephalopathy, myocarditis, intestinal perforation
Yersinia spp.	Northern and central Europe	Pigs, cows, puppies, cats	Pork, milk, water	Clustered cases	Ileum, appendix, right colon	Abdominal pain, fever, diarrhea	Reactive arthritis, erythema nodosum
Escherichia coli							
Enterotoxigenic (ETEC)	Developing countries	Unknown	Food or fecal-oral	Infants, adolescents, travelers	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
Enteropathogenic (EPEC)	Worldwide	Humans	Fecal-oral	Infants	Small intestine	Watery diarrhea	Dehydration, electrolyte imbalances
Enterohemorrhagic (EHEC)	Worldwide	Widespread, includes cattle	Beef, milk, produce	Sporadic and epidemic	Colon	Bloody diarrhea	Hemolytic-uremic syndrome
Enteroinvasive (EIEC)	Developing countries	Unknown	Cheese, other foods, water	Young children	Colon	Bloody diarrhea	Unknown
Enteroaggregative (EAEC)	Worldwide	Unknown	Unknown	Children, adults, travelers	Colon	Nonbloody diarrhea, afebrile	Poorly defined
Pseudomembranous colitis (*C. difficile*)	Worldwide	Humans, hospitals	Antibiotics allow emergence	Immunosuppressed, antibiotic-treated	Colon	Watery diarrhea, fever	Relapse, toxic megacolon
Whipple disease	Rural > urban	Unknown	Unknown	Rare	Small intestine	Malabsorption	Arthritis, CNS disease
Mycobacterial infection	Worldwide	Unknown	Unknown	Immunosuppressed, endemic	Small intestine	Malabsorption	Pneumonia, infection at other sites

CNS, Central nervous system; *GI,* gastrointestinal.

been endemic in the Ganges Valley of India and Bangladesh for all of recorded history. *V. cholerae* is transmitted primarily by contaminated drinking water. However, it can also be present in food and causes rare cases of seafood-associated disease. There is a marked seasonal variation in most locales due to rapid growth of *Vibrio* bacteria at warm temperatures. The only animal reservoirs are shellfish and plankton.

Pathogenesis

***Vibrio* organisms are noninvasive but cause disease by producing a toxin that interferes with the absorptive function of enterocytes.** Flagellar proteins, which are involved in motility and attachment, are necessary for efficient bacterial colonization, and a secreted metalloproteinase that also has hemagglutinin activity is important for bacterial detachment and shedding in the stool. However, it is the *preformed enterotoxin,* cholera toxin, which causes disease. The toxin, which is composed of five B subunits that direct endocytosis and a single active A subunit, is delivered to the endoplasmic reticulum by *retrograde transport.* A fragment of the A subunit is transported from the endoplasmic reticulum lumen into the cytosol, where it interacts with cytosolic ADP ribosylation factors to ribosylate and activate the G protein $G_{s\alpha}$. This stimulates adenylate cyclase, and the resulting increases in intracellular cyclic adenosine monophosphate (cAMP) open the cystic fibrosis transmembrane conductance regulator (CFTR), which releases chloride ions into the lumen. This creates an osmotic gradient that draws water into the lumen, leading to massive *secretory diarrhea.* Remarkably, mucosal biopsy specimens show only minimal morphologic alterations.

Clinical Features

Most exposed individuals are asymptomatic or suffer only mild diarrhea. Those with severe disease have an abrupt onset of watery diarrhea and vomiting after an incubation period of 1 to 5 days. The volume of diarrhea may reach 1 L per hour, leading to dehydration, hypotension, electrolyte imbalances, muscular cramping, anuria, shock, loss of consciousness, and death. Most deaths occur within the first 24 hours of presentation. Although the mortality rate for severe cholera is 50% to 70% without treatment, fluid replacement can save more than 99% of patients.

Campylobacter Enterocolitis

***Campylobacter jejuni* is the most common bacterial enteric pathogen in developed countries and is an important cause of traveler's diarrhea.** Most infections are associated with ingestion of improperly cooked chicken, but outbreaks also can be caused by unpasteurized milk or contaminated water.

Pathogenesis

The pathogenesis of *Campylobacter* infection remains poorly defined, but four major virulence properties contribute: motility, adherence, toxin production, and invasion. Flagella allow *Campylobacter* to be motile. This facilitates adherence and colonization, which are also necessary for mucosal invasion. Cytotoxins that cause epithelial damage and a cholera toxin–like enterotoxin are also released by some *C. jejuni* isolates. *Dysentery* or bloody diarrhea, is generally associated with invasion and only occurs with a small minority of *Campylobacter* strains. *Enteric fever* occurs when bacteria proliferate within the lamina propria and mesenteric lymph nodes.

Campylobacter infection can result in reactive arthritis, primarily in patients with HLA-B27. Other extraintestinal complications, including erythema nodosum and Guillain-Barré syndrome (Chapter 22), a flaccid paralysis caused by autoimmune-induced inflammation of peripheral nerves, are not HLA-linked. Fortunately, Guillain-Barré syndrome develops in 0.1% or less of individuals infected with *Campylobacter.*

MORPHOLOGY

Campylobacter, Shigella, Salmonella, and many other bacterial infections, including ***Yersinia*** and ***E. coli,*** all induce a similar microscopic picture, termed ***acute self-limited colitis.*** Specific diagnosis is primarily by stool culture. The histology of acute self-limited colitis includes prominent lamina propria and intraepithelial neutrophil infiltrates (Fig. 15.23A); **cryptitis** (neutrophil infiltration of the crypts) and **crypt abscesses** (crypts with accumulations of luminal neutrophils) also may be present. The preservation of crypt architecture in most cases of acute self-limited colitis is helpful in distinguishing these infections from chronic inflammatory illnesses such as inflammatory bowel disease (Fig. 15.23B).

Clinical Features

Ingestion of as few as 500 *C. jejuni* organisms can cause disease after an incubation period of up to 8 days. Watery diarrhea, either acute or with onset after an influenza like prodrome, is the primary manifestation, and dysentery develops in 15% to 50% of patients. Patients may shed

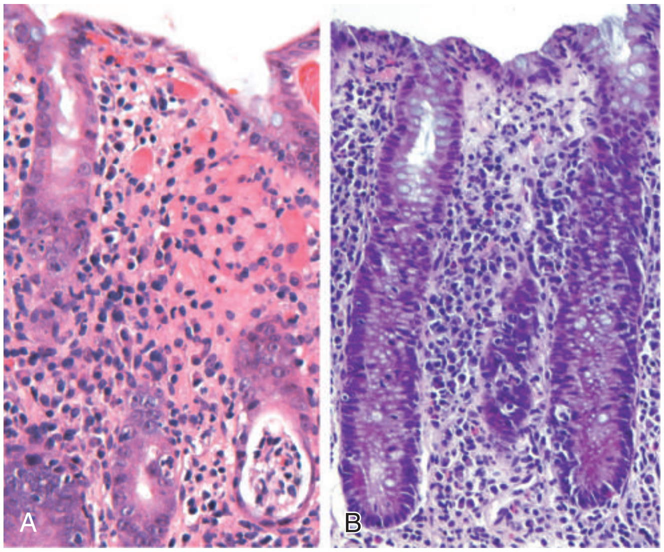

Fig. 15.23 Bacterial enterocolitis. (A) *Campylobacter jejuni* infection produces acute, self-limited colitis. Neutrophils can be seen within surface and crypt epithelium, and a crypt abscess is present *(lower right).* (B) Enteroinvasive *Escherichia coli* infection is similar to other acute, self-limited colitides. Note the maintenance of normal crypt architecture and spacing, despite abundant intraepithelial neutrophils.

bacteria for 1 month or more after clinical resolution. The disease is self-limited, and antibiotic therapy generally is not required.

Shigellosis

***Shigella* are gram-negative bacilli that are unencapsulated, nonmotile, facultative anaerobes responsible for one of the most common causes of bloody diarrhea.** Shigellae are highly transmissible by the fecal-oral route or through ingestion of contaminated water and food; the *infective dose is fewer than 100 organisms,* and each gram of stool contains as many as 10^9 organisms during acute phases of the disease.

In the United States and Europe, children in day care centers, migrant workers, travelers to developing countries, and residents of nursing homes are most commonly affected. Most *Shigella*-associated infections and deaths occur in children younger than 5 years of age; in countries in which *Shigella* is endemic, it is responsible for approximately 10% of all cases of pediatric diarrheal disease and as many as 75% of diarrheal deaths.

Pathogenesis

***Shigella* organisms are resistant to the harsh acidic environment of the stomach, which partially explains the very low infective dose.** Once in the intestine, organisms are taken up by M (microfold) epithelial cells, which are specialized for sampling and uptake of luminal antigens. After intracellular proliferation, the bacteria escape into the lamina propria. These bacteria then infect small-intestinal and colonic epithelial cells through the basolateral membranes, which express bacterial receptors. Alternatively, luminal shigellae can directly modulate epithelial tight junctions to expose basolateral bacterial receptors. The latter is partly mediated by virulence proteins, some of which are directly injected into the host cytoplasm by a type III secretion system. Some *Shigella dysenteriae* serotypes also release the Shiga toxin Stx, which inhibits eukaryotic protein synthesis and causes host cell death.

MORPHOLOGY

Shigella infections are most prominent in the left colon, but the ileum may also be involved, perhaps reflecting the abundance of M cells in the epithelium overlying Peyer patches. The histologic appearance in early cases is similar to that in other acute self-limited colitides. In more severe cases, the mucosa is hemorrhagic and ulcerated, and pseudomembranes may be present. Perhaps because of the tropism for M cells, aphthous-appearing ulcers similar to those seen in Crohn disease also may occur. The potential for confusion with chronic inflammatory bowel disease is substantial, particularly if there is distortion of crypt architecture.

Clinical Features

***Shigella* causes self-limited disease characterized by about 6 days of diarrhea, fever, and abdominal pain.** After an incubation period of 1 to 7 days, the initial watery diarrhea progresses to a dysenteric phase in approximately 50% of patients, and constitutional symptoms can persist for as long as 1 month. A subacute presentation also can develop in a minority of adults. Antibiotic treatment shortens the clinical course and reduces the duration over which organisms are shed in the stool, but anti-diarrheal medications are contraindicated because they can prolong symptoms by delaying bacterial clearance.

Complications of *Shigella* infection are uncommon and include *reactive arthritis,* a triad of sterile arthritis, urethritis, and conjunctivitis that preferentially affects HLA-B27–positive men between 20 and 40 years of age. Hemolytic uremic syndrome, which typically is associated with *enterohemorrhagic Escherichia coli (EHEC),* also may occur after infection with shigellae that secrete Shiga toxin.

Escherichia coli

Escherichia coli are gram-negative bacilli that colonize the healthy gastrointestinal tract; most are nonpathogenic, but a subset cause human disease. The latter are classified according to morphology, mechanism of pathogenesis, and in vitro behavior (see Table 15.4). Here we summarize their pathogenic mechanisms:

- *Enterotoxigenic E. coli (ETEC) organisms* are the principal cause of traveler's diarrhea, and are spread by the fecal-oral route. They express a heat-labile toxin (LT) that is similar to cholera toxin and a heat-stable toxin (ST) that increases intracellular cGMP with effects similar to the cAMP elevations caused by LT.
- *Enteropathogenic E. coli (EPEC) organisms* are characterized by their ability to produce attaching and effacing (A/E) lesions in which bacteria attach tightly to the enterocyte apical membranes and cause local loss (i.e., effacement) of the microvilli. The proteins necessary for creating A/E lesions are all encoded by a large genomic pathogenicity island, the locus of enterocyte effacement (LEE). This locus also encodes a type III secretion system, similar to that in *Shigella,* that injects bacterial effector proteins into the epithelial cell cytoplasm. EPEC can cause endemic diarrhea as well as diarrheal outbreaks particularly in children younger than 2 years of age.
- *Enterohemorrhagic E. coli (EHEC) organisms* are categorized as O157:H7 and non-O157:H7 serotypes. Outbreaks of *E. coli* O157:H7 in developed countries have been associated with the consumption of inadequately cooked ground beef, milk, and vegetables. Both O157:H7 and non-O157:H7 serotypes produce Shiga-like toxins and can cause dysentery. They can also trigger hemolytic-uremic syndrome (Chapter 14).
- *Enteroinvasive E. coli (EIEC) organisms* resemble *Shigella* bacteriologically but do not produce toxins. They invade the gut epithelial cells and produce a bloody diarrhea.
- *Enteroaggregative E. coli (EAEC) organisms* attach to enterocytes by adherence fimbriae. Although they produce LT and Shiga-like toxins, histologic damage is minimal.

Salmonellosis

***Salmonella* species, which are members of the Enterobacteriaceae family of gram-negative bacilli, are divided into *Salmonella typhi*, the causative agent of typhoid fever and nontyphoid *Salmonella* strains that cause gastroenteritis.** Nontyphoid *Salmonella* infection usually is due to *Salmonella enteritidis;* more than 1 million cases occur each year in the United States, which result in 2000 deaths; the

prevalence is greater in many other countries. Infection is most common in young children and older adults, with a peak incidence in summer and fall. Transmission usually is through contaminated food, particularly raw or undercooked meat, poultry, eggs, and milk.

Pathogenesis

Very few viable *Salmonella* organisms are necessary to cause infection, and the absence of gastric acid, as in individuals with atrophic gastritis or those on acid-suppressive therapy, further reduces the required inoculum. Salmonellae possess *virulence genes that encode a type III secretion system* capable of transferring bacterial proteins into M cells and enterocytes. The transferred proteins activate host cell Rho GTPases, thereby triggering actin rearrangement and bacterial uptake into phagosomes where the bacteria can grow. Salmonellae also secrete a molecule that induces epithelial release of a chemoattractant eicosanoid that draws neutrophils into the lumen and potentiates mucosal damage. Stool cultures are essential for diagnosis.

Typhoid Fever

Typhoid fever, also referred to as *enteric fever,* is caused by *Salmonella typhi* and *Salmonella paratyphi*. It affects up to 30 million individuals worldwide each year. Infection by *S. typhi* is more common in endemic areas, where children and adolescents are most often affected. By contrast, *S. paratyphi* predominates in travelers and those living in developed countries. Humans are the sole reservoir for *S. typhi* and *S. paratyphi,* and transmission occurs from person to person or via contaminated food or water. Gallbladder colonization may be associated with gallstones and a chronic carrier state. Acute infection is associated with anorexia, abdominal pain, bloating, nausea, vomiting, and bloody diarrhea followed by a short asymptomatic phase that gives way to bacteremia and fever with flulike symptoms. It is during this phase that detection of organisms by blood culture may prompt antibiotic treatment and prevent further disease progression. Cultures are positive in 90% of cases during the febrile phase Without such treatment, the febrile phase is followed by up to 2 weeks of sustained high fevers with abdominal tenderness that may mimic appendicitis. *Rose spots,* small erythematous maculopapular lesions, are seen on the chest and abdomen. Systemic dissemination may cause *extraintestinal complications* including encephalopathy, meningitis, seizures, endocarditis, myocarditis, pneumonia, and cholecystitis. Patients with sickle cell disease are particularly susceptible to *Salmonella* osteomyelitis.

Like *S. enteritidis, S. typhi* and *S. paratyphi* are taken up by M cells and then engulfed by mononuclear cells in the underlying lymphoid tissue. Thus, infection causes Peyer patches in the terminal ileum to enlarge into plateau like elevations up to 8 cm in diameter. Mucosal shedding creates oval ulcers oriented along the long axis of the ileum. However, unlike *S. enteritidis, S. typhi* and *S. paratyphi* can disseminate via lymphatic and blood vessels. This causes reactive hyperplasia of draining lymph nodes, in which bacteria-containing phagocytes accumulate. In addition, the spleen is enlarged and soft with pale red pulp, obliterated follicular markings, and prominent phagocyte hyperplasia. Randomly scattered small foci of parenchymal necrosis with macrophage aggregates, termed *typhoid nodules,* can be found in the liver, bone marrow, and lymph nodes. Definitive diagnosis depends on positive blood cultures. Serologic tests are of limited utility, especially in endemic areas unless rising titers of antibodies can be demonstrated.

Pseudomembranous Colitis

Pseudomembranous colitis, generally caused by *C. difficile,* also is referred to as *antibiotic-associated colitis* or *antibiotic-associated diarrhea.* While antibiotic-associated diarrhea also may be caused by other organisms such as *Salmonella, C. perfringens* type A, or *Staphylococcus aureus,* only *C. difficile* causes pseudomembranous colitis. It is likely that disruption of the normal colonic microbiota by antibiotics allows *C. difficile* overgrowth. Almost any antibiotic may be responsible; the most important determinants of the disease are frequency of use and the effect on colonic microbiota. Toxins released by *C. difficile* cause the ribosylation of small GTPases, such as Rho, and lead to disruption of the epithelial cytoskeleton, tight junction barrier loss, cytokine release, and apoptosis.

MORPHOLOGY

Fully developed *C. difficile*–associated colitis is accompanied by formation of **pseudomembranes** (Fig. 15.24A), made up of an adherent layer of inflammatory cells and debris at sites of colonic mucosal injury. The surface epithelium is denuded, and the superficial lamina propria contains a dense infiltrate of neutrophils and occasional fibrin thrombi within capillaries. Damaged crypts are distended by a mucopurulent exudate that "erupts" to the surface in a fashion reminiscent of a volcano (Fig. 15.24B).

Clinical Features

In addition to antibiotic exposure, risk factors for *C. difficile*–associated colitis include advanced age, hospitalization,

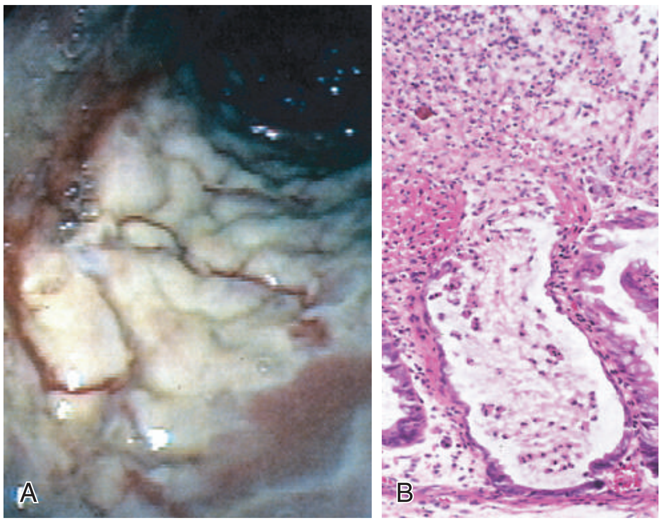

Fig. 15.24 *Clostridium difficile* colitis. (A) The colon is coated by tan pseudomembranes composed of neutrophils, dead epithelial cells, and inflammatory debris (endoscopic view). (B) Typical pattern of neutrophils emanating from a crypt is reminiscent of a volcanic eruption.

and immunosuppression. The organism is particularly prevalent in hospitals; as many as 20% of hospitalized adults are colonized with *C. difficile* (a rate 10 times higher than in the general population), but most colonized patients are free of disease. Individuals with *C. difficile*–associated colitis usually present with watery diarrhea and abdominal cramping; dehydration, fever, and leukocytosis may be seen in more severe cases. Fecal leukocytes and occult blood may be present, but grossly bloody diarrhea is rare. Diagnosis of *C. difficile*–associated colitis usually is accomplished by detection of *C. difficile* toxin, rather than culture, and is supported by the characteristic histopathologic findings. Regimens of metronidazole or vancomycin are generally effective treatments, but antibiotic-resistant and hypervirulent *C. difficile* strains are increasingly common, and the infection may recur in at-risk patients. Recent reports suggest that, particularly in patients with recurrent disease, fecal microbial transplantation may restore a normal microbiota and lead to lasting cure.

Mycobacterial Infection

Mycobacterial species, including *M. tuberculosis, M. bovis,* and *M. avium* species can involve the gastrointestinal tract primarily or be part of disseminated infection. Gastrointestinal tuberculosis is uncommon in Western countries, except in immunosuppressed individuals. In such cases, *M. avium* infection is most common. In endemic areas, including India and Pakistan, intestinal *M. tuberculosis* generally presents in the third and fourth decades of life and typically afflicts those of lower socioeconomic status. In such settings, primary intestinal infection is more common than disseminated disease. As the incidence of Crohn disease increases in these areas, differentiation between *M. tuberculosis* and Crohn disease has become more difficult.

M. avium tends to accumulate within the cytoplasm and distend lamina propria histiocytes. In some cases, this may result in a sheet-like expansion of histiocytes that fill the lamina propria and, in the small intestine, compress lympatic vessels leading to malabsorption. These cases can mimic Whipple disease clinically and morphologically. However, *M. avium* is positive by acid fast stain, while *Tropheryma whippelii* is not; both organisms are labelled by the periodic acid-Schiff (PAS) stain.

M. tuberculosis can present with granulomatous disease. In contrast to Crohn disease, these granulomas, which are generally multiple, often have caseous necrosis, but this can be difficult to determine on biopsies. Because the granulomas can be present in all layers of the bowel wall, transmural disease with fibrosis, perforation, and stenoses, or strictures, can be present. Patients may also have peritoneal dissemination with ascites.

Norovirus

***Norovirus*, previously known as *Norwalk-like virus*, causes approximately half of all gastroenteritis outbreaks worldwide and is a common cause of sporadic gastroenteritis in developed countries.** Local outbreaks are usually related to contaminated food or water, but person-to-person transmission underlies most sporadic cases. Infections spread easily within schools, hospitals, nursing homes and, on other densely populated communities including cruise ships. After a short incubation period, affected individuals develop nausea, vomiting, watery diarrhea, and abdominal pain. Biopsy morphology is nonspecific. The disease is self-limited.

Rotavirus

The encapsulated *rotavirus* infects 140 million individuals and causes 1 million deaths each year, making rotavirus the most common cause of severe childhood diarrhea and diarrhea-related deaths worldwide. Children between 6 and 24 months of age are most vulnerable. Protection in the first 6 months of life is probably due to the presence of antibodies to rotavirus in breast milk, while protection beyond 2 years of age is due to immunity that develops after the first infection. Outbreaks in hospitals and day care centers are common, and infection spreads easily; the estimated minimal infective inoculum is only 10 viral particles. *Rotavirus selectively infects and destroys mature (absorptive) enterocytes in the small intestine, and the villus surface is repopulated by immature secretory cells.* This change in functional capacity results in loss of absorptive function and net secretion of water and electrolytes, compounded by an osmotic diarrhea from incompletely absorbed nutrients. Like norovirus, rotavirus infection becomes symptomatic after a short incubation period and manifests as several days of vomiting and watery diarrhea. Vaccines are now available, and their use is beginning to change the epidemiology of rotavirus infection. Unfortunately, oral rotavirus vaccines have been less effective in developing countries where they are most needed.

Parasitic Disease

Parasitic disease and protozoal infections affect over half of the world's population on a chronic or recurrent basis. The small intestine can harbor as many as 20 species of parasites, including nematodes, such as the roundworms *Ascaris* and *Strongyloides;* hookworms and pinworms; cestodes, including flatworms and tapeworms; trematodes (flukes); and protozoa.

- *Ascaris lumbricoides.* This nematode infects more than 1 billion individuals worldwide as a result of human fecal-oral contamination. Ingested eggs hatch in the intestine, and larvae penetrate the intestinal mucosa. From there, the larvae migrate via the splanchnic circulation to the liver, creating hepatic abscesses, and then through the systemic circulation to the lung, where they can cause *Ascaris* pneumonitis. In the latter case, larvae migrate up the trachea, are swallowed, and arrive again in the intestine to mature into adult worms. Diagnosis is made by detection of eggs in the stools.
- *Strongyloides.* The larvae of *Strongyloides* live in fecally contaminated ground soil and can penetrate unbroken skin. They migrate through the lungs to the trachea from where they are swallowed and then mature into adult worms in the intestines. Unlike other intestinal worms, which require an ovum or larval stage outside the human, the eggs of *Strongyloides* can hatch within the intestine and release larvae that penetrate the mucosa, creating a vicious cycle referred to as *autoinfection*. Hence, *Strongyloides* infection can persist for life,

and immunosuppressed individuals can develop overwhelming infections.

- *Necator americanus* and *Ancylostoma duodenale.* These hookworms infect 1 billion individuals worldwide and cause significant morbidity. Infection is initiated by larval penetration through the skin. After further development in the lungs, the larvae migrate up the trachea and are swallowed. Once in the duodenum, the larvae mature and the adult worms attach to the mucosa, suck blood, and reproduce. Hookworms are a leading cause of iron-deficiency anemia in the developing world. Detection of eggs in the stools is used for diagnosis.
- *Giardia lamblia.* This flagellated protozoan, also referred to as *Giardia duodenalis* or *Giardia intestinalis,* is the *most common pathogenic parasite in humans* and is spread by fecally contaminated water or food. Infection may occur after ingestion of as few as 10 cysts and is characterized by acute or chronic malabsorptive diarrhea. Because cysts are resistant to chlorine, *Giardia* organisms are endemic in unfiltered public and rural water supplies. In the acidic environment of the stomach, excystation occurs and trophozoites are released. Secretory IgA and mucosal IL-6 responses are important for clearance of *Giardia* infections, and immunosuppressed, agammaglobulinemic, or malnourished individuals often are severely affected. *Giardia* evades immune clearance through continuous modification of the major surface antigen, variant surface protein, and can persist for months or years while causing intermittent symptoms. *Giardia* infection reduces expression of brush border enzymes, including lactase, and causes microvillous damage and apoptosis of small-intestinal epithelial cells. *Giardia* trophozoites are noninvasive and can be identified in duodenal biopsy specimens by their characteristic pear shape. The availability of a stool antigen assay for Giardia has simplified the diagnosis of Giardia infection.
- *Entamoeba histolytica.* This protozoan causes amebiasis and is spread by fecal-oral transmission. *E. histolytica* infects approximately 500 million people in countries such as India, Mexico, and Colombia, and causes 40 million cases of dysentery and liver abscess annually.

While amebiasis affects the cecum and ascending colon most often, the sigmoid colon, rectum, and appendix can also be involved. Dysentery develops when the amebae attach to the colonic epithelium, induce apoptosis, invade crypts, and burrow laterally into the lamina propria. This recruits neutrophils, causes tissue damage, and creates a flask-shaped ulcer with a narrow neck and broad base. Parasites may penetrate splanchnic vessels and embolize to the liver to produce abscesses in about 40% of patients with amebic dysentery. Amebic liver abscesses, which can exceed 10 cm in diameter, have a scant inflammatory reaction at their margins and a shaggy fibrin lining. The abscesses persist after the acute intestinal illness has passed and may rarely reach the lung and the heart by direct extension. Amebae may also spread to the kidneys and brain via the bloodstream.

Individuals with amebiasis may present with abdominal pain, bloody diarrhea, or weight loss. Occasionally, acute necrotizing colitis and megacolon occur, and both are associated with significant mortality.

SUMMARY

INFECTIOUS ENTEROCOLITIS

- *Vibrio cholerae* secretes a preformed toxin that causes massive chloride secretion. Water follows the resulting osmotic gradient, leading to secretory diarrhea.
- *Campylobacter jejuni* is the most common bacterial enteric pathogen in developed countries and also causes traveler's diarrhea. Most isolates are noninvasive. *Salmonella* and *Shigella* spp. are invasive and associated with exudative bloody diarrhea (dysentery). *Salmonella* infection is a common cause of food poisoning. *S. typhi* can cause systemic disease (typhoid fever).
- Pseudomembranous colitis is often triggered by antibiotic therapy that disrupts the normal microbiota and allows *C. difficile* to colonize and grow. The organism produces toxins that disrupt epithelial function. Fecal microbial transplantation is becoming more common as a therapeutic approach in individuals with recurrent disease.
- *Rotavirus* is the most common cause of severe childhood diarrhea and diarrheal mortality worldwide. The diarrhea is secondary to loss of mature enterocytes, resulting in malabsorption as well as secretion.
- *Parasitic* and *protozoal* infections affect over half of the world's population on a chronic or recurrent basis.

INFLAMMATORY INTESTINAL DISEASE

Sigmoid Diverticulitis

In general, diverticular disease refers to acquired pseudodiverticular outpouchings of the colonic mucosa and submucosa. Such *colonic diverticula* are rare in individuals younger than 30 years of age, but the prevalence approaches 50% in Western adult populations older than 60 years of age. Diverticula generally are multiple, and the condition is referred to as *diverticulosis.* This disease is much less common in developing countries, probably because of dietary differences.

Pathogenesis

Colonic diverticula tend to develop under conditions of elevated intraluminal pressure in the sigmoid colon. This is facilitated by the unique structure of the colonic muscularis propria, where nerves, arterial vasa recta, and their connective tissue sheaths penetrate the inner circular muscle coat to create discontinuities in the muscle wall. In other parts of the intestine, these gaps are reinforced by the external longitudinal layer of the muscularis propria, but in the colon, this muscle layer is discontinuous, being gathered into three bands termed *taeniae coli.* High luminal pressures may be generated by exaggerated peristaltic contractions, with spasmodic sequestration of bowel segments that may be exacerbated by diets low in fiber, which reduce stool bulk.

MORPHOLOGY

Anatomically, colonic diverticula are small, flasklike outpouchings, usually 0.5 to 1 cm in diameter, that occur in a regular distribution in between the taeniae coli (Fig. 15.25A and B). They are most common in the sigmoid colon, but other regions of the colon may be affected. Colonic diverticula have a thin wall composed of a flattened or atrophic mucosa, compressed submucosa, and attenuated muscularis propria—often, this last component is totally absent (Fig. 15.25C and D). Obstruction of diverticula with stasis of contents, leads to inflammatory changes, producing **diverticulitis** and peridiverticulitis. Because the wall of the diverticulum is supported only by the muscularis mucosa and a thin layer of subserosal adipose tissue, inflammation, increased pressure, and mucosal ucleration within an obstructed diverticulum can readily result in **perforation.** With or without perforation, recurrent diverticulitis may cause segmental colitis, fibrotic thickening in and around the colonic wall, or stricture formation.

Clinical Features

Most individuals with diverticular disease remain asymptomatic throughout their lives. About 20% of those affected develop complaints including intermittent cramping, continuous lower abdominal discomfort, constipation, and diarrhea. Longitudinal studies have shown that while diverticula can regress early in their development they often become more numerous and larger over time. Whether a high-fiber diet prevents such progression or protects against diverticulitis is unclear. Even when diverticulitis occurs, it most often resolves spontaneously or after antibiotic treatment, and relatively few patients require surgical intervention.

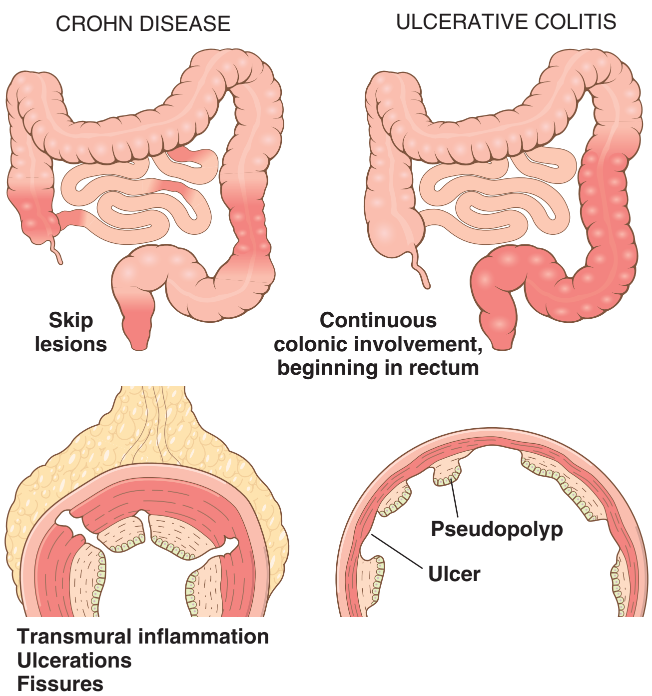

Fig. 15.26 Distribution of lesions in inflammatory bowel disease. The distinction between Crohn disease and ulcerative colitis is based primarily on morphology.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a chronic condition resulting from complex interactions between intestinal microbiota and host immunity in genetically predisposed individuals resulting an inappropriate mucosal immune activation. IBD encompasses two entities, *Crohn disease* and *ulcerative colitis*. The distinction between ulcerative colitis and Crohn disease is based, in large part, on the distribution of affected sites and the morphologic expression of disease at those sites (Fig. 15.26; Table 15.5). *Ulcerative colitis is limited to the colon and rectum and extends only into the mucosa and submucosa.* By contrast, *Crohn disease, also referred to as regional enteritis (because of frequent ileal involvement), may involve any area of the gastrointestinal tract and is frequently transmural.*

Epidemiology

Both Crohn disease and ulcerative colitis frequently present during adolescence or in young adults, although some studies suggest a second, smaller peak in the incidence of both diseases after the fifth decade. In Western

Table 15.5 Features of Crohn Disease and Ulcerative Colitis

Feature	Crohn Disease	Ulcerative Colitis
Macroscopic		
Bowel region affected	Ileum ± colon	Colon only
Rectal involvement	Sometimes	Always
Distribution	Skip lesions	Diffuse
Stricture	Yes	Rare
Bowel wall appearance	Thick	Thin
Inflammation	Transmural	Limited to mucosa and submucosa
Pseudopolyps	Moderate	Marked
Ulcers	Deep, knifelike	Superficial, broad-based
Lymphoid reaction	Marked	Moderate
Fibrosis	Marked	Mild to none
Serositis	Marked	No
Granulomas	Yes (~35%)	No
Fistulas/sinuses	Yes	No
Clinical		
Perianal fistula	Yes (in colonic disease)	No
Fat/vitamin malabsorption	Yes	No
Malignant potential	With colonic involvement	Yes
Recurrence after surgery	Common	No
Toxic megacolon	No	Yes

NOTE: Not all features may be present in a single case.

industrialized nations, IBD is most common among whites and, in the United States, occurs three to five times more often among eastern European (Ashkenazi) Jews. This predilection is at least partly due to genetic factors, as discussed below. The geographic distribution of IBD is highly variable, but it is most prevalent in North America, northern Europe, and Australia. The incidence of IBD worldwide is on the rise and it is becoming more common in regions in which the prevalence was historically low. The *hygiene hypothesis*, first applied to asthma, says that childhood and even prenatal exposure to environmental microbes resets the immune system in a way that prevents excessive reactions. Extrapolated to IBD, it suggests that a reduced frequency of enteric infections due to improved hygiene has resulted in inadequate development of regulatory processes that limit mucosal immune responses early in life. While attractive and commonly stated, firm evidence is lacking and hence the increasing incidence of IBD remains mysterious.

Pathogenesis

Although precise causes are not yet defined, **most investigators believe that IBD results from the combined effects of alterations in host interactions with intestinal microbiota, intestinal epithelial dysfunction, aberrant mucosal immune responses, and altered composition of the gut microbiome.** This view is supported by epidemiologic, genetic, and clinical studies as well as data from laboratory models of IBD (Fig. 15.27).

- *Genetics.* Risk for disease is increased when there is an affected family member, and in Crohn disease, the concordance rate for monozygotic twins is approximately 50%. By contrast, concordance of monozygotic twins for ulcerative colitis is only 16%, suggesting that genetic factors are less dominant in this form of IBD.
  - Molecular linkage analyses of affected families have identified *NOD2* (nucleotide oligomerization binding domain 2) as a susceptibility gene in Crohn disease. *NOD2* encodes a protein that binds to intracellular bacterial peptidoglycans and subsequently activates NF-κB. Some studies suggest that the disease-associated form of NOD-2 is ineffective at defending against intestinal bacteria. The result is that bacteria are able to enter through the epithelium into the wall of the intestine, where they trigger inflammatory reactions. It should, however, be recognized that disease develops in less than 10% of individuals carrying specific *NOD2* polymorphisms, and these polymorphisms are uncommon in African and Asian patients with Crohn disease.
  - The search for IBD-associated genes using genome-wide association studies (GWAS) that assess single-nucleotide polymorphisms (SNPs) as well as high throughput sequencing and other approaches have yielded a rich harvest of over 200 genes associated with IBD. Among these, *NOD2,* discussed above, and two autophagy–related genes are of particular interest. They are *ATG16L1* (autophagy-related 16–like-1) and *IRGM* (immunity-related GTPase M)

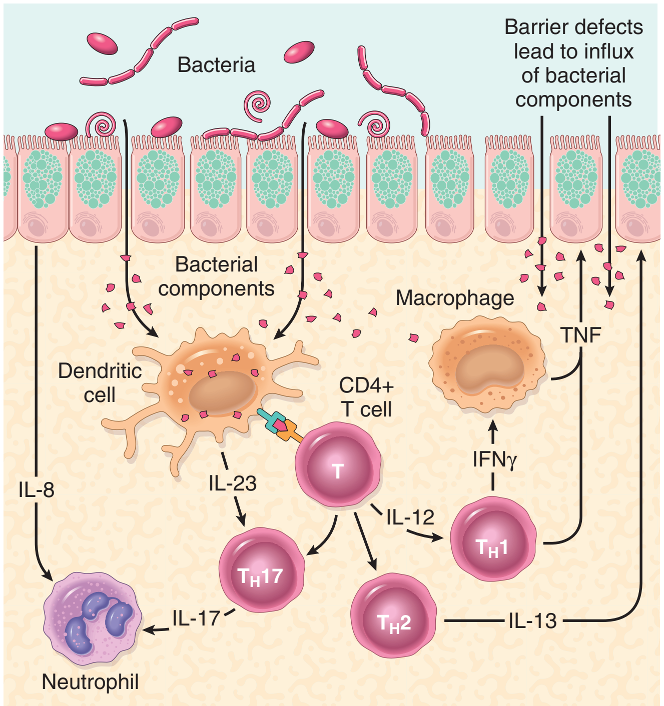

Fig. 15.27 A model of pathogenesis of inflammatory bowel disease (IBD). Aspects of both Crohn disease and ulcerative colitis are shown.

genes. Both are part of the autophagosome pathway and, like NOD-2, are involved in host cell responses to intracellular bacteria, supporting the hypothesis that inadequate defense against luminal bacteria may be important in the pathogenesis of IBD. None of these genes is associated with ulcerative colitis.

- *Mucosal immune responses.* Although the mechanisms by which mucosal immunity contributes to the pathogenesis of ulcerative colitis and Crohn disease are still being deciphered, immunosuppressive and immunomodulatory agents remain mainstays of IBD therapy. Polarization of helper T cells to the T_H1 type is well recognized in Crohn disease, and some data suggest that T_H17 T cells also contribute to disease pathogenesis. Consistent with this, certain polymorphisms of the IL-23 receptor confer protection from Crohn disease and ulcerative colitis (IL-23 is involved in the development and maintenance of T_H17 cells). However, agents that block IL-17 or its receptor have provided no benefit, whereas an antibody that inhibits both T_H1- and T_H17-inducing cytokines is effective, suggesting that the two T cell subsets may have a synergistic role in the disease. Some data suggest that mucosal production of the T_H2-derived cytokine IL-13 is increased in ulcerative colitis, and, to a lesser degree, Crohn disease.

  Defects in regulatory T cells, especially the IL-10-producing subset, are believed to underlie the inflammation especially in Crohn disease. Mutations in the IL-10 receptor are associated with severe, early-onset colitis. Thus, some combination of excessive immune activation by intestinal microbes and defective immune regulation likely is responsible for the chronic inflammation in both forms of IBD.
- *Epithelial defects.* A variety of epithelial defects have been described in Crohn disease, ulcerative colitis, or both. For example, defects in intestinal epithelial tight junction barrier function occur in patients with Crohn disease and a subset of their healthy first-degree relatives. This barrier dysfunction cosegregates with specific disease-associated *NOD2* polymorphisms, and experimental models demonstrate that barrier dysfunction can activate innate and adaptive mucosal immunity and sensitize subjects to disease. Interestingly, the Paneth cell granules, which contain anti-microbial peptides that can affect composition of the luminal microbiota, are abnormal in patients with Crohn disease carrying *ATG16L1* mutations, thus providing one potential mechanism in which a defective feedback loop between the epithelium and microbiota could contribute to disease pathogenesis.
- *Microbiota.* The quantity of microbial organisms in the gastrointestinal lumen is enormous, amounting to as many as 10^{12} organisms/mL of fecal material in the colon (50% of fecal mass). There is significant interindividual variation in the composition of this microbial population, which is modified by diet and disease. Microbial transfer studies are able to promote or reduce disease in animal models of IBD, and clinical trials suggest that probiotic (or beneficial) bacteria or even fecal microbial transplants from healthy individuals may benefit IBD patients.

One model that unifies the roles of intestinal microbiota, epithelial function, and mucosal immunity suggests a cycle by which transepithelial flux of luminal bacterial components activates innate and adaptive immune responses. In a genetically susceptible host, the subsequent release of TNF and other immune signals directs epithelia to increase tight junction permeability, which further increases the flux of luminal material. These events may establish a self-amplifying cycle in which a stimulus at any site may be sufficient to initiate IBD.

With this background of pathogenesis we will discuss next the morphologic and clinical features of each of the two forms of IBD.

Crohn Disease

MORPHOLOGY

Crohn disease, also known as *regional enteritis*, may occur in any area of the gastrointestinal tract but the most common sites involved at presentation are the **terminal ileum, ileocecal valve,** and **cecum.** Disease is limited to the small intestine alone in about 40% of cases; the small intestine and the colon both are involved in 30% of patients; and the remainder of cases are characterized by colonic involvement only. Infrequently, Crohn disease may involve the esophagus or stomach. The presence of multiple, separate, sharply delineated areas of disease, resulting in **skip lesions,** is characteristic of Crohn disease and may help in differentiation from ulcerative colitis. Strictures are common (Fig. 15.28A).

The earliest lesion, the **aphthous ulcer,** may progress, and multiple lesions often coalesce into elongated, serpentine ulcers oriented along the axis of the bowel. Edema and loss of normal mucosal folds are common. Sparing of interspersed mucosa results in a coarsely textured, **cobblestone** appearance in which diseased tissue is depressed below the level of normal mucosa (Fig. 15.28B). **Fissures** frequently develop between mucosal folds and may extend deeply to become sites of perforation or fistula tracts. The intestinal wall is thickened as a consequence of transmural edema, inflammation, submucosal fibrosis, and hypertrophy of the muscularis propria, all of which contribute to stricture formation. In cases with extensive transmural disease, mesenteric fat frequently extends around the serosal surface **(creeping fat)** (Fig. 15.28C).

The microscopic features of active Crohn disease include abundant neutrophils that infiltrate and damage crypt epithelium. Clusters of neutrophils within a crypt are referred to as a **crypt abscess** and often are associated with crypt destruction. Ulceration is common in Crohn disease, and there may be an abrupt transition between ulcerated and normal mucosa. Repeated cycles of crypt destruction and regeneration lead to **distortion of mucosal architecture;** the normally straight and parallel crypts take on bizarre branching shapes and unusual orientations to one another (Fig. 15.29A). Epithelial metaplasia, another consequence of chronic relapsing injury, often takes the form of gastric antral-appearing glands (pseudopyloric metaplasia). **Paneth cell metaplasia** may occur in the left colon, where Paneth cells are normally absent. These architectural and metaplastic changes may persist, even when active inflammation has resolved. Mucosal atrophy, with loss of crypts, may follow years of disease. **Noncaseating granulomas**

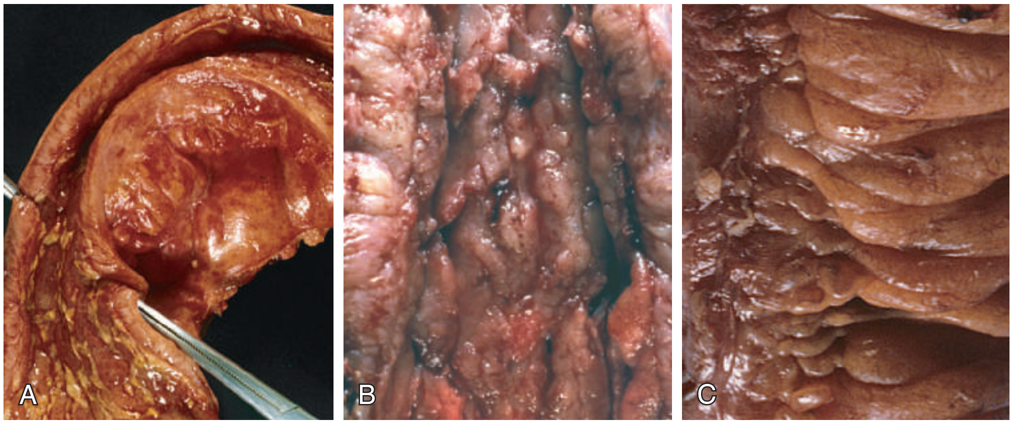

Fig. 15.28 Gross pathology of Crohn disease. (A) Small-intestinal stricture. (B) Linear mucosal ulcers and thickened intestinal wall. (C) Creeping fat.

(Fig. 15.29B), a hallmark of Crohn disease, are found in approximately 35% of cases and may arise in areas of active disease or uninvolved regions in any layer of the intestinal wall (Fig. 15.29C). Granulomas also may be found in mesenteric lymph nodes. Cutaneous granulomas form nodules that are referred to (misleadingly) as **metastatic Crohn disease. The absence of granulomas does not preclude a diagnosis of Crohn disease.**

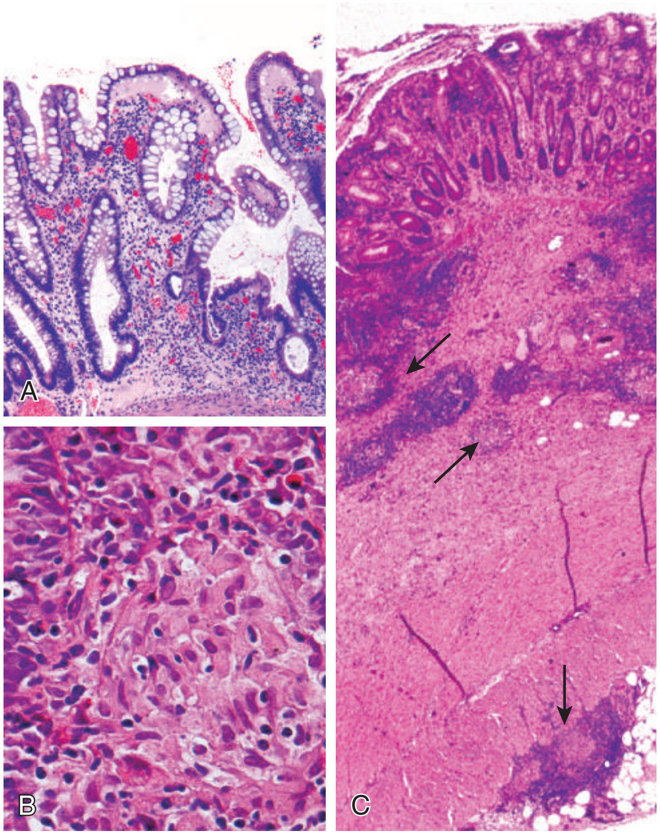

Fig. 15.29 Microscopic pathology of Crohn disease. (A) Haphazard crypt organization results from repeated injury and regeneration. (B) Noncaseating granuloma. (C) Transmural Crohn disease with submucosal and serosal granulomas *(arrows)*.

Clinical Features

The clinical manifestations of Crohn disease are extremely variable. In most patients, disease begins with intermittent attacks of relatively mild diarrhea, fever, and abdominal pain. Approximately 20% of patients present acutely with right lower-quadrant pain and fever, which may mimic acute appendicitis or bowel perforation. Patients with colonic involvement may present with bloody diarrhea and abdominal pain, creating a differential diagnosis with some colonic infections. Periods of disease activity typically are interrupted by asymptomatic intervals that last for weeks to many months. Disease reactivation can be associated with a variety of external triggers, including physical or emotional stress, specific dietary items, NSAID use, and cigarette smoking.

Iron-deficiency anemia may develop in individuals with colonic disease, while extensive small-bowel disease may result in serum protein loss and hypoalbuminemia, generalized nutrient malabsorption, or malabsorption of vitamin B_{12} and bile salts. Fibrosing strictures, particularly of the terminal ileum, are common and require surgical resection. Disease often recurs at the site of anastomosis, and as many as 40% of patients require additional resections within 10 years. Fistulas develop between loops of bowel and may also involve the urinary bladder, vagina, and abdominal or perianal skin. Perforations and peritoneal abscesses can also occur.

Extraintestinal manifestations of Crohn disease include uveitis, migratory polyarthritis, sacroiliitis, ankylosing spondylitis, erythema nodosum, and clubbing of the fingertips, any of which may develop before intestinal disease is recognized. Pericholangitis and primary sclerosing cholangitis may occur in Crohn disease but are more common in ulcerative colitis. As discussed later, the risk for development of colonic adenocarcinoma is increased in patients with long-standing colonic Crohn disease.

Ulcerative Colitis

MORPHOLOGY

Ulcerative colitis always involves the rectum and extends proximally in a continuous fashion to involve part or the entire colon that can be diffusely ulcerated (Fig. 15.30A). Skip lesions are not

seen (although focal appendiceal or cecal inflammation occasionally may be present in those with left-sided disease). Disease of the entire colon is termed *pancolitis* (Fig. 15.30B). Disease limited to the rectum or rectosigmoid may be referred to descriptively as ***ulcerative proctitis*** or ***ulcerative proctosigmoiditis.*** The small intestine is normal, although mild mucosal inflammation of the distal ileum, **backwash ileitis,** may be present in severe cases of pancolitis.

On gross evaluation, involved colonic mucosa may be slightly red and granular-appearing or exhibit extensive **broad-based ulcers.** The transition between diseased and uninvolved colon can be abrupt (see Fig. 15.30C). Ulcers are aligned along the long axis of the colon but typically do not replicate the serpentine ulcers of Crohn disease. Isolated islands of regenerating mucosa often bulge into the lumen to create small elevations, termed ***pseudopolyps.*** Chronic disease may lead to **mucosal atrophy** and a flat, smooth mucosal surface lacking normal folds. Unlike in Crohn disease, **mural thickening is absent, the serosal surface is normal, and strictures do not occur.** However, inflammation and inflammatory mediators can damage the muscularis propria and disturb neuromuscular function leading to colonic dilation and **toxic megacolon,** which carries a significant risk for perforation.

Histologic features of mucosal disease in ulcerative colitis are similar to those in colonic Crohn disease and include inflammatory infiltrates, crypt abscesses, crypt distortion, and epithelial metaplasia. However, **skip lesions are absent, and inflammation generally is limited to the mucosa and superficial submucosa** (Fig. 15.30D). This distinction may not be demonstrated by endoscopic biopsies, which typically sample the mucosa and little or no submucosa. In severe cases, mucosal damage may be accompanied by ulcers that extend more deeply into the submucosa, but the muscularis propria is rarely involved. Submucosal fibrosis, mucosal atrophy, and distorted mucosal architecture remain as residua of healed disease, but the histologic pattern also may revert to near normal after prolonged remission. **Granulomas are not present.**

Some extraintestinal manifestations of ulcerative colitis overlap with those of Crohn disease, including migratory polyarthritis, sacroiliitis, ankylosing spondylitis, uveitis, skin lesions, pericholangitis, and primary sclerosing cholangitis.

Clinical Features

Ulcerative colitis is a relapsing disorder characterized by attacks of bloody diarrhea with expulsion of stringy, mucoid material and lower abdominal pain and cramps that are temporarily relieved by defecation. These symptoms may persist for days, weeks, or months before they subside, and occasionally the initial attack may be severe enough to constitute a medical or surgical emergency. More than half of patients have mild disease, but almost all experience at least one relapse during a 10-year period. Colectomy cures intestinal disease, but extraintestinal manifestations may persist.

The factors that trigger ulcerative colitis are not known; infectious enteritis precedes disease onset in some cases. The onset of symptoms can occur shortly after smoking cessation in some patients, and smoking may partially relieve symptoms. Unfortunately, studies of nicotine as a therapeutic agent have been disappointing.

Colitis-Associated Neoplasia

One of the most feared long-term complications of ulcerative colitis and colonic Crohn disease is the development of neoplasia. This process begins as dysplasia, which, just as in Barrett esophagus and chronic gastritis, is a step along the road to full-blown carcinoma. The risk for development of dysplasia is related to several factors:

- *Duration of disease.* Risk increases beginning 8 to 10 years after disease initiation.
- *Extent of involvement.* Patients with pancolitis are at greater risk than those with only left-sided disease.

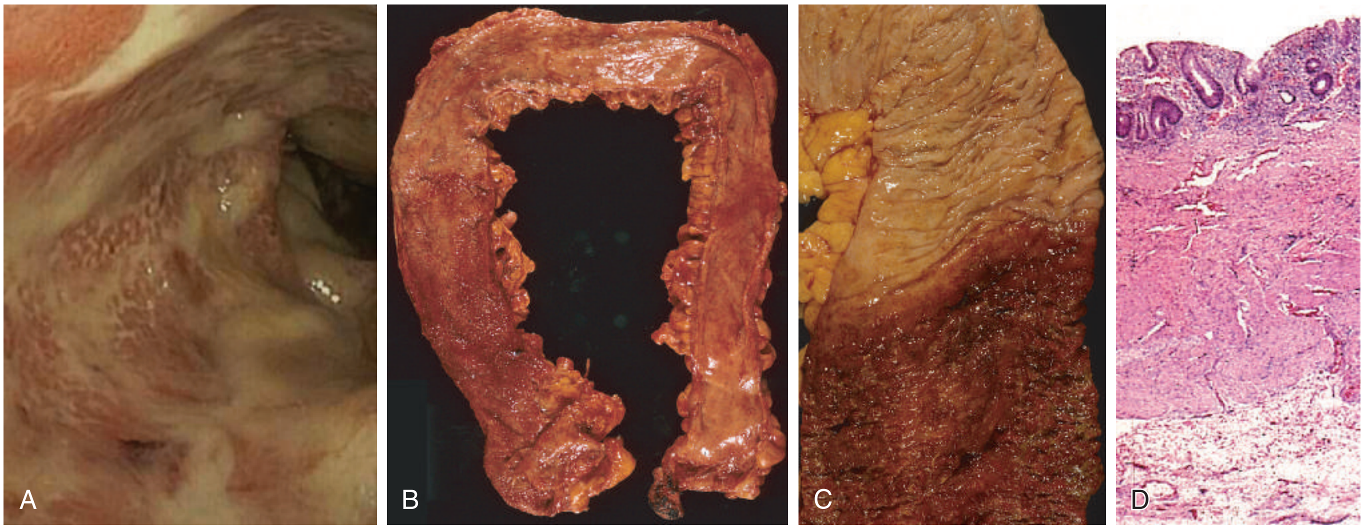

Fig. 15.30 Pathology of ulcerative colitis. (A) Endoscopic view of severe ulcerative colitis with ulceration and adherent mucopurulent material. (B) Total colectomy with pancolitis showing active disease, with red, granular mucosa in the cecum *(left)* and smooth, atrophic mucosa distally *(right).* (C) Sharp demarcation between active ulcerative colitis *(bottom)* and normal *(top).* (D) This full-thickness histologic section shows that disease is limited to the mucosa. Compare with Fig. 15.29C. *(Endoscopic image courtesy of Dr. Ira Hanan, The University of Chicago, Chicago, Illinois.)*

- *Inflammation.* Greater frequency and severity of active inflammation (characterized by the presence of neutrophils) may increase risk. This is another example of the enabling effect of inflammation on carcinogenesis (Chapter 6).

To facilitate early detection of neoplasia, patients typically are enrolled in surveillance programs approximately 8 years after diagnosis of IBD. An important exception to this approach is in patients with primary sclerosing cholangitis, who are at markedly greater risk for development of dysplasia and generally are enrolled for surveillance at the time of diagnosis. Surveillance requires regular and extensive mucosal biopsy, making it a costly practice. In many cases, dysplasia occurs in flat areas of mucosa that do not appear abnormal by eye. Thus, advanced endoscopic imaging techniques are being developed to try to enable the detection of early dysplastic changes.

SUMMARY
INFLAMMATORY BOWEL DISEASE

- Inflammatory bowel disease (IBD) is an umbrella term for Crohn disease and ulcerative colitis.
- Crohn disease most commonly affects the terminal ileum and cecum, but any site within the gastrointestinal tract can be involved; skip lesions and noncaseating granulomas are common.
- Ulcerative colitis is limited to the colon, is continuous from the rectum, and ranges in extent from only rectal disease to pancolitis; neither skip lesions nor granulomas are present.
- Both Crohn disease and ulcerative colitis can have extraintestinal manifestations.
- IBD is thought to arise from a combination of alterations in host interactions with intestinal microbiota, intestinal epithelial dysfunction, and aberrant mucosal immune responses.
- The risk for development of colonic epithelial dysplasia and adenocarcinoma is increased in patients who have had colonic IBD for more than 8 to 10 years.

COLONIC POLYPS AND NEOPLASTIC DISEASE

Polyps are most common in the colon but may occur in the esophagus, stomach, or small intestine. Those without stalks are referred to as *sessile.* As sessile polyps enlarge, proliferation of cells adjacent to the polyp and the effects of traction on the luminal protrusion may combine to create a stalk. Polyps with stalks are termed *pedunculated.* In general, intestinal polyps can be classified as *nonneoplastic* or *neoplastic.* The most common neoplastic polyp is the adenoma, which has the potential to progress to cancer. Nonneoplastic colonic polyps can be further classified as inflammatory, hamartomatous, or hyperplastic.

Inflammatory Polyps

The *solitary rectal ulcer syndrome* is associated with a purely inflammatory polyp. Patients present with the clinical triad of rectal bleeding, mucus discharge, and an inflammatory lesion of the anterior rectal wall. The underlying cause is impaired relaxation of the anorectal sphincter, creating a sharp angle at the anterior rectal shelf. This leads to recurrent abrasion and ulceration of the overlying rectal mucosa. Chronic cycles of injury and healing produce a polypoid mass composed of inflamed and reactive mucosal tissue.

Hamartomatous Polyps

Hamartomatous polyps occur sporadically and as components of various genetically determined or acquired syndromes (Table 15.6). As described previously, hamartomas are disorganized, tumorlike growths composed of mature cell types normally present at the site at which the polyp develops. Hamartomatous polyposis syndromes are rare, but they are important to recognize because of associated intestinal and extraintestinal manifestations and the need to screen family members.

Juvenile Polyps

Juvenile polyps are the most common type of hamartomatous polyp. They may be sporadic or syndromic. Sporadic juvenile polyps are usually solitary, but the number varies from 3 to as many as 100 in individuals with the autosomal dominant syndrome of juvenile polyposis. In adults, the sporadic form is sometimes also referred to as an *inflammatory polyp,* particularly when dense inflammatory infiltrates are present. The vast majority of juvenile polyps occur in children younger than 5 years of age. Juvenile polyps characteristically are located in the rectum and most manifest with rectal bleeding. In some cases, prolapse occurs and the polyp protrudes through the anal sphincter. Dysplasia occurs in a small proportion of (mostly syndrome-associated) juvenile polyps, and the juvenile polyposis syndrome is associated with an increased risk for development of adenocarcinoma within the colon and at other sites (Table 15.6). Colectomy may be required to limit the hemorrhage associated with polyp ulceration in juvenile polyposis.

MORPHOLOGY

Individual sporadic and syndromic juvenile polyps often are indistinguishable. They typically are pedunculated, smooth-surfaced, reddish lesions that are less than 3 cm in diameter and display characteristic cystic spaces on cut sections. Microscopic examination shows the spaces to be dilated glands filled with mucin and inflammatory debris (Fig. 15.31A). Some data suggest that mucosal hyperplasia is the initiating event in polyp development, and this mechanism is consistent with the discovery that mutations in pathways that regulate cellular growth, such as transforming growth factor-β (TGF-β) signaling, are associated with autosomal dominant juvenile polyposis.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is a rare autosomal dominant disorder defined by the presence of multiple gastrointestinal hamartomatous polyps and mucocutaneous hyperpigmentation that carries an increased risk for

Table 15.6 Gastrointestinal (GI) Polyposis Syndromes

Syndrome	Mean Age at Presentation (Years)	Mutated Gene(s)	GI Lesions	Selected Extragastrointestinal Manifestations
Peutz-Jeghers syndrome	10–15	*LKB1/STK11*	Arborizing polyps—small intestine > colon > stomach; colonic adenocarcinoma	Mucocutaneous pigmentation; increased risk for thyroid, breast, lung, pancreas, gonadal, and bladder cancers
Juvenile polyposis	<5	*SMAD4, BMPR1A*	Juvenile polyps; increased risk for gastric, small-intestinal, colonic, and pancreatic adenocarcinoma	Pulmonary arteriovenous malformations, digital clubbing
Cowden syndrome, Bannayan-Ruvalcaba-Riley syndrome	<15	*PTEN*	Hamartomatous polyps, lipomas, ganglioneuromas, inflammatory polyps; increased risk for colon cancer	Benign skin tumors, benign and malignant thyroid and breast lesions
Cronkhite-Canada syndrome	>50	Nonhereditary	Hamartomatous colon polyps, crypt dilatation and edema in nonpolypoid mucosa	Nail atrophy, hair loss, abnormal skin pigmentation, cachexia, anemia
Tuberous sclerosis	Infancy to adulthood	*TSC1, TSC2*	Hamartomatous polyps (rectal)	Facial angiofibroma, cortical tubers, renal angiomyolipoma
Familial adenomatous polyposis (FAP)				
Classic FAP	10–15	*APC*	Multiple adenomas	Congenital RPE hypertrophy
Attenuated FAP	40–50	*APC*	Multiple adenomas	
Gardner syndrome	10–15	*APC*	Multiple adenomas	Osteomas, desmoids, skin cysts
Turcot syndrome	10–15	*APC*	Multiple adenomas	CNS tumors, medulloblastoma

CNS, Central nervous system; *RPE*, retinal pigment epithelium.

development of several malignancies, including cancers of the colon, pancreas, breast, lung, ovaries, uterus, and testes, as well as other unusual neoplasms. Germ line loss-of-function mutations in the *LKB1/STK11* gene are present in approximately half of the patients with the familial form of Peutz-Jeghers syndrome, as well as a subset of patients with the sporadic form. *LKB1/STK11* encodes a tumor suppressive protein kinase that regulates cellular metabolism, yet another example of links between alterned metabolism, abnormal cell growth, and cancer risk. Intestinal polyps are most common in the small intestine, although they may also occur in the stomach and colon and, rarely, in the bladder and lungs. On gross evaluation, the polyps are large and pedunculated with a lobulated contour. Histologic examination demonstrates a characteristic arborizing network of connective tissue, smooth muscle, lamina propria, and glands lined by normal-appearing intestinal epithelium (Fig. 15.31B).

Hyperplastic Polyps

Colonic hyperplastic polyps are common epithelial proliferations that typically are discovered in the sixth and seventh decades of life. The pathogenesis of hyperplastic polyps is incompletely understood, but formation of these lesions is thought to result from decreased epithelial cell turnover and delayed shedding of surface epithelial cells, leading to a "pileup" of goblet cells. Although these lesions have no malignant potential, they must be distinguished from sessile serrated adenomas, histologically similar lesions that have malignant potential, as described later.

MORPHOLOGY

Hyperplastic polyps are most commonly found in the left colon and typically are less than 5 mm in diameter. They are smooth, nodular protrusions of the mucosa, often on the crests of mucosal folds. They may occur singly but more frequently are multiple, particularly in the sigmoid colon and rectum. Histologically, hyperplastic polyps are composed of mature goblet and absorptive cells. The delayed shedding of these cells leads to crowding that creates the serrated surface architecture, the morphologic hallmark of these lesions (Fig. 15.32).

Adenomas

The most common and clinically important neoplastic polyps are colonic adenomas, benign polyps that give rise to a majority of colorectal adenocarcinomas. Most adenomas, however, do not progress to adenocarcinoma.

Colorectal adenomas are characterized by the presence of epithelial dysplasia. These growths range from small, often pedunculated polyps to large sessile lesions. There is no gender predilection, and they are present in nearly 50% of adults living in the Western world beginning at age 50. Because these polyps are precursors to colorectal cancer, current recommendations are that all adults in the United States undergo screening colonoscopy starting at 50 years of age. Because individuals with a family history are at risk for developing colon cancer earlier in life, they are typically screened at least 10 years before the youngest age at which a relative was diagnosed. While adenomas are less

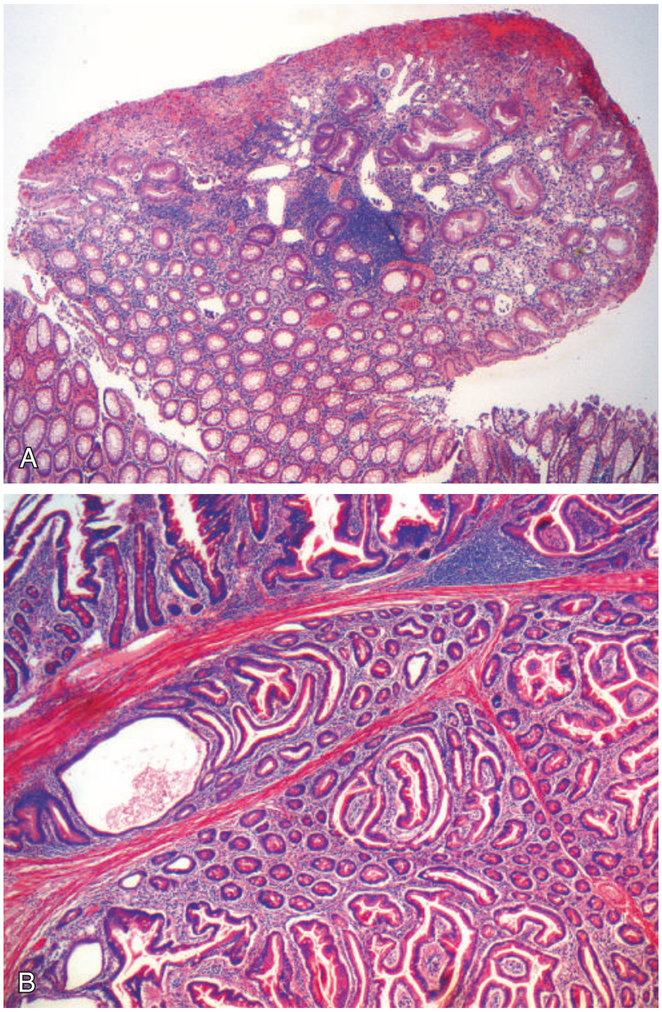

Fig. 15.31 Hamartomatous polyps. (A) Juvenile polyp. Note the surface erosion and cystically dilated crypts filled with mucus, neutrophils, and debris. (B) Peutz-Jeghers polyp. Complex glandular architecture and bundles of smooth muscle help to distinguish Peutz-Jeghers polyps from juvenile polyps.

common in Asia, their frequency has risen (in parallel with an increasing incidence of colorectal adenocarcinoma) as Western diets and lifestyles become more common.

MORPHOLOGY

Typical adenomas range from 0.3 to 10 cm in diameter and can be **pedunculated** (Fig. 15.33A) or **sessile,** with the surface of both types having a texture resembling velvet (Fig. 15.33B) or a raspberry, due to the abnormal epithelial growth pattern. Histologically, the cytologic hallmark of **epithelial dysplasia** (Fig. 15.34C) is nuclear hyperchromasia, elongation, and stratification. These changes are most easily appreciated at the surface of the adenoma, because the epithelium fails to mature as cells migrate out of the crypt. Pedunculated adenomas have slender fibromuscular stalks (see Fig. 15.33C) containing prominent blood vessels derived from the submucosa. The stalk usually is covered by nonneoplastic epithelium, but dysplastic epithelium is sometimes present.

Adenomas can be classified as **tubular, tubulovillous,** or **villous** on the basis of their architecture. These categories, however, have little clinical significance in isolation. Tubular adenomas tend to be small, pedunculated polyps composed of small, rounded, or tubular glands (Fig. 15.34A). By contrast, villous adenomas, which often are larger and sessile, are covered by slender villi (Fig. 15.34B). Tubulovillous adenomas have a mixture of tubular and villous elements. Although foci of invasion are more frequent in villous adenomas than in tubular adenomas, villous architecture alone does not increase cancer risk when polyp size is considered.

The histologic features of **sessile serrated adenomas,** which are also referred to as sessile serrated polyps, overlap with those of hyperplastic polyps and lack typical cytologic features of dysplasia (Fig. 15.34D). Nevertheless, sessile serrated adenomas, which are most common in the right colon, have a malignant potential similar to that of conventional adenomas. The most useful histologic feature that distinguishes sessile serrated adenomas from hyperplastic polyps is the presence of serrated architecture throughout the full length of the glands, including the crypt base, associated with crypt dilation and lateral growth, in the former (Fig. 15.34D). By contrast, serrated architecture typically is confined to the surface of hyperplastic polyps.

Although most colorectal adenomas behave in a benign fashion, a small proportion harbor invasive cancer at the time of detection. **Size is the most important characteristic that correlates with risk for malignancy.** For example, while

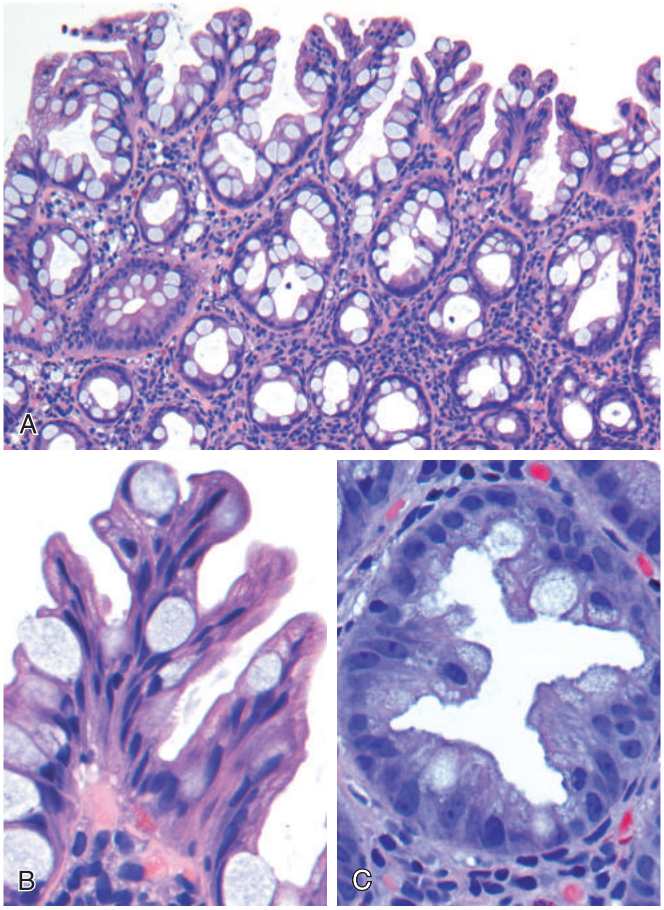

Fig. 15.32 Hyperplastic polyp. (A) Polyp surface with irregular tufting of epithelial cells. (B) Tufting results from epithelial overcrowding. (C) Epithelial crowding produces a serrated architecture when glands are cut in cross-section.

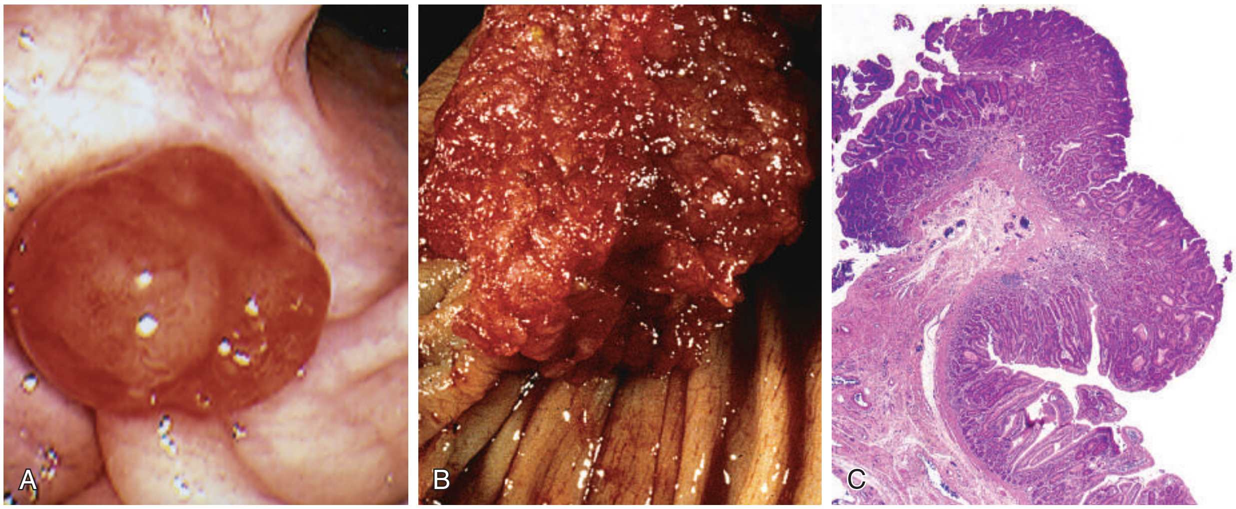

Fig. 15.33 Colonic adenomas. (A) Pedunculated adenoma (endoscopic view). (B) Adenoma with a velvety surface. (C) Low-magnification photomicrograph of a pedunculated tubular adenoma.

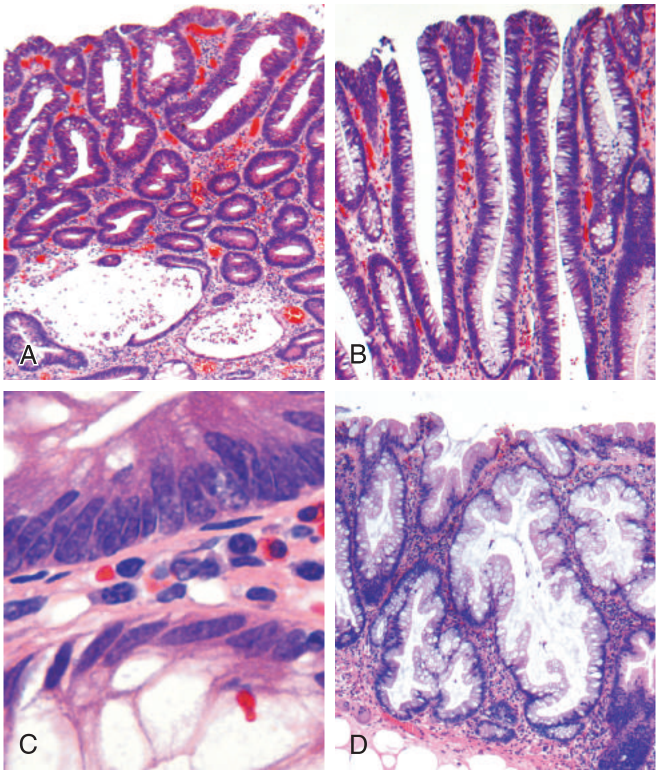

Fig. 15.34 Histologic appearance of colonic adenomas. (A) Tubular adenoma with a smooth surface and rounded glands. In this case, crypt dilation and rupture, with associated reactive inflammation, can be seen at the bottom of the field. (B) Villous adenoma with long, slender projections that are reminiscent of small-intestinal villi. (C) Dysplastic epithelial cells *(top)* with an increased nuclear-to-cytoplasmic ratio, hyperchromatic and elongated nuclei, and nuclear pseudostratification. Compare with the nondysplastic epithelium *(bottom)*. (D) Sessile serrated adenoma lined by goblet cells without typical cytologic features of dysplasia. This lesion is distinguished from a hyperplastic polyp by involvement of the crypts. Compare with the hyperplastic polyp in Fig. 15.32.

cancer is extremely rare in adenomas less than 1 cm in diameter, some studies suggest that nearly 40% of lesions larger than 4 cm in diameter contain foci of invasive cancer. In addition to size, high-grade dysplasia is a risk factor for cancer in an individual polyp (but not other polyps in the same patient).

Familial Syndromes

Several syndromes associated with colonic polyps and increased rates of colon cancer have been described. The genetic basis of these disorders has been established and has greatly enhanced the current understanding of sporadic colon cancer (Table 15.7).

Familial Adenomatous Polyps

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder marked by the appearance of numerous colorectal adenomas by the teenage years. It is caused by mutations of the *adenomatous polyposis coli* gene (*APC*). *A count of at least 100 polyps is necessary for a diagnosis of classic FAP,* and as many as several thousand may be present (Fig. 15.35). Except for their remarkable numbers, these growths are morphologically indistinguishable from sporadic adenomas. Colorectal adenocarcinoma develops in 100% of patients with untreated FAP, often before 30 years of age. As a result, prophylactic colectomy is standard therapy for individuals carrying *APC* mutations. However, patients remain at risk for *extraintestinal manifestations,* including neoplasia at other sites. Specific *APC* mutations are also associated with the development of other manifestations of FAP and explain variants such as *Gardner syndrome* and *Turcot syndrome*. In addition to intestinal polyps, clinical features of Gardner syndrome, a variant of FAP, may include osteomas of the mandible, skull, and long bones; epidermal cysts; desmoid and thyroid tumors; and dental abnormalities, including unerupted and supernumerary teeth. Turcot syndrome is rarer and is characterized by intestinal adenomas and tumors of the central nervous system. Two-thirds of

Table 15.7 Common Patterns of Sporadic and Familial Colorectal Neoplasia

Etiology	Molecular Defect	Target Gene(s)	Transmission	Predominant Site(s)	Histology
Familial adenomatous polyposis (70% of FAP)	APC/WNT pathway	*APC*	Autosomal dominant	None	Tubular, villous; typical adenocarcinoma
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	*MSH2, MLH1*	Autosomal dominant	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (80%)	APC/WNT pathway	*APC*	None	Left side	Tubular, villous; typical adenocarcinoma
Sporadic colon cancer (10%–15%)	DNA mismatch repair	*MSH2, MLH1*	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma

FAP, Familial adenomatous polyposis.

patients with Turcot syndrome have *APC* gene mutations and develop medulloblastomas. The remaining one-third have mutations in one of several genes involved in DNA repair and develop glioblastomas. Some patients with hundreds of adenomas lack APC mutations but instead have mutations of the base excision repair gene *MUTYH* (also called MUTYH polyposis). The role of these genes in tumor development is discussed later.

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as *Lynch syndrome,* originally was described as familial clustering of cancers at several sites including the colorectum, endometrium, stomach, ovary, ureters, brain, small bowel, hepatobiliary tract, and skin. Colon cancers in patients with HNPCC tend to occur at younger ages than do sporadic colon cancers and often are located in the right colon (Table 15.7). Adenomas are present in HNPCC, but excessive numbers (i.e., polyposis) is not. In many cases, sessile serrated adenomas are associated with HNPCC, and mucin production may be a prominent in the subsequent adenocarcinomas.

Just as identification of *APC* mutations in FAP has provided molecular insights into the pathogenesis of a majority of sporadic colon cancers, dissection of the defects in HNPCC has shed light on the mechanisms responsible for most of the remaining sporadic cases. **HNPCC is caused by inherited germ line mutations in genes that encode proteins responsible for the detection, excision, and repair of errors that occur during DNA replication.** At least five such mismatch repair genes have been recognized, but a majority of HNPCC cases involve either *MSH2* or *MLH1.* Patients with HNPCC inherit one mutated DNA repair gene and one normal allele. When the second copy is lost through mutation or epigenetic silencing, defects in mismatch repair lead to the accumulation of mutations at rates up to 1000 times higher than normal, mostly in regions containing short repeating DNA sequences referred to as *microsatellite DNA.* The human genome contains approximately 50,000 to 100,000 microsatellites, which are prone to undergo expansion during DNA replication and represent the most frequent sites of mutations in HNPCC. The consequences of mismatch repair defects and the resulting *microsatellite instability* are discussed next in the context of colonic adenocarcinoma.

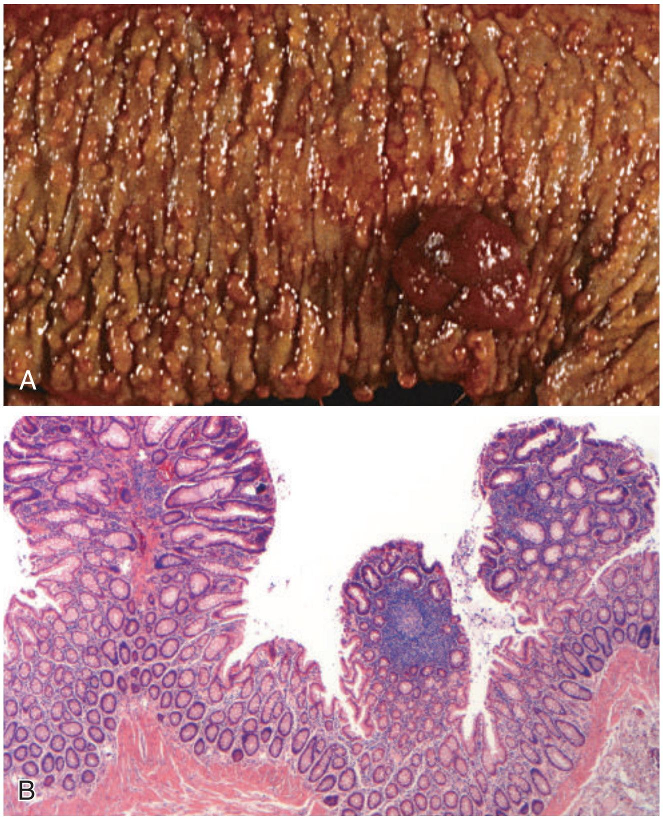

Fig. 15.35 Familial adenomatous polyposis. (A) Hundreds of small colonic polyps are present along with a dominant polyp *(right).* (B) Three tubular adenomas are present in this single microscopic field.

Adenocarcinoma

Adenocarcinoma of the colon is the most common malignancy of the gastrointestinal tract and is a major contributor to morbidity and mortality worldwide. By contrast, the small intestine, which accounts for 75% of the overall length of the gastrointestinal tract, is an uncommon site for benign and malignant tumors. Among malignant small-intestinal tumors, adenocarcinomas and carcinoid (neuroendocrine) tumors have roughly equal rates of occurrence, followed by lymphomas and sarcomas.

Epidemiology

Each year in the United States, there are more than 130,000 new cases and nearly 50,000 deaths from colorectal

adenocarcinoma. This represents nearly 15% of all cancer-related deaths, second only to lung cancer. Colorectal cancer incidence peaks at 60 to 70 years of age; less than 20% of cases occur before 50 years of age. Males are affected slightly more often than females. Colorectal carcinoma is most prevalent in the United States, Canada, Australia, New Zealand, Denmark, Sweden, and other (so-called) developed countries that share lifestyles and diet. The incidence of this cancer is as much as 30-fold lower in India, South America, and Africa. In Japan, where incidence was previously very low, rates have now risen to intermediate levels (similar to those in the United Kingdom), presumably as a result of changes in lifestyle and diet.

The dietary factors most closely associated with increased colorectal cancer rates are low intake of unabsorbable vegetable fiber and high intake of refined carbohydrates and fat. In addition to dietary modification, pharmacologic chemoprevention has become an area of great interest. Several epidemiologic studies suggest that aspirin or other NSAIDs have a protective effect. This is consistent with studies showing that some NSAIDs cause polyp regression in patients with FAP in whom the rectum was left in place after colectomy. It is suspected that this effect is mediated by inhibition of the enzyme cyclooxygenase-2 (COX-2), which is highly expressed in 90% of colorectal carcinomas and 40% to 90% of adenomas and is known to promote epithelial proliferation, particularly in response to injury.

Pathogenesis

Studies of colorectal carcinogenesis have provided fundamental insights into the general mechanisms of cancer evolution. The combination of molecular events that lead to colonic adenocarcinoma is heterogeneous and includes genetic and epigenetic abnormalities. At least two distinct genetic pathways, the APC/β-catenin pathway and the microsatellite instability pathway, have been described. In simplest terms, mutations involving the APC/β-catenin pathway lead to increased WNT signaling, whereas those involving the microsatellite instability pathway are associated with defects in DNA mismatch repair (see Table 15.7). Both pathways involve the stepwise accumulation of multiple mutations, but the genes involved and the mechanisms by which the mutations accumulate differ. Epigenetic events, the most common of which is methylation-induced gene silencing, may enhance progression along both pathways.

- *The APC/β-catenin pathway.* The classic *adenoma-carcinoma sequence,* which accounts for as much as 80% of sporadic colon tumors, typically involves mutation of the *APC* tumor suppressor early in the neoplastic process (Fig. 15.36). For adenomas to develop, both copies of the *APC* gene must be functionally inactivated, either by mutation or epigenetic events. *APC is a key negative regulator of β-catenin, a component of the WNT signaling pathway* (Chapter 6). The APC protein normally binds to and promotes degradation of β-catenin. With loss of APC function, β-catenin accumulates and translocates to the nucleus, where it activates the transcription of genes, such as those encoding MYC and cyclin D1, that promote proliferation. This is followed by additional mutations, including activating mutations in *KRAS,* which also promote growth and prevent apoptosis. The conclusion that mutation of *KRAS* is a late event is supported by the observations that mutations are present in fewer than 10% of adenomas less than 1 cm in diameter, 50% of adenomas greater than 1 cm in diameter, and 50% of invasive adenocarcinomas. Neoplastic progression also is associated with mutations in other tumor suppressor genes such as *SMAD2* and *SMAD4*, which encode effectors of TGF-β signaling. Because TGF-β signaling normally inhibits the cell cycle, loss of these genes may allow unrestrained cell growth.

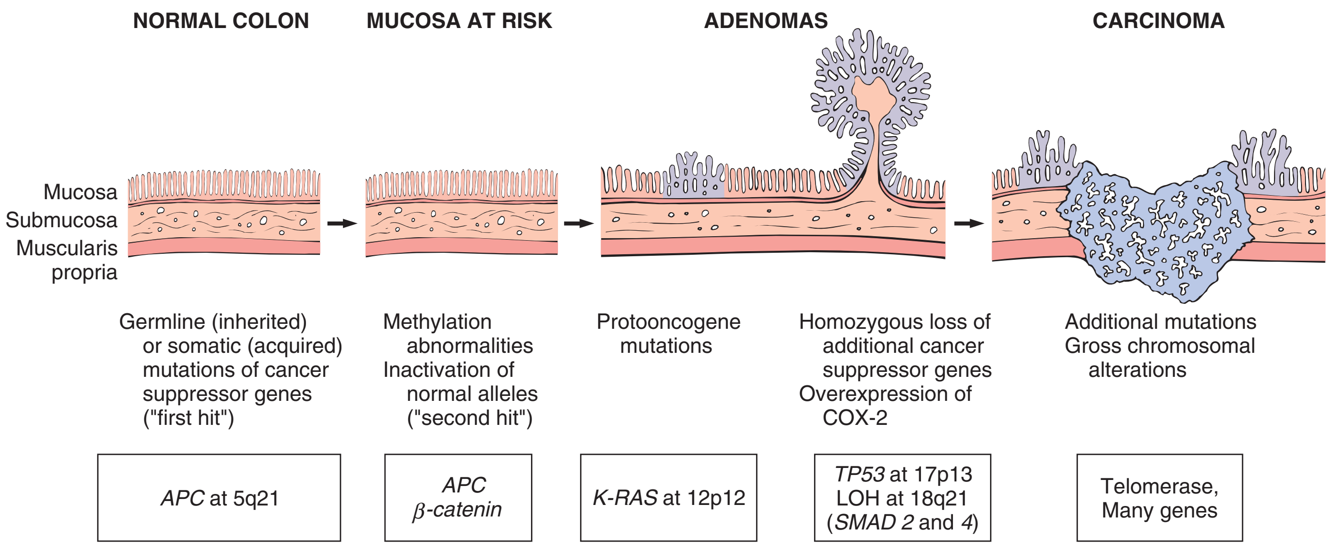

Fig. 15.36 Morphologic and molecular changes in the adenoma-carcinoma sequence. It is postulated that loss of one normal copy of the tumor suppressor gene *APC* occurs early. Individuals may be born with one mutant allele, making them extremely prone to the development of colon cancer, or inactivation of APC may occur later in life. This is the "first hit" according to Knudson's hypothesis. The loss of the intact copy of *APC* follows ("second hit"). Other mutations involving *KRAS, SMAD2, and SMAD4*, and the tumor suppressor gene *TP53*, lead to the emergence of carcinoma, in which additional mutations occur. Although there may be a preferred temporal sequence for these changes, it is the aggregate effect of the mutations, rather than their order of occurrence, that appears most critical.

The tumor suppressor gene *TP53* is mutated in 70% to 80% of colon cancers but is uncommonly affected in adenomas, suggesting that *TP53* mutations also occur at late stages of tumor progression. Loss of function of *TP53* and other tumor suppressor genes is often caused by chromosomal deletions, highlighting *chromosomal instability as a hallmark of the APC/β-catenin pathway.* Alternatively, tumor suppressor genes may be silenced by methylation of CpG islands, a 5′ region of some genes that frequently includes the promoter and transcriptional start site. Expression of telomerase also increases as lesions become more advanced.

- *The microsatellite instability pathway.* In patients with DNA mismatch repair deficiency (due to loss of mismatch repair genes, as discussed earlier), mutations accumulate in microsatellite repeats, a condition referred to as *microsatellite instability.* These mutations generally are silent, because microsatellites typically are located in noncoding regions, but other microsatellite sequences are located in the coding or promoter regions of genes involved in regulation of cell growth, such as those encoding the type II TGF-β receptor and the pro-apoptotic protein BAX (Fig. 15.37). Because TGF-β inhibits colonic epithelial cell proliferation, type II TGF-β receptor mutants can contribute to uncontrolled cell growth, while loss of *BAX* may enhance the survival of genetically abnormal clones.
- *CpG island hypermethylation phenotype (CIMP).* In a subset of colon cancers with microsatellite instability, there are no mutations in DNA mismatch repair enzymes. These tumors demonstrate the CpG island hypermethylation phenotype (CIMP). In these tumors, the MLH1 promoter region is typically hypermethylated, thereby reducing MLH1 expression and repair function. Activating mutations in the *BRAF* oncogene are common in these cancers. In contrast, KRAS and TP53 are not typically mutated. Thus, the combination of microsatellite instability, BRAF mutation, and methylation of specific targets, such as MLH1, is the signature of this pathway of carcinogenesis.

MORPHOLOGY

Overall, adenocarcinomas are distributed approximately equally over the entire length of the colon. **Tumors in the proximal colon often grow as polypoid, exophytic masses** that extend along one wall of the large-caliber cecum and ascending colon; these tumors rarely cause obstruction (Fig. 15.38A). By contrast, **carcinomas in the distal colon tend to be annular lesions that produce "napkin ring"** constrictions and luminal narrowing (Fig. 15.38B), sometimes to the point of obstruction. Both forms grow into the bowel wall over time and may be palpable as firm masses (Fig. 15.38C). The general microscopic characteristics of right- and left-sided colonic adenocarcinomas are similar. Most tumors are composed of tall columnar cells that resemble dysplastic epithelium found in adenomas (Fig. 15.39A). The invasive component of these tumors elicits a strong stromal desmoplastic response, which is responsible for their characteristic firm consistency. Some poorly differentiated tumors form few glands (Fig. 15.39B). Others may produce abundant mucin that accumulates within the intestinal wall, and these carry a poor prognosis. Tumors also may be composed of signet ring cells similar to those in gastric cancer (Fig. 15.39C).

Clinical Features

The availability of endoscopic screening combined with the recognition that most carcinomas arise within adenomas presents a unique opportunity for cancer prevention. Unfortunately, colorectal cancers develop insidiously and may therefore go undetected for long periods. Cecal and other *right-sided colon cancers* most often are called to clinical attention by the appearance of *fatigue and weakness due to iron-deficiency anemia.* **Thus, it is a clinical maxim that the underlying cause of iron-deficiency anemia in an older male or postmenopausal female is gastrointestinal cancer until proven otherwise.** *Left-sided colorectal adenocarcinomas* may produce *occult bleeding, changes in bowel habits, or cramping* left lower-quadrant discomfort.

Although poorly differentiated and mucinous histologic patterns are associated with poor prognosis, *the two most important prognostic factors are depth of invasion and the*

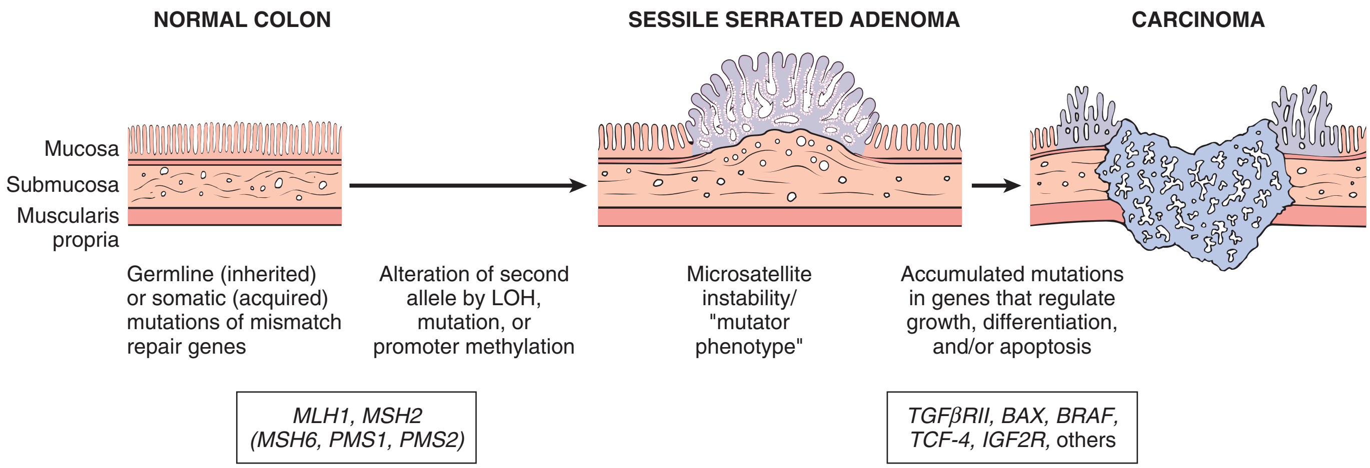

Fig. 15.37 Morphologic and molecular changes in the mismatch repair pathway of colon carcinogenesis. Defects in mismatch repair genes result in microsatellite instability and permit accumulation of mutations in numerous genes. If these mutations affect genes involved in cell survival and proliferation, cancer may develop. *LOH*, Loss of heterozygosity.

presence or absence of lymph node metastases. These factors were originally recognized by Dukes and Kirklin and form the core of the TNM (tumor-node-metastasis) classification and staging system from the American Joint Committee on Cancer. Staging systems have become more complex with time, reflecting more nuanced treatment approaches and personalized therapeutic strategies. The most important distinctions are:

- *Depth of invasion*. Tumors limited to the submucosa (i.e., those that do not cross the muscularis mucosae) have 5-year survival rates approaching 100%, while invasion into the submucosa or muscularis propria reduces 5-year survival to 95% and 70% to 90%, respectively (for tumors limited to the primary site). Invasion through the visceral serosal surface or into adjacent organs and tissues reduces survival further.
- *The presence of lymph node metastases* (Fig. 15.40A) further compromises survival. As a result, most cases with lymph node metastases receive radiation or chemotherapy. In some cases, these treatments may be administered prior to primary tumor resection, a process termed neoadjuvant therapy. Molecular characterization of the tumor can be helpful in guiding the specific therapeutic approach.
- *Distant metastases* to lung (Fig. 15.40B), liver (Fig. 15.40C), or other sites also limits survival, and only 15% or fewer of patients with tumors at this stage are alive 5 years after diagnosis. Because of the portal drainage, the liver is the most common site of metastatic lesions. However, the rectum does not drain by way of the portal circulation, and metastases from carcinomas of the anorectum region often circumvent the liver.

Regardless of stage, however, some patients with small numbers of metastases do well for years after resection of distant tumor nodules. This is particularly true of metastases to liver or lung and emphasizes the clinical and molecular heterogeneity of colorectal carcinomas.

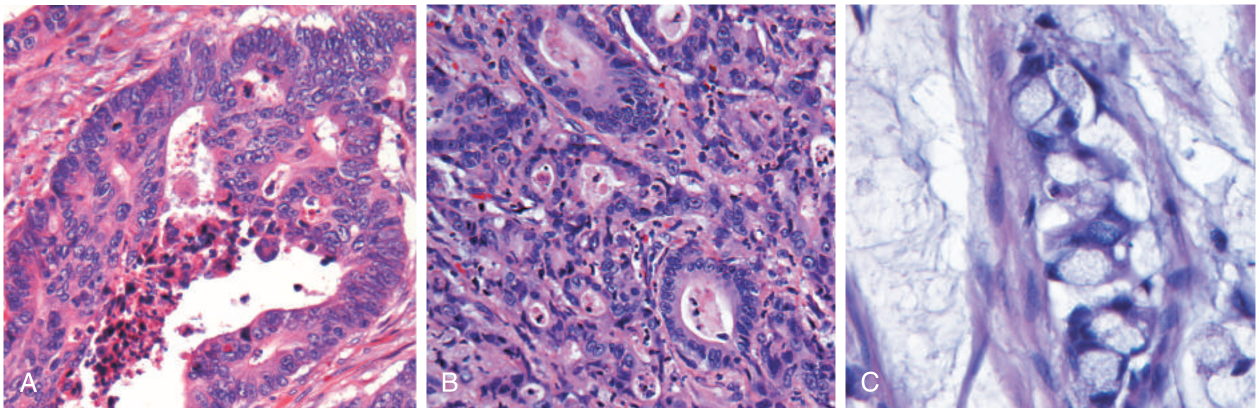

Fig. 15.39 Histologic appearance of colorectal carcinoma. (A) Well-differentiated adenocarcinoma. Note the elongated, hyperchromatic nuclei. Necrotic debris, present in the gland lumen, is typical. (B) Poorly differentiated adenocarcinoma forms a few glands but is largely composed of infiltrating nests of tumor cells. (C) Mucinous adenocarcinoma with signet ring cells and extracellular mucin pools.

(B) Solitary subpleural nodule of colorectal carcinoma metastatic to the lung. (C) Liver containing two large and many smaller metastases. Note the central necrosis within metastases.

SUMMARY

COLONIC POLYPS, ADENOMAS, AND ADENOCARCINOMAS

- *Intestinal polyps* can be classified as *nonneoplastic* or *neoplastic*. The nonneoplastic polyps can be further defined as *inflammatory, hamartomatous,* or *hyperplastic*.
- *Inflammatory polyps* form as a result of chronic cycles of injury and healing.
- *Hamartomatous polyps* occur sporadically or as a part of genetic diseases. In the latter case, they often are associated with increased risk for malignancy.
- *Hyperplastic polyps* are benign epithelial proliferations most commonly found in the left colon and rectum. They are not reactive in origin, in contrast with gastric hyperplastic polyps; have no malignant potential; and must be distinguished from sessile serrated adenomas or polyps.
- *Benign epithelial neoplastic polyps* of the colon are termed *adenomas*. The hallmark feature of these lesions, which are the precursors of colonic adenocarcinomas, is cytologic dysplasia.
- In contrast with traditional adenomas, *sessile serrated adenomas*, or polyps, lack cytologic dysplasia and share some morphologic features with hyperplastic polyps.
- *Familial adenomatous polyposis (FAP)* and *hereditary nonpolyposis colorectal cancer (HNPCC)* are the most common forms of familial colon cancer. FAP is caused by *APC* mutations, and patients typically have over 100 adenomas and develop colon cancer before 30 years of age.
- HNPCC is caused by mutations in DNA mismatch repair genes. Patients with HNPCC have far fewer polyps and develop cancer at an older age than that typical for patients with FAP but at a younger age than in patients with sporadic colon cancer.
- The vast majority of colonic cancers are adenocarcinomas. They arise either by APC-β-catenin pathway or the microsatellite instability pathway. The two most important prognostic factors are depth of invasion and the presence or absence of metastases to lymph nodes or distant organs.

Appendix

The appendix is a normal true diverticulum of the cecum. Like any diverticulum, it is prone to acute and chronic inflammation, and acute appendicitis is a relatively common entity. Other lesions, including tumors, can also occur in the appendix but are far less common.

ACUTE APPENDICITIS

Acute appendicitis is most common in adolescents and young adults but may occur in any age group. The lifetime risk for appendicitis is 7%; males are affected slightly more often than females. Despite the prevalence of acute appendicitis, the diagnosis can be difficult to confirm preoperatively, and the condition may be confused with mesenteric lymphadenitis, acute salpingitis, ectopic pregnancy, mittelschmerz (pain associated with ovulation), and Meckel diverticulitis.

Pathogenesis

Acute appendicitis is thought to be initiated by progressive increase in intraluminal pressure that compromises venous outflow. In 50% to 80% of cases, acute appendicitis is associated with overt luminal obstruction, usually by a small, stone-like mass of stool, or *fecalith,* or, less commonly, a gallstone, tumor, or mass of worms. Ischemic injury and stasis of luminal contents, which favor bacterial proliferation, trigger inflammatory responses including tissue edema and neutrophilic infiltration of the lumen, muscular wall, and periappendiceal soft tissues.

MORPHOLOGY

In early acute appendicitis, subserosal vessels are congested, and a modest perivascular neutrophilic infiltrate is present within all layers of the wall. The inflammatory reaction transforms

the normal glistening serosa into a dull, granular-appearing, erythematous surface. Although mucosal neutrophils and focal superficial ulceration often are present, these findings are not specific, and diagnosis of acute appendicitis requires neutrophilic infiltration of the muscularis propria. In more severe cases, focal abscesses may form within the wall **(acute suppurative appendicitis),** and these may even progress to large areas of hemorrhagic ulceration and gangrenous necrosis that extend to the serosa, creating **acute gangrenous appendicitis,** which often is followed by rupture and suppurative peritonitis.

Clinical Features

Typically, early acute appendicitis produces periumbilical pain that ultimately localizes to the right lower quadrant, followed by nausea, vomiting, low-grade fever, and a mildly elevated peripheral white blood cell count. A classic physical finding is *McBurney's sign,* deep tenderness noted at a location two-thirds of the distance from the umbilicus to the right anterior superior iliac spine (McBurney's point). These signs and symptoms however, are often absent, creating difficulty in clinical diagnosis.

TUMORS OF THE APPENDIX

The most common tumor of the appendix is the *carcinoid,* or well-differentiated neuroendocrine tumor. It usually is discovered incidentally at the time of surgery or on examination of a resected appendix. This neoplasm most frequently involves the distal tip of the appendix, where it produces a solid bulbous swelling up to 2 to 3 cm in diameter. Although intramural and transmural extension may be evident, nodal metastases are very infrequent, and distant spread is exceptionally rare. Conventional *adenomas* or *non–mucin-producing adenocarcinomas* also occur in the appendix and may cause obstruction and enlargement that mimics the changes of acute appendicitis. *Mucocele,* a dilated appendix filled with mucin, may simply stem from an obstructed appendix containing inspissated mucin or may be a consequence of *mucinous cystadenoma* or *mucinous cystadenocarcinoma.* In the latter instance invasion through the appendiceal wall can lead to intraperitoneal seeding and spread. In women, the resulting peritoneal implants may be mistaken for mucinous ovarian tumors. In the most advanced cases, the abdomen fills with tenacious, semisolid mucin, a condition called *pseudomyxoma peritonei.* This disseminated intraperitoneal disease may be held in check for years by repeated debulking, but ultimately is fatal in most instances.

SUMMARY

APPENDIX

- Acute appendicitis is most common in children and adolescents. It is thought to be initiated by increased intraluminal pressure consequent to obstruction of the appendiceal lumen, which compromises venous outflow.
- The most common tumor of the appendix, the *carcinoid*, or *well-differentiated neuroendocrine tumor*, is most often discovered incidentally and is almost always benign
- The clinical presentation of appendiceal adenocarcinoma can be indistinguishable from that of acute appendicitis, although the former tends to present in older patients.

CHAPTER

16 Liver and Gallbladder

CHAPTER OUTLINE

The Liver and Bile Ducts

The normal adult liver weighs 1400 to 1600 gm. It has a dual blood supply, with the portal vein providing 60% to 70% of hepatic blood flow and the hepatic artery supplying the remaining 30% to 40%. The portal vein and the hepatic artery enter the inferior aspect of the liver through the hilum, or *porta hepatis*. Within the liver, the branches of the portal veins, hepatic arteries, and bile ducts travel in parallel within *portal tracts,* ramifying variably through 10 to 12 orders of branches.

The most common terminology used to describe the hepatic microarchitecture is based on the lobular model (Fig. 16.1). This model divides the liver into lobules 1- to 2-mm in diameter that are centered on a terminal tributary of the hepatic vein and demarcated by portal tracts at their periphery. These lobules are often drawn as hexagonal structures, though in humans the shapes are far more variable; nonetheless, it is a useful simplification. A second model divides the liver into triangular acini (see Fig. 16.1) based on the position of hepatocytes relative to their blood supply. The hepatocytes in the vicinity of the terminal hepatic vein are called *centrilobular;* those near the portal tract are *periportal.* **Division of the lobular parenchyma into zones is an important concept because each zone differs with respect to its metabolic activities and susceptibility to certain forms of hepatic injury.**

Within the lobule, hepatocytes are organized into anastomosing sheets or "plates" extending from portal tracts to the terminal hepatic veins. Between the trabecular plates of hepatocytes are vascular *sinusoids*. Blood traverses the sinusoids and exits into the terminal hepatic veins through numerous orifices in the vein wall. Hepatocytes are thus bathed by well-mixed portal venous blood on one side and hepatic arterial blood on the other. The sinusoids are lined by a fenestrated endothelium that overlies a perisinusoidal space (the *space of Disse*) into which abundant hepatocyte microvilli protrude. Attached to the luminal face of the sinusoids are scattered *Kupffer cells,* specialized long-lived tissue macrophages that arise early in embryogenesis. Another specialized cell type, the *hepatic stellate cell,* is found in the space of Disse and has a role in the storage of vitamin A. Between abutting hepatocytes are *bile canaliculi,* channels 1 to 2 µm in diameter that are formed by grooves in the plasma membranes of adjacent hepatocytes and are separated from the vascular space by tight junctions. These channels drain successively into the intralobular *canals of Hering,* periportal *bile ductules,* and finally into the *terminal bile ducts* within the portal tracts.

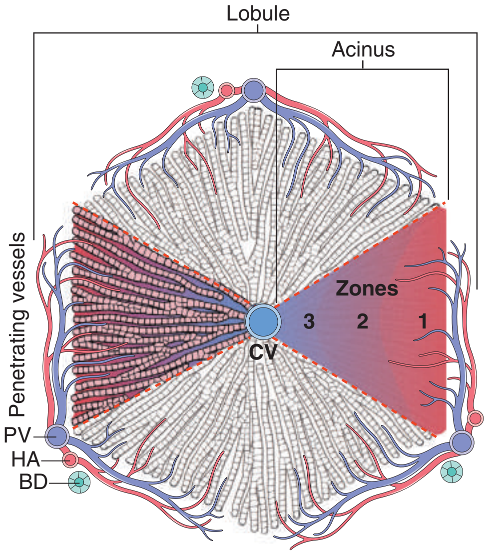

Fig. 16.1 Models of liver anatomy. In the lobular model, the terminal hepatic vein is at the center of a "lobule," while the portal tracts are at the periphery. Pathologists often refer to the regions of the parenchyma as "periportal and centrilobular." In the acinar model, on the basis of blood flow, three zones can be defined, zone 1 being the closest to the blood supply and zone 3 being the farthest. *BD*, Bile duct; *CV*, central hepatic vein; *HA*, hepatic artery; *PV*, portal tracts.

Table 16.1 Laboratory Evaluation of Liver Disease

Test Category	Blood Measurement*
Hepatocyte integrity	Cytosolic hepatocellular enzymes† *Serum aspartate aminotransferase* (AST) *Serum alanine aminotransferase* (ALT) Serum lactate dehydrogenase (LDH)
Biliary excretory function	Substances normally secreted in bile† *Serum bilirubin* *Total:* unconjugated plus conjugated *Direct:* conjugated only Urine bilirubin Serum bile acids Plasma membrane enzymes (from damage to bile canaliculus)† *Serum alkaline phosphatase* *Serum γ-glutamyl transpeptidase (GGT)*
Hepatocyte function	Proteins secreted into the blood *Serum albumin*‡ *Prothrombin time (PT)*† *Partial thromboplastin time (PTT)*† Hepatocyte metabolism Serum ammonia† Aminopyrine breath test (hepatic demethylation)‡

*Most commonly used tests are in italics; †an elevation suggests liver disease; ‡a decrease suggests liver disease.

GENERAL FEATURES OF LIVER DISEASE

The major primary diseases of the liver are viral hepatitis, alcoholic liver disease, nonalcoholic fatty liver disease (NAFLD), and hepatocellular carcinoma (HCC). The liver also is frequently damaged secondarily in a variety of common disorders, such as cardiac disease, disseminated cancer, and extrahepatic infections. The functional reserve of the liver masks the clinical impact of mild liver damage, but severe diffuse liver disease often has life-threatening consequences.

With the rare exception of fulminant hepatic failure, liver disease is an insidious process in which the signs and symptoms of hepatic decompensation appear weeks, months, or even years after the onset of injury. The hepatic injury may be imperceptible to the patient and be manifest only by laboratory test abnormalities (Table 16.1), and liver injury and healing also may be subclinical. Hence, individuals with hepatic abnormalities who are referred to hepatologists most frequently have chronic liver disease.

Mechanisms of Injury and Repair

Injured hepatocytes may show several potentially reversible changes, such as accumulation of fat and bilirubin (cholestasis); when injury is not reversible, hepatocytes die by necrosis or apoptosis. Necrosis (Fig. 16.2) is commonly seen following hepatic injury caused by hypoxia and ischemia. Apoptotic cell death (Fig. 16.3) predominates in viral, autoimmune, and drug- and toxin-induced hepatitides.

Widespread death of hepatocytes may produce *confluent necrosis*. This may be seen in acute toxic or ischemic injuries or in severe chronic viral or autoimmune hepatitis. Confluent necrosis begins as a zone of hepatocyte dropout around the central vein. With increasing severity necrosis

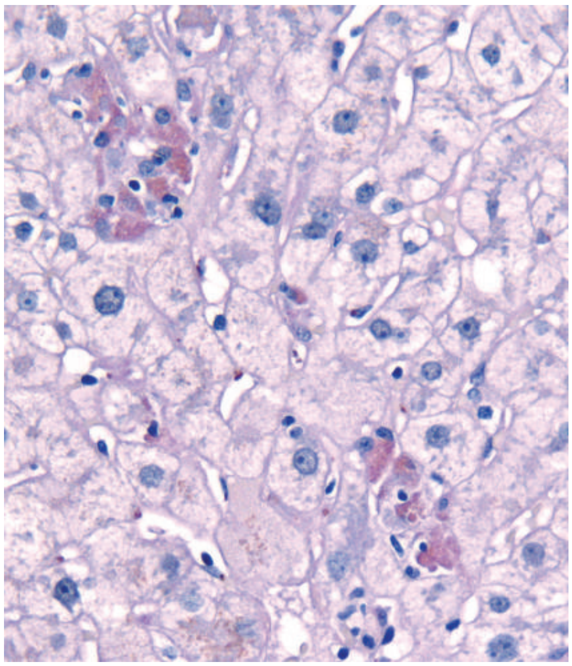

Fig. 16.2 Hepatocyte necrosis. In this PAS-D–stained biopsy from a patient with acute hepatitis B, clusters of pigmented hepatocytes with eosinophilic cytoplasm indicate foci of hepatocytes undergoing necrosis. *PAS-D*, Periodic acid-Schiff stain after diastase digestion.

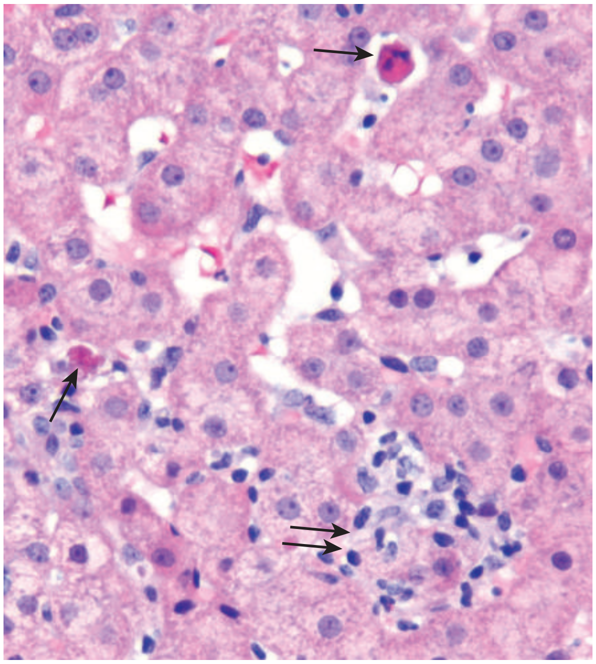

Fig. 16.3 Hepatocyte apoptosis. This biopsy from a patient with lobular hepatitis due to chronic hepatitis C shows scattered apoptotic hepatocytes ("acidophil bodies"; *single arrows*) and a patchy inflammatory infiltrate *(double arrows)*.

"bridges" central veins and portal tracts or adjacent portal tracts.

Regeneration of lost hepatocytes takes place primarily by mitotic replication of hepatocytes adjacent to those that have died. In more severe forms of acute liver injury hepatic stem cells located in a niche near the canal of Hering may also begin to divide, but the contribution of stem cells to the replenishment of hepatocytes in the setting of acute liver damage remains uncertain. In longstanding chronic liver diseases, however, there is clear evidence that stem cell proliferation and differentiation make significant contributions to parenchymal restoration, probably following the replicative senescence of preexisting hepatocytes. The differentiating progeny of these tissue stem cells produce duct-like structures, called *ductular reactions,* a morphologic marker of stem cell–mediated liver regeneration.

Scar formation may follow very severe acute injury, but occurs more often as a reaction to chronic injury. The principal cell type involved in scar deposition is the perisinusoidal hepatic stellate cell. Following liver injury, stellate cells may become activated and convert into highly fibrogenic myofibroblasts, which produce the fibrous scar. Stellate cell activation involves complex interactions between Kupffer cells, hepatocytes, and inflammatory cells. When there is severe injury that causes death of large number of hepatocytes and the drop out of liver cells, there may be collapse of the underlying reticulin, precluding orderly regeneration of hepatocytes. In such cases, there is activation of stellate cells, and the areas of liver cell loss are replaced by fibrous septae. Eventually, these fibrous septa encircle surviving, regenerating hepatocytes in late-stage chronic liver disease, many forms of which are described as *cirrhosis*.

Inflammation and immunologic reactions are involved in many forms of liver disease. Systemic inflammation alters the metabolic and biosynthetic activities of the liver, leading to increased secretion of acute-phase reactants such as C-reactive protein, serum amyloid A protein (a precursor of some forms of amyloid) and hepcidin, a key regulator of iron metabolism (Chapter 12). As we will discuss, adaptive immune cells play a critical role in viral hepatitis, with CD4+ and CD8+ T cells being particularly important in the eradication of virus-infected hepatocytes and, in chronic disease, liver injury.

Liver Failure

The most severe clinical consequence of liver disease is liver failure. It primarily occurs in three clinical scenarios: acute, chronic, and acute-on-chronic liver failure.

Acute Liver Failure

Acute liver failure is defined as a liver disease that produces hepatic encephalopathy within 6 months of the initial diagnosis. The condition is known as *fulminant liver failure* when the encephalopathy develops within 2 weeks of the onset of jaundice, and as *subfulminant liver failure* when the encephalopathy develops within 3 months. In the United States, accidental or deliberate ingestion of acetaminophen accounts for almost 50% of cases of acute liver failure, while autoimmune hepatitis, other drugs and toxins, and acute hepatitis A and B infections account for the remainder of cases. In Asia, acute hepatitis B and E predominate as causes of acute liver failure.

MORPHOLOGY

The clinical syndrome of acute liver failure is reflected anatomically and histologically as **massive hepatic necrosis.** The liver is small and shrunken due to loss of parenchyma (Fig. 16.4A). Microscopically, there are large zones of destruction surrounding occasional islands of regenerating hepatocytes (Fig. 16.4B). Scar is mostly absent given the acute nature of the process.

Clinical Features

Acute liver failure manifests with nausea, vomiting, jaundice, and fatigue, which are followed by the onset of life-threatening encephalopathy, coagulation defects, and portal hypertension associated with ascites. Typically, transaminase levels in the serum are elevated into the thousands. The liver is initially enlarged by swelling and edema related to inflammation, but then as parenchyma is destroyed the liver shrinks dramatically. Eventually, as hepatocytes are lost, serum transaminase values level off and then decline rapidly as their source disappears. Worsening jaundice, coagulopathy, and encephalopathy develop; with unabated progression, the end result is multiorgan failure and, without transplantation, death. Manifestations of acute liver failure include the following:

- *Jaundice* and *icterus* (yellow discoloration of the skin and sclera, respectively) due to retention of bilirubin, and *cholestasis* due to systemic retention of not only bilirubin but also other solutes eliminated in bile.

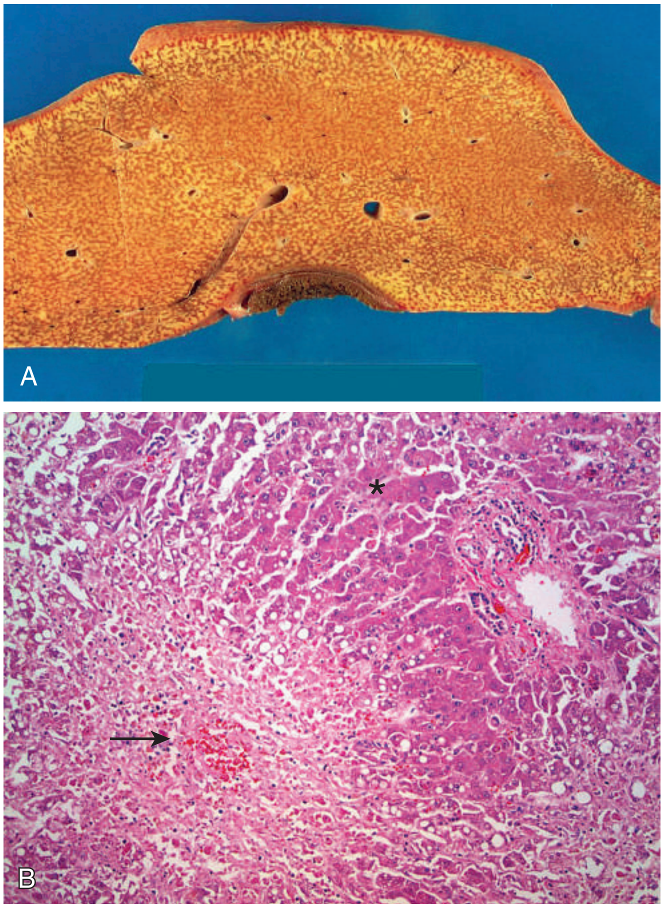

Fig. 16.4 Massive liver necrosis. (A) The liver is small (700 g), bile-stained, soft, and congested. (B) Hepatocellular necrosis caused by acetaminophen overdose. Confluent necrosis is seen in the perivenular region (zone 3, *arrow*). There is little inflammation. Residual normal tissue is indicated by the *asterisk*. *(Courtesy of Dr. Matthew Yeh, University of Washington, Seattle, Washington).*

- *Hepatic encephalopathy* encompasses a spectrum of disturbances in consciousness ranging from subtle behavioral abnormalities, to confusion and stupor, to coma and death. Encephalopathy may develop over days, weeks, or a few months after acute injury. Fluctuating neurologic signs, including rigidity, hyperreflexia, and *asterixis,* may develop. Asterixis refers to a nonrhythmic rapid extension-flexion movement of the head and extremities, best seen as "flapping" of the hands when the arms are held in extension with dorsiflexed wrists. Elevated ammonia levels in blood and the central nervous system correlate with impaired neuronal function and brain edema.
- *Coagulopathy.* The liver is the source of a number of coagulation factors that decline in the face of liver failure, leading to easy bruising and bleeding. Paradoxically, *disseminated intravascular coagulation* (Chapter 12) also may occur due to failure of the damaged liver to remove activated coagulation factors.
- *Portal hypertension* arises when there is diminished flow through the portal venous system, which may occur because of obstruction at the prehepatic, intrahepatic, or posthepatic level. While it can occur in acute live failure, portal hypertension is more commonly seen with chronic liver failure and is discussed later. In acute liver failure, the obstruction is usually intrahepatic and the major clinical consequences are *ascites* and *hepatic encephalopathy*. In chronic liver disease, portal hypertension develops over months to years, and its effects are more complex and widespread (see later).
- *Hepatorenal syndrome* is a form of renal failure occurring in individuals with liver failure in whom there are no intrinsic morphologic or functional causes for kidney dysfunction. Sodium retention, impaired free-water excretion, and decreased renal perfusion and glomerular filtration rate are the main renal functional abnormalities. There is decreased renal perfusion pressure due to systemic vasodilation, activation of the renal sympathetic nervous system and vasoconstriction of the afferent renal arterioles, and increased activation of the renin-angiotensin axis, causing vasoconstriction that further decreases glomerular filtration. The syndrome's onset begins with a decrease in urine output and rising blood urea nitrogen and creatinine levels.

Chronic Liver Failure and Cirrhosis

Cirrhosis is the morphologic change most often associated with chronic liver disease; it refers to the diffuse transformation of the liver into regenerative parenchymal nodules surrounded by fibrous bands (Fig. 16.5). The leading causes of chronic liver failure worldwide include chronic hepatitis B, chronic hepatitis C, non-alcoholic fatty liver disease (NAFLD), and alcoholic liver disease. While cirrhosis is a common feature of a number of chronic liver diseases, it is not a specific entity, and it is important to recognize that not all chronic liver disease terminates in cirrhosis, and that not all cirrhosis leads to end-stage liver disease. For example, chronic biliary tract diseases often do not give rise to cirrhosis even at end stage, whereas patients with treated autoimmune hepatitis or cured hepatitis C may have adequate liver function in the face of cirrhosis. Even in diseases that are likely to give rise to cirrhosis, such as untreated viral hepatitis, alcoholic liver disease, NAFLD, and metabolic diseases, the morphology and pathophysiology of cirrhosis in each may be different.

Fig. 16.5 Cirrhosis resulting from chronic viral hepatitis. Note the broad scars separating bulging regenerative nodules over the liver surface.

MORPHOLOGY

Liver failure in **chronic** liver disease is most often associated with cirrhosis, which is marked by the diffuse transformation of the entire liver into **regenerative parenchymal nodules surrounded by fibrous bands**. The nodular nature of the process is readily evident both grossly (Fig. 16.5) and microscopically (Fig. 16.6, *A*). The size of the nodules, the pattern of scarring (linking of portal tracts to each other vs. linking of portal tracts to central veins), the degree of parenchymal loss, and the frequency of vascular thrombosis (particularly of the portal vein) all vary between diseases and even, in some cases, between individuals with the same disease.

As mentioned earlier, stem cell activation and differentiation gives rise to duct-like structures, the so called ductular reactions. **In chronic liver disease, ductular reactions increase with disease progression and are usually most prominent in cirrhosis.** Ductular reactions may incite some of the scarring in chronic liver disease and thus may have a negative effect on progressive liver disease.

Regression of fibrosis and even of fully established cirrhosis may follow disease remission or cure. Scars become thinner, more densely compacted, and eventually start to fragment (see Fig. 16.6, *B*). As fibrous septa break apart, adjacent nodules of regenerating parenchyma coalesce into larger islands. All cirrhotic livers show elements of both progression and regression, with the balance being dictated by the severity and persistence of the underlying disease.

Clinical Features

About 40% of individuals with cirrhosis are asymptomatic until the most advanced stages of the disease. Even at late stages, they present with nonspecific clinical manifestations, such as anorexia, weight loss, weakness, and, eventually signs and symptoms of liver failure discussed earlier. Jaundice, encephalopathy, and coagulopathy may result from chronic liver disease, much the same as in acute liver failure. However, there are some significant additional features:

- Chronic severe jaundice can lead to *pruritus* (itching), the intensity of which may be so profound that patients scratch their skin raw and risk repeated bouts of potentially life-threatening infection. In some patients, severe pruritus is the primary indication for liver transplantation. Pruritus also is frequently seen in other disorders associated with cholestasis, suggesting that it is somehow related to the build up of bile salts in the body, but its precise pathogenesis is unknown.
- *Portal hypertension* is more frequent and manifests in more complex ways in chronic liver failure than in acute liver failure (Fig. 16.7). *Portosystemic shunts* develop when blood flow is reversed from the portal to systemic circulation. These shunts are principally produced by dilation of collateral vessels. Most notably, venous bypasses develop wherever the systemic and the portal circulations share common capillary beds, the most clinically important of which are *esophagogastric varices,* which appear in about 40% of individuals with advanced-stage liver disease. These often cause massive, frequently fatal hematemesis, particularly when there is compounding coagulopathy. Portal hypertension often occurs and may lead to congestive *splenomegaly,* which can lower the platelet count due to sequestration of these elements in the expanded red pulp.
- *Hyperestrogenemia* due to impaired estrogen metabolism in male patients with chronic liver failure can give rise to *palmar erythema* (a reflection of local vasodilatation) and *spider angiomas* of the skin. Such male hyperestrogenemia also leads to *hypogonadism* and *gynecomastia*. Hypogonadism also may occur in women from disruption of hypothalamic-pituitary axis functioning.
- Most chronic liver diseases predispose to development of *hepatocellular carcinoma* (HCC, discussed later).

The course and severity of chronic liver disease with cirrhosis vary widely from patient to patient. Even in instances in which cirrhosis regresses following disease remission or cure, portal hypertension may persist due to the presence of irreversible shunts. The causes of death are

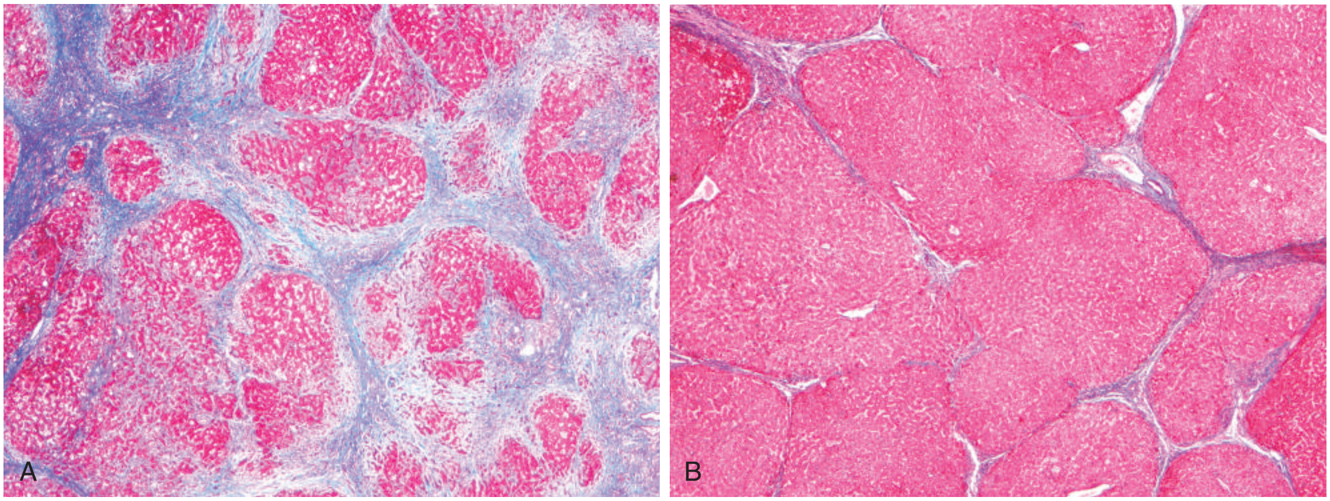

Fig. 16.6 Alcoholic cirrhosis in an active drinker (A) and following long-term abstinence (B). *A,* Thick bands of collagen separate rounded cirrhotic nodules. *B,* After 1 year of abstinence, most scars are gone (Masson trichrome stain). *(Courtesy of Drs. Hongfa Zhu and Isabel Fiel, Mount Sinai School of Medicine, New York, New York.)*

liver failure (as in acute liver disease) and HCC. Clinical and laboratory findings are the main criteria used to gauge prognosis and disease progression. It some centers, portal venous wedge pressures are measured to assess the degree of vascular obstruction. Liver biopsy findings correlate with the presence and severity of portal hypertension. For example, specimens with thin fibrous septa and large islands of regenerated parenchyma are unlikely to be associated with portal hypertension, whereas broad bands of fibrosis and loss of parenchyma portend the development of portal hypertension and end-stage liver disease.

Acute-on-Chronic Liver Failure

Some individuals after years of stable, well-compensated, chronic disease suddenly develop signs of acute liver failure. In such patients, there is often established cirrhosis with extensive vascular shunting, or large volumes of functioning liver parenchyma with a borderline vascular supply, both of which leave the liver vulnerable to superimposed, potentially lethal insults. The short-term mortality of patients with this form of liver failure is around 50%.

Hepatic insults that cause sudden decompensation of patients with chronic liver disease include: hepatitis D superinfection in those with chronic hepatitis B; emergence of resistance to medical therapy in those with viral hepatitis; development of ascending bacterial cholangitis in patients with primary sclerosing cholangitis; or replacement of liver parenchyma by primary or metastatic carcinoma. In other instances the cause may be a systemic disorder, such as sepsis, acute cardiac failure or a superimposed toxic injury that tips a well-compensated cirrhotic patient into liver failure.

SUMMARY

LIVER FAILURE

- Liver failure may follow acute injury or chronic injury, or it may occur as an acute insult superimposed on otherwise well-compensated chronic liver disease.
- The mnemonic for causes of acute liver failure are as follows:
  - A: acetaminophen, hepatitis A, autoimmune hepatitis
  - B: hepatitis B
  - C: cryptogenic, hepatitis C
  - D: drugs/toxins, hepatitis D
  - E: hepatitis E, esoteric causes (Wilson disease, Budd-Chiari syndrome)
  - F: fatty change of the microvesicular type (fatty liver of pregnancy, valproate, tetracycline, Reye syndrome)
- Potentially fatal sequelae of liver failure include coagulopathy, encephalopathy, portal hypertension and ascites, hepatorenal syndrome, and portopulmonary hypertension.

INFECTIOUS DISORDERS

Viral Hepatitis

The terminology for acute and chronic viral hepatitis can be confusing, because the same word, *hepatitis,* can be used to describe several different entities; careful attention to context can clarify its meaning in any situation. Firstly, *hepatitis* is the name applied to viruses (hepatitis A, B, C, D, and E virus) that are *hepatotropic,* that is, have a specific affinity for the liver. Secondly, *hepatitis* is applied to patterns of acute and chronic hepatic injuries that are produced not only by hepatotropic viruses, but also by damage produced by other viruses such as EBV, CMV , and yellow fever as well as autoimmune reactions, drugs, and toxins. In this section, we will focus on the main features of hepatotropic viruses, which are summarized in Table 16.2, and we will then discuss the clinicopathologic characteristics of acute and chronic viral hepatitis.

Hepatitis A Virus (HAV)

HAV usually is a benign self-limited infection that does not cause chronic hepatitis and rarely (in about 0.1% of cases) produces fulminant hepatitis. HAV has an incubation period of 3-6 weeks. It is typically cleared by the host immune response, so it does not establish a carrier state. The infection occurs throughout the world and is endemic in countries with poor hygiene and sanitation.

Table 16.2 The Hepatitis Viruses

Virus	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)	Hepatitis D (HDV)	Hepatitis E (HEV)
Viral genome	ssRNA	partially dsDNA	ssRNA	Circular defective ssRNA	ssRNA
Viral family	Hepatovirus; related to picornavirus	Hepadnavirus	*Flaviviridae*	Subviral particle in *Deltaviridae* family	Calicivirus
Route of transmission	Fecal-oral (contaminated food or water)	Parenteral, sexual contact, perinatal	Parenteral; intranasal cocaine use is a risk factor	Parenteral	Fecal-oral
Incubation period	2–6 weeks	2–26 weeks (mean 8 weeks)	4–26 weeks (mean 9 weeks)	Same as HBV	4–5 weeks
Frequency of chronic liver disease	Never	5%–10%	>80%	10% (coinfection); 90%–100% for superinfection	In immunocompromised hosts only
Diagnosis	Detection of serum IgM antibodies	Detection of HBsAg or antibody to HBcAg; PCR for HBV DNA	ELISA for antibody detection; PCR for HCV RNA	Detection of IgM and IgG antibodies, HDV RNA in serum, or HDAg in liver biopsy	Detection of serum IgM and IgG antibodies; PCR for HEV RNA

ssRNA, Single-stranded RNA; *dsDNA*, double-stranded DNA; *HBcAg*, hepatitis B core antigen; *HBsAg*, hepatitis B surface antigen; *HDAg*, hepatitis D antigen; *ELISA*, enzyme-linked immunosorbent assay.

Acute HAV tends to cause a febrile illness associated with jaundice and nonspecific symptoms such as fatigue and loss of appetite. Overall, HAV accounts for about 25% of clinically evident acute hepatitis worldwide.

HAV is a small, nonenveloped, positive-strand RNA picornavirus that occupies its own genus, *Hepatovirus*. Ultrastructurally, HAV is an icosahedral capsid 27 nm in diameter. The receptor for HAV is HAVcr-1, a membrane glycoprotein that also may serve as a receptor for Ebola virus. *HAV is spread by ingestion of contaminated water and food and is shed in the stool for 2 to 3 weeks before and 1 week after the onset of jaundice.* Thus, close personal contact with an infected individual or fecal-oral contamination accounts for most cases and explains outbreaks in institutional settings such as schools and nurseries, as well as water-borne epidemics in places where people live in overcrowded, unsanitary conditions. HAV can also be detected in serum and saliva of infected individuals.

In developed countries, sporadic infections may be contracted by the consumption of raw or steamed shellfish that have concentrated the virus from seawater contaminated with human sewage. Infected workers in the food industry are another source of outbreaks. HAV itself does not seem to be cytopathic. The cellular immune response, particularly that involving cytotoxic CD8+ T cells, plays a key role in HAV-mediated hepatocellular injury.

Because HAV viremia is transient, blood-borne transmission is very rare; therefore, donated blood is not specifically screened for this virus. IgM antibody against HAV appears in blood at the onset of symptoms and is a reliable marker of acute infection (Fig. 16.8). Fecal shedding of the virus ends as the IgM titer rises. The IgM response usually declines in a few months followed by the appearance of IgG anti-HAV that persists for years, often conferring life-long immunity. However, there are no routinely available tests for IgG anti-HAV; the presence of IgG anti-HAV is inferred from the difference between total and IgM anti-HAV. The HAV vaccine, available since 1992, is effective in preventing infection.

Hepatitis B Virus (HBV)

The outcome of HBV infection varies widely, from (1) acute hepatitis with recovery and clearance of the virus; (2) nonprogressive chronic hepatitis; (3) progressive chronic disease ending in cirrhosis; (4) fulminant hepatitis with massive liver necrosis; and (5) an asymptomatic

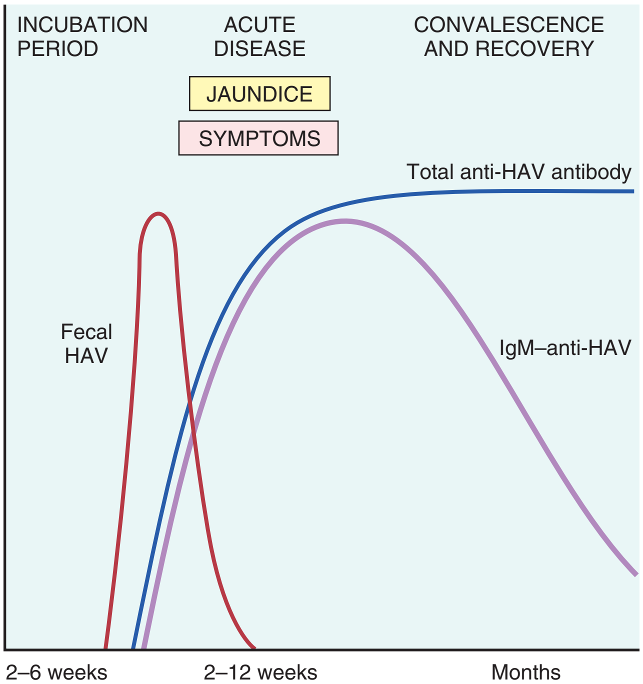

Fig. 16.8 Temporal changes in serologic markers in acute hepatitis A infection. *HAV*, Hepatitis A virus.

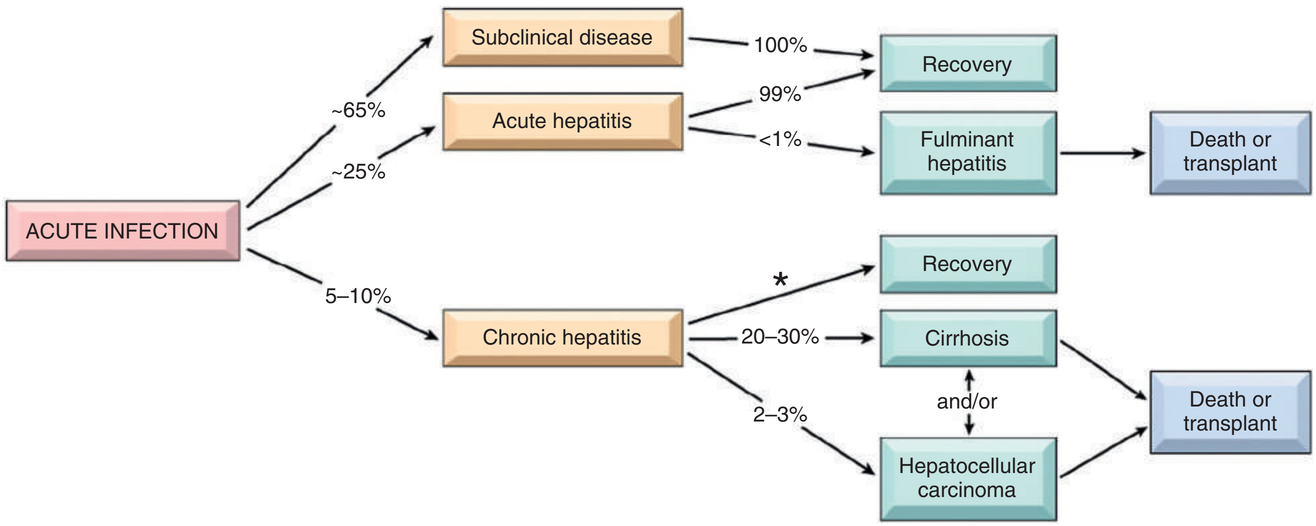

Fig. 16.9 Potential outcomes of hepatitis B infection in adults, with their approximate frequencies in the United States. *Spontaneous HBsAg clearance occurs during chronic HBV infection at an estimated annual incidence of 1% to 2% in Western countries. As mentioned in the text, fulminant hepatitis and acute hepatic failure are used interchangeably.

"healthy" carrier state. HBV-induced chronic liver disease is also an important precursor for the development of HCC. The approximate frequencies of various clinical outcomes of HBV infection are depicted in Fig. 16.9.

Liver disease due to HBV infection is an enormous global health problem. One-third of the world's population (2 billion individuals) has been infected with HBV, and 400 million individuals have chronic infections. Seventy-five percent of chronic carriers live in Asia and the Western Pacific rim. The global prevalence of chronic hepatitis B infection varies from greater than 8% in parts of Africa to less than 2% in Western Europe, North America, and Australia.

The mode of transmission of HBV also varies with the geographic locale. In high-prevalence regions of the world, perinatal transmission during childbirth accounts for 90% of cases. In areas with intermediate prevalence, horizontal transmission, especially in early childhood, dominates. Spread among children usually occurs through minor breaks in the skin or mucous membranes following physical contact with infected individuals. In low-prevalence areas, unprotected sex and intravenous drug abuse (sharing of needles and syringes) are the chief modes of spread. Transfusion-related spread has been reduced greatly by screening of donated blood for HBsAg and by cessation of the practice of paying blood donors. Vaccination induces a protective antibody response in 95% of infants, children, and adolescents. Universal vaccination has had notable success in Taiwan and Gambia, but has yet to be adopted worldwide.

HBV has a prolonged incubation period (2–26 weeks). Unlike HAV, HBV remains in the blood during active episodes of acute and chronic hepatitis. Approximately 70% of adults with newly acquired HBV have mild or no symptoms and do not develop jaundice. The remaining 30% have nonspecific constitutional symptoms such as anorexia, fever, jaundice, and right upper-quadrant pain. In most cases, the infection is self-limited and resolves without treatment, but chronic disease develops in 10% of infected individuals. Fulminant hepatitis is rare, occurring in approximately 0.1% to 0.5% of acutely infected individuals.

HBV is a member of *Hepadnaviridae,* a family of DNA viruses that cause hepatitis in multiple animal species. The HBV genome is a partially double-stranded, 3200-nucleotide, circular DNA with four open reading frames, which encode the following proteins:

- *Nucleocapsid "core" protein* (HBcAg, hepatitis B core antigen) and a longer polypeptide with a precore and core region, designated HBeAg (hepatitis B e antigen). The precore region directs the secretion of the HBeAg polypeptide into blood, whereas HBcAg remains in hepatocytes, where it participates in the assembly of virions.
- *Envelope glycoproteins* (HBsAg, hepatitis B surface antigen). Infected hepatocytes synthesize and secrete massive quantities of noninfective envelope glycoproteins (mainly small HBsAg).
- A *polymerase (Pol)* with both DNA polymerase activity and reverse transcriptase activity, which enables genomic replication to occur through a unique DNA → RNA → DNA cycle via an intermediate RNA template. This unusual polymerase is the target of drugs used to treat hepatitis B infection (described later).
- *HBx protein,* which is required for virus replication and which may act as a transcriptional transactivator for viral genes and a wide variety of host genes. It has been implicated in the pathogenesis of HBV-associated liver cancer.

The course of the disease can be followed clinically by monitoring certain serum markers (Fig. 16.10).

- HBsAg appears before the onset of symptoms, peaks during symptomatic disease, and then usually declines to undetectable levels in 12 weeks (though it may occasionally persist as long as 24 weeks).

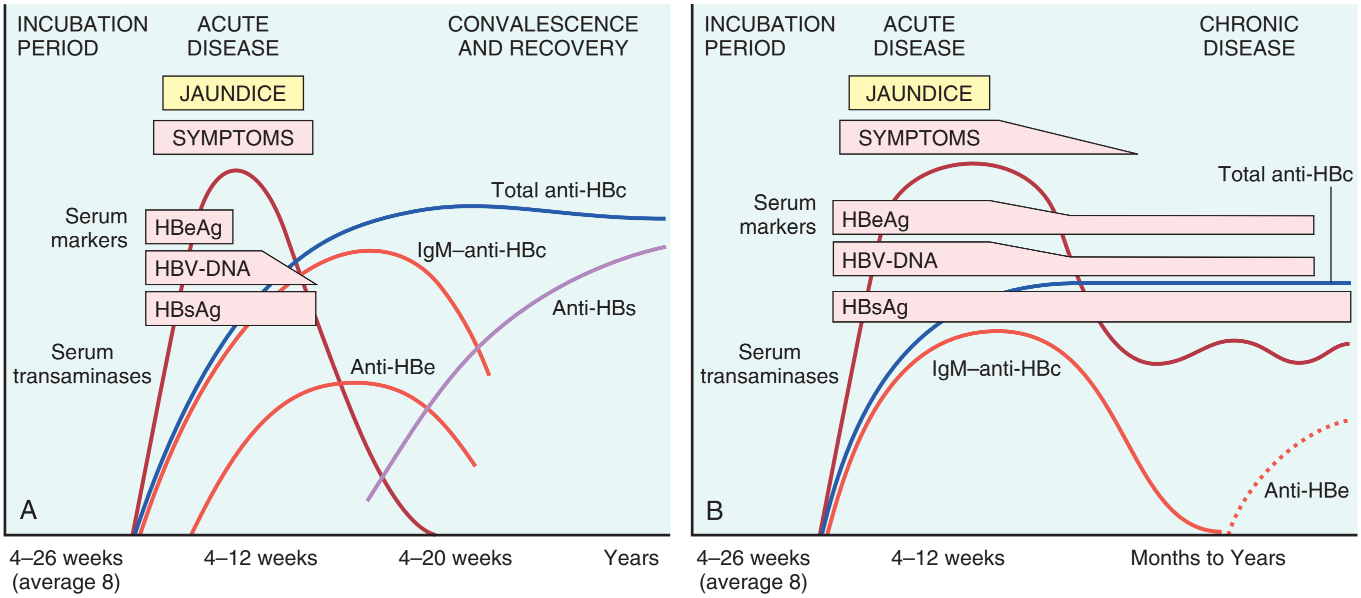

Fig. 16.10 Temporal changes in serologic markers for hepatitis B viral infection. (A) Acute infection with resolution. (B) progression to chronic infection. Note in some cases of chronic HBV infection, serum transaminases may become normal.

- Anti-HBs antibody appears after the acute disease is over and usually is not detected until a few weeks to several months after HBsAg disappears. Anti-HBs may persist for life and confers protection, which is the rationale for current vaccines containing HBsAg.
- HBeAg and HBV DNA appear in serum soon after HBsAg and signify ongoing viral replication. Persistence of HBeAg is an indicator of progression to chronic hepatitis. The appearance of anti-HBe antibodies implies that an acute infection has peaked and is on the wane.
- IgM anti-HBc becomes detectable in serum shortly before the onset of symptoms, concurrent with the onset of elevated serum aminotransferase levels (indicative of hepatocyte destruction). Over a period of months, the IgM anti-HBc antibody is replaced by IgG anti-HBc. As in the case of anti-HAV, there is no direct assay for IgG anti-HBc; its presence is inferred from decline of IgM anti-HBc in the face of rising total anti-HBc.

Occasionally, mutated strains of HBV emerge that do not produce HBeAg but are replication competent and express HBcAg. In such patients, the HBeAg may be low or undetectable despite the presence of serum HBV DNA. A second ominous development is the appearance of HBV mutants in vaccinated individuals that replicate in the presence of normally protective anti-HBs antibodies.

The host immune response is the main determinant of the outcome of the infection. Innate immune mechanisms protect the host during initial phases of the infection, and a strong response by virus-specific CD4+ and CD8+ interferon γ–producing cells is associated with the resolution of acute infection. HBV generally is not directly hepatotoxic, and most hepatocyte injury is caused by CD8+ cytotoxic T cells attacking infected cells.

Patient age at the time of infection is the best predictor of chronicity. In general, the younger the age at the time of HBV infection, the higher the chance of chronic infection. Treatment of chronic hepatitis B with viral polymerase inhibitors and interferon can slow disease progression, reduce liver damage, and prevent liver cirrhosis or liver cancer but does not eliminate the infection. As a result, treatment sometimes fails due to emergence of viruses bearing mutations that lead to drug resistance.

Hepatitis C Virus (HCV)

HCV is a major cause of liver disease, with approximately 170 million individuals affected worldwide. Approximately 4.1 million Americans (1.6% of the population) have chronic HCV infection. Notably, there has been a decrease in the annual incidence of infection from a mid-1980s peak of over 230,000 new infections per year to 30,000 new infections per year currently, due primarily to a reduction in transfusion-associated cases as a result of effective screening procedures. Until recently, the number of patients with chronic infection appeared likely to continue to increase, but new therapies (discussed later) are changing the outlook for the better.

According to data from the Centers for Disease Control and Prevention (CDC), the most common risk factors for HCV infection are as follows:

- Intravenous drug abuse
- Multiple sex partners
- Having had surgery within the last 6 months
- Needle stick injury
- Multiple contacts with an HCV-infected individual
- Employment in the medical or dental field

Currently, transmission of HCV by blood transfusion is close to zero in the United States; the risk for acquiring HCV by needle stick is about six times higher than that for HIV (1.8 vs. 0.3%). For children, the major route of infection is vertical perinatal transmission from the mother. Some patients have multiple risk factors, but one-third of

individuals have no identifiable risk factors, an enduring mystery.

HCV, discovered in 1989, is a member of the *Flaviviridae* family. Just as in the case of HIV, an understanding of viral replication and assembly has facilitated the development of highly effective anti-HCV drugs (described below). HCV is a small, enveloped, single-stranded RNA virus with a 9600-base genome encoding a single polyprotein that is processed by several proteases into 10 functional proteins. Included among these viral proteins is a viral protease that is needed for complete processing of the polyprotein; NS5A, a protein that is essential for assembly of HCV into mature virions; and a viral RNA polymerase that is necessary for replication of the viral genome (Fig. 16.11). Because of the low fidelity of the HCV RNA polymerase, the viral genome is inherently unstable, giving rise to new genetic variants at a high pace. This has led to the appearance of six major HCV genotypes worldwide, each with one or more "subspecies." Infections in most individuals are due to a virus of a single genotype, but new genetic variants are generated in the host as long as viral replication persists. As a result, each patient usually comes to be infected with a population of divergent but closely related HCV variants known as *quasispecies.*

The incubation period for HCV hepatitis ranges from 4 to 26 weeks, with a mean of 9 weeks. In about 85% of individuals, the acute infection is asymptomatic and goes unrecognized. HCV RNA is detectable in blood for 1 to 3 weeks, coincident with elevations in serum transaminases (Fig. 16.12). In symptomatic acute HCV infection, anti-HCV antibodies are detected in only 50% to 70% of patients; in the remaining patients, the anti-HCV antibodies emerge after 3 to 6 weeks. The clinical course of acute HCV hepatitis is milder than that of HBV. It is not known why only a small minority of individuals is capable of clearing HCV infection.

Persistent infection and chronic hepatitis are the hallmarks of HCV infection, despite the generally asymptomatic nature of the acute illness. In contrast to HBV, chronic disease occurs in the majority of HCV-infected individuals (80%–90%), and cirrhosis eventually occurs in as many as one-third. The mechanisms leading to chronicity are not well understood, but it is clear that the virus uses multiple strategies to evade host anti-viral immunity. In addition to rapid generation of genetic variants, which may allow the virus to elude neutralizing antibodies, HCV encodes proteins that inhibit Toll-like receptor and interferon signaling in hepatocytes, activites that would otherwise allow hepatocytes to resist viral infection.

In chronic HCV infection, circulating HCV RNA persists in 90% of patients despite the presence of neutralizing antibodies (see Fig. 16.12). Hence, testing for HCV RNA must be done to confirm the diagnosis of chronic HCV infection. A characteristic clinical feature of chronic HCV infection is episodic elevations in serum aminotransferases separated by periods of normal or near-normal enzyme levels. However, even HCV-infected patients with normal transaminases are at high risk for developing permanent liver damage, and anyone with detectable serum HCV RNA needs treatment and long-term medical follow-up.

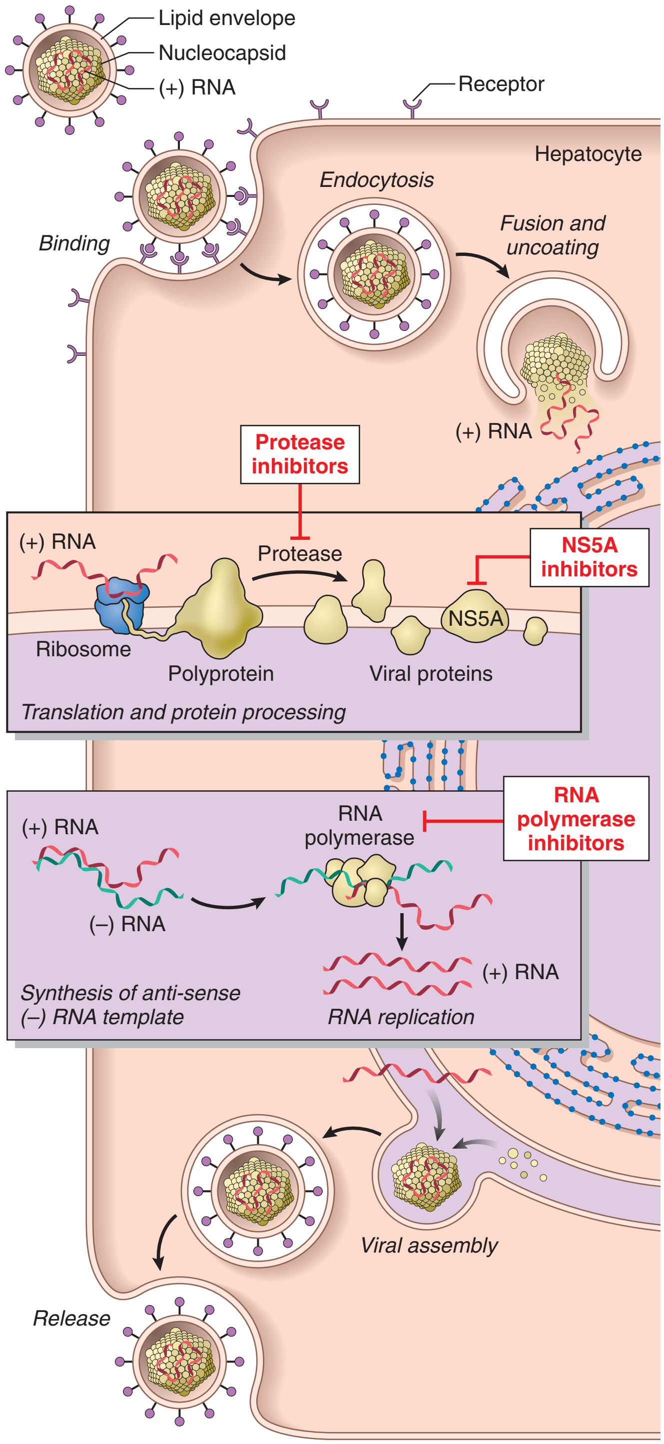

Fig. 16.11 Life cycle of hepatitis C. Viral entry, replication, assembly, and budding are shown, emphasizing steps that can be effectively targeted with anti-viral drugs.

Fortunately, **recent years have seen dramatic improvements in treatment of HCV infection that stem from development of drugs that specifically target the viral protease, RNA polymerase, and NS5A protein, all of**

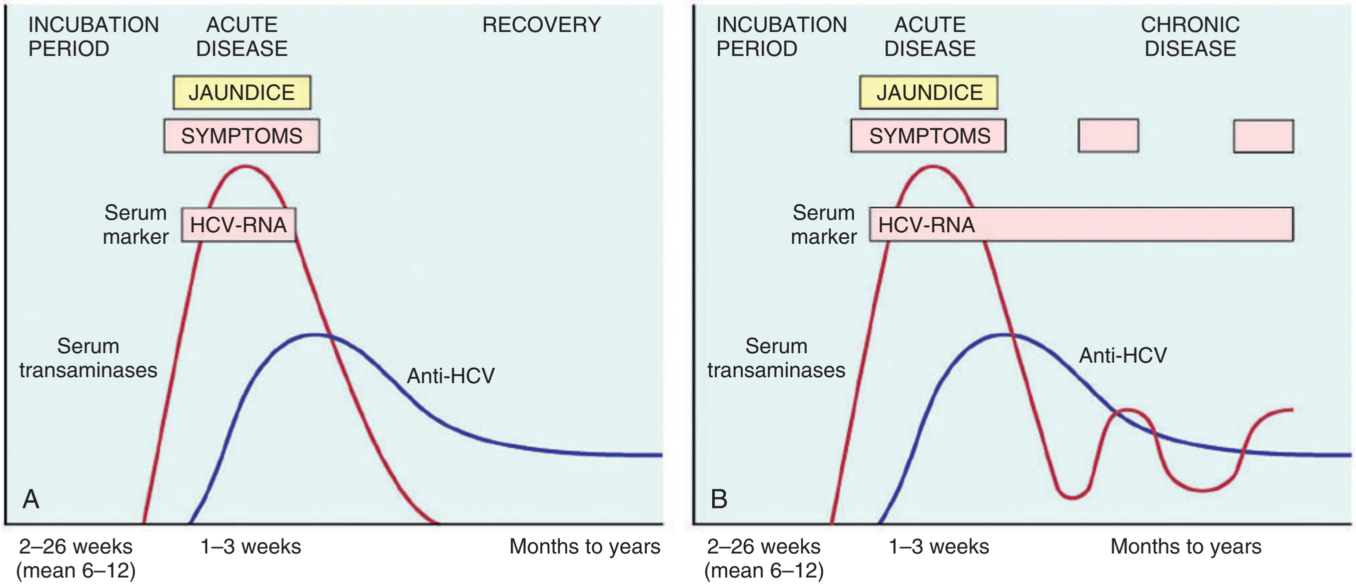

Fig. 16.12 Temporal changes in serologic markers in hepatitis C infection. (A) Acute infection with resolution; (B) progression to chronic infection.

which are required for production of virus (Fig. 16.11). Combination therapy with these drugs (a strategy akin to triple drug therapy for HIV) has proven to be remarkably effective. The goal of current treatment is to eradicate HCV RNA, which is defined by the absence of detectable HCV RNA in the blood 6 months after treatment is stopped and is associated with a high probability of cure. Currently, over 95% of HCV infections are curable, and this can be expected to improve further as new anti-viral drugs become available. The major downside of these advances is their very high cost; a curative course of drug therapy costs over $100,000, and it is estimated that treatment of HCV infections in the United States alone may generate expenses of over $50 billion over the next 5 years.

Hepatitis D Virus (HDV)

Also called the *delta agent*, HDV is a unique RNA virus that is dependent for its life cycle on HBV. Infection with HDV arises in the following settings:

- *Coinfection* by HDV and HBV. The HBV must become established first to provide the HBsAg, which is necessary for production of complete HDV virions. Coinfection with HBV and HDV is associated with higher rates of severe acute hepatitis and fulminant liver failure, particularly in intravenous drug abusers, and higher rates of progression to chronic infection, which is often complicated by emergence of liver cancer.
- *Superinfection* of a chronic HBV carrier by HDV. The superinfection presents 30 to 50 days later as severe acute hepatitis in a previously unrecognized HBV carrier or as an exacerbation of preexisting chronic hepatitis B. Chronic HDV infection occurs in 80% to 90% of such patients. The superinfection may have two phases: an acute phase with active HDV replication and suppression of HBV with high ALT levels, followed by a chronic phase in which HDV replication decreases, HBV replication increases, ALT levels fluctuate, and the disease progresses to cirrhosis and hepatocellular cancer.

HDV infection occurs worldwide and affects an estimated 15 million individuals (about 5% of the 300 million individuals infected by HBV). Its prevalence varies, being highest in the Amazon basin, Africa, the Middle East, and Southern Italy, and lowest in Southeast Asia and China. In most western countries, it is largely restricted to intravenous drug abusers and those who have had multiple blood transfusions.

HDV RNA is detectable in the blood and liver at the time of onset of acute symptomatic disease. IgM anti-HDV is a reliable indicator of recent HDV exposure, but is frequently short-lived. Acute coinfection by HDV and HBV is associated with the presence of IgM against HDAg and HBcAg (denoting new infection with hepatitis B). With chronic delta hepatitis arising from HDV superinfection, HBsAg is present in serum, and anti-HDV antibodies (IgG and IgM) persist for months or longer. Because of its dependency on HBV, HDV infection is prevented by vaccination against HBV.

Hepatitis E Virus (HEV)

HEV is an enterically transmitted, water-borne infection that usually produces a self-limiting disease. The virus typically infects young to middle-aged adults. HEV is a zoonotic disease with animal reservoirs that include monkeys, cats, pigs, and dogs. Epidemics have been reported in Asia and the Indian subcontinent, sub-Saharan Africa, and Mexico, and sporadic cases are seen in Western nations, particularly where pig farming is common and in travelers returning from regions of high incidence. Of greater importance, HEV infection accounts for 30% to 60% of cases of sporadic acute hepatitis in India, exceeding the frequency of HAV. **A characteristic feature of HEV infection is the high mortality rate among pregnant women,**

approaching 20%. In most cases, HEV is not associated with chronic liver disease or persistent viremia. The average incubation period following exposure is 4 to 5 weeks.

Discovered in 1983, HEV is an unenveloped, positive-stranded RNA virus in the *Hepevirus* genus. Virions are shed in stool during the acute illness. Before the onset of clinical illness, HEV RNA and HEV virions can be detected by PCR in stool and serum. The onset of rising serum aminotransferases, clinical illness, and elevated IgM anti-HEV titers are virtually simultaneous. Symptoms resolve in 2 to 4 weeks, during which time the IgM titers fall and IgG anti-HEV titers rise.

Clinicopathologic Syndromes of Viral Hepatitis

As already discussed, infection with hepatitis viruses produces a wide range of outcomes. Acute infection by each of the hepatotropic viruses may be symptomatic or asymptomatic. HAV and HEV do not cause chronic hepatitis, and only a small number of HBV-infected adults develop chronic hepatitis. In contrast, HCV is notorious for producing chronic infections. Fulminant hepatitis is unusual and is seen primarily with HAV, HBV, or HDV infections. Although HBV and HCV are responsible for most cases of chronic hepatitis, there are many other causes of similar clinicopathologic presentations, including autoimmune hepatitis and drug- and toxin-induced hepatitis (discussed later). Therefore, serologic and molecular studies are essential for the diagnosis of viral hepatitis and for distinguishing between the various types.

Acute Asymptomatic Infection With Recovery. Patients in this group are identified incidentally on the basis of elevated serum transaminases or the presence of anti-viral antibodies. HAV and HBV infections, particularly in childhood, are frequently subclinical.

Acute Symptomatic Infection With Recovery. Whichever virus is involved, acute disease follows a similar course, consisting of: (1) an incubation period of variable length (see Table 16.2); (2) a symptomatic preicteric phase; (3) a symptomatic icteric phase; and (4) convalescence. Peak infectivity occurs during the last asymptomatic days of the incubation period and the early days of acute symptoms.

Fulminant Hepatic Failure. Viral hepatitis is responsible for about 12% of cases of fulminant hepatic failure; of these, two-thirds are caused by HBV infection and the rest by HAV. Survival for more than 1 week may permit recovery to occur via replication of residual hepatocytes. Activation of the stem/progenitor cells in the canals of Hering gives rise to very prominent ductular reactions but is usually insufficient to accomplish full restitution. Fulminant hepatic failure that follows acute viral hepatitis is treated supportively. Liver transplantation is the only option for patients whose disease does not resolve, as death from secondary infections and failure of other organs is otherwise inevitable.

Chronic Hepatitis. Chronic hepatitis is defined as persistent or relapsing hepatic disease for a period of more than 6 months. The clinical features are extremely variable and are not predictive of outcome. In some patients, the only signs of chronic disease are elevations of serum transaminases. Laboratory studies also may reveal prolongation of the prothrombin time and, in some instances, hyperglobulinemia, hyperbilirubinemia, and mild elevations in alkaline phosphatase levels. In symptomatic individuals, the most common finding is fatigue; less commonly, there is malaise, loss of appetite, and bouts of mild jaundice. In precirrhotic chronic hepatitis, physical findings are few, the most common being spider angiomas, palmar erythema, mild hepatomegaly, hepatic tenderness, and mild splenomegaly. Occasionally, in cases of HBV and HCV, immune complex disease develops that results in vasculitis (subcutaneous or visceral, Chapter 10) and glomerulonephritis (Chapter 14). Cryoglobulinemia is found in about 35% of individuals with chronic hepatitis C.

The Carrier State. A *carrier* is an individual who is chronically infected with a hepatropic virus and has no or subclinical evidence of liver disease. In both cases, particularly the latter, these individuals constitute reservoirs for infection. In the case of HBV, "healthy carriers" typically have serum studies that show an absence of HBeAg, the presence of anti-HBe, normal aminotransferases, and low or undetectable serum HBV DNA and liver biopsies showing a lack of significant inflammation or parenchymal injury. HBV infection acquired early in life in endemic areas (such as Southeast Asia, China, and sub-Saharan Africa) gives rise to a carrier state in more than 90% of cases, whereas in nonendemic regions the carrier state is rare. By contrast, it has been estimated that HCV infection in the United States produces a carrier state in 10% to 40% of cases.

HIV and Chronic Viral Hepatitis. Because of their similar transmission modes and overlapping risk factors, coinfection of HIV and hepatitis viruses is a common clinical problem. In the United States, 10% of HIV-infected individuals are coinfected with HBV and 25% with HCV, and, when untreated, chronic HBV and HCV infection are important causes of morbidity and mortality in HIV-infected individuals, even in those who receive effective anti-HIV therapy. Similarly, in individuals who progress to acquired immunodeficiency syndrome (AIDS), liver disease is the second most common cause of death. However, in adequately treated immunocompetent HIV patients, the severity and progression of HBV and HCV infection and response to anti–hepatitis virus therapy resembles that seen in non-HIV–infected individuals.

MORPHOLOGY

Clinical assessment of chronic hepatitis sometimes requires liver biopsy in addition to clinical and serologic data. Liver biopsy is helpful in confirming the clinical diagnosis, excluding common concomitant conditions (e.g., fatty liver disease, hemochromatosis), assessing histologic features associated with an increased risk for malignancy (discussed later), grading the extent of hepatocyte injury and inflammation, and staging the progression of scarring. Historically, histologic grading and staging of chronic hepatitis in liver biopsy specimens have been central

to determinations of whether to attempt treatment of the underlying disease; however, with the new, highly effective targeted antiviral therapies for hepatitis C, fewer pretreatment biopsies are being performed.

The general morphologic features of acute and chronic viral hepatitis are depicted schematically in Fig. 16.13. **The morphologic changes in acute and chronic viral hepatitis are shared among the hepatotropic viruses and can be mimicked by drug reactions or autoimmune hepatitis**.

Acute viral hepatitis. Grossly, livers involved by mild acute hepatitis appear normal or slightly mottled. At the other end of the spectrum, massive hepatic necrosis may produce a greatly shrunken liver, as discussed earlier. Microscopically, there is considerable morphologic overlap in acute hepatitis caused by various hepatropic viruses. As is typical of many viral infections, mononuclear cells predominate in all phases of viral hepatitis. A subtle difference is that the mononuclear infiltrate in hepatitis A may be especially rich in plasma cells. Most parenchymal injury is scattered throughout the hepatic lobule as "spotty necrosis" or **lobular hepatitis**. Portal inflammation in acute hepatitis is minimal or absent. As discussed earlier, hepatocyte injury may result in necrosis or apoptosis. In the former, the cytoplasm appears empty, with only scattered wisps of cytoplasmic remnants, and eventual rupture of cell membranes leads to "dropout" of hepatocytes. In their place, collapsed sinusoidal collagen reticulin framework remains behind along with scavenger macrophages. With apoptosis, hepatocytes shrink, becoming intensely eosinophilic, and their nuclei become pyknotic and fragmented; effector T cells may be present in the immediate vicinity.

In severe acute hepatitis, confluent necrosis of hepatocytes is seen around central veins. In these areas, there may be cellular debris, collapsed reticulin fibers, congestion/hemorrhage, and variable inflammation. With increasing severity, there is central-portal bridging necrosis, followed by parenchymal collapse. In its most severe form, massive hepatic necrosis and fulminant liver failure ensue.

Chronic viral hepatitis. The defining histologic feature of chronic viral hepatitis is mononuclear portal infiltration. It may be mild to severe and variable from one portal tract to the other. There is often **interface hepatitis** as well, in addition to lobular hepatitis, distinguished by its location at the interface between hepatocellular parenchyma and portal tract stroma. The hallmark of progressive chronic liver damage is scarring. At first, only portal tracts exhibit fibrosis, but in some patients, with time, fibrous septa—bands of dense scar—will extend between portal tracts. In the most severe cases, continued scarring and nodule formation leads to the development of cirrhosis, as discussed earlier.

Certain histologic features point to specific viral etiologies in chronic hepatitis. In chronic hepatitis B, **"ground-glass" hepatocytes** (cells with endoplasmic reticulum swollen by HBsAg) are a diagnostic hallmark, and the presence of viral antigen in these cells can be confirmed by immunostaining (Fig. 16.14). Liver biopsies involved by chronic hepatitis C quite commonly show

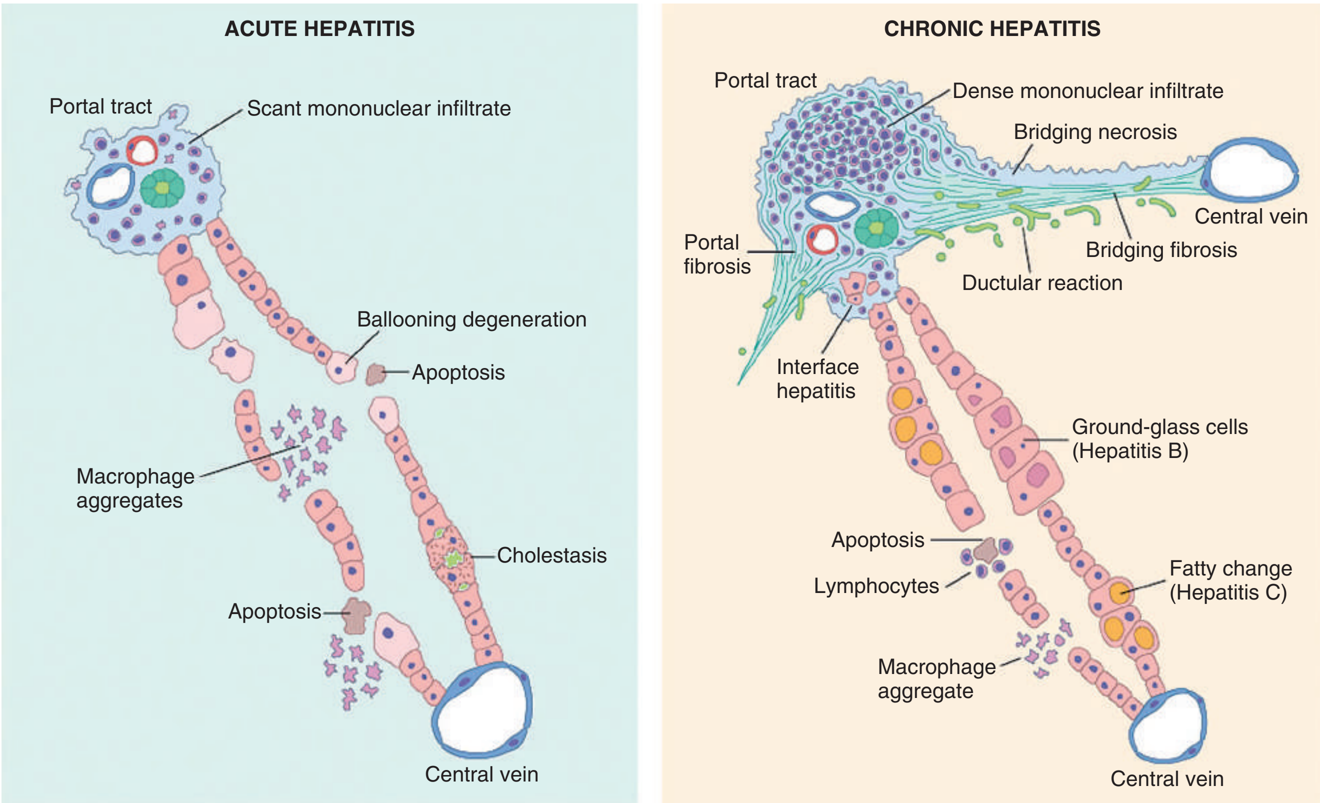

Fig. 16.13 Morphologic features of acute and chronic hepatitis. There is very little portal mononuclear infiltration in acute hepatitis (or sometimes none at all), while in chronic hepatitis portal infiltrates are dense and prominent—the defining feature of chronic hepatitis. Bridging necrosis and fibrosis are shown only for chronic hepatitis, but bridging necrosis may also occur in more severe acute hepatitis. Ductular reactions in chronic hepatitis are minimal in early stages of scarring, but become extensive in late-stage disease.

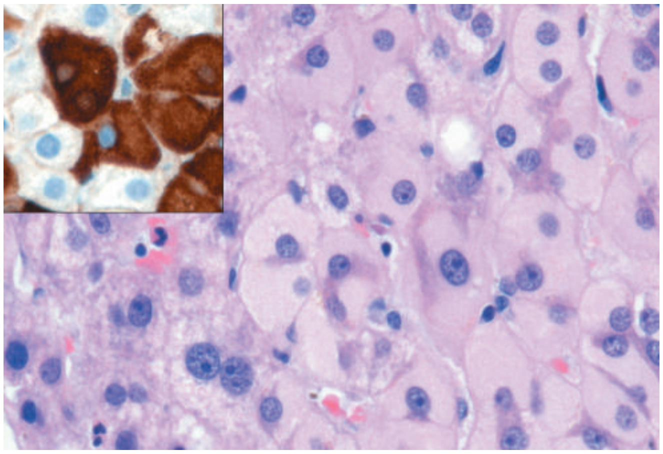

Fig. 16.14 Ground-glass hepatocytes in chronic hepatitis B, caused by accumulation of hepatitis B surface antigen. Hematoxylin-eosin staining shows the presence of abundant, finely granular pink cytoplasmic inclusions; immunostaining *(inset)* with a specific antibody confirms the presence of surface antigen *(brown)*.

large lymphoid aggregates (Fig. 16.15). Often, hepatitis C, particularly genotype 3, is associated with fatty change in scattered hepatocytes. Bile duct injury is also prominent in some cases of hepatitis C and may mimic the histologic changes seen in primary biliary cholangitis (see later); clinical parameters distinguish these two diseases easily, however.

SUMMARY

VIRAL HEPATITIS

- In the alphabet of hepatotropic viruses, some easy mnemonic devices may be useful:
  - The vowels (hepatitis A and E) never cause chronic hepatitis, only AcutE hepatitis.
  - Only the consonants (hepatitis B, C, D) have the potential to cause chronic disease (C for consonant and for chronic).
  - Hepatitis B can be transmitted by blood, birthing, and "bonking" (as they say in the United Kingdom).
  - Hepatitis C is the single virus that is more often chronic than not (almost never detected acutely; 85% or more of patients develop chronic hepatitis, 20% of whom will develop cirrhosis).
  - Hepatitis D, the delta agent, is a defective virus, requiring hepatitis B coinfection for its own capacity to infect and replicate.
  - Hepatitis E is endemic in equatorial regions and frequently epidemic.
- The inflammatory cells in both acute and chronic viral hepatitis are mainly T cells; it is the pattern of injury that is different, not the nature of the infiltrate.
- Patients with long-standing HBV or HCV infections are at increased risk for development of HCC.

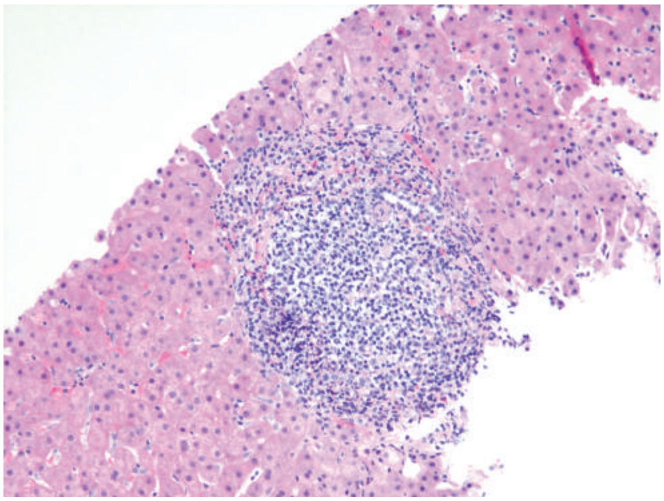

Fig. 16.15 Chronic viral hepatitis due to HCV, showing characteristic portal tract expansion by a dense lymphoid infiltrate.

Bacterial, Parasitic, and Helminthic Infections

A multitude of organisms can infect the liver and biliary tree, including bacteria, fungi, helminths and other parasites, and protozoa. Infectious organisms can reach the liver through several pathways:

- *Ascending infection,* via the gut and biliary tract (ascending cholangitis)
- *Vascular seeding,* most often through the portal system via the gastrointestinal tract
- *Direct invasion,* from an adjacent source (e.g., bacterial cholecystitis)
- *Penetrating injury*

Bacteria that may establish an infection in the liver via the blood include *Staphylococcus aureus* in toxic shock syndrome, *Salmonella typhi* in typhoid fever, and *Treponema pallidum* in secondary or tertiary syphilis. Ascending infections are most common in the setting of partial or complete biliary tract obstruction and are typically caused by gut flora, which may colonize the static bile in the ducts. Whatever the source of the bacteria, with pyogenic organisms intrahepatic abscesses may develop, producing fever, right upper-quadrant pain, and tender hepatomegaly. Although antibiotic therapy may sterilize small abscesses, surgical drainage is often necessary for larger lesions. More commonly, extrahepatic bacterial infections, particularly sepsis, induce mild hepatic inflammation and varying degrees of hepatocellular cholestasis indirectly, without establishing an infectious nidus in the liver.

Other non-viral infectious agents cause liver disease with important or unusual pathogenic features that merit specific comment. These include the following:

- Schistosomiasis, most commonly found in Asia, Africa, and South America, is one of the most common causes of noncirrhotic portal hypertension worldwide. Adult worms in the gut produce numerous eggs, some of which find their way into the portal circulation, where they lodge and induce a granulomatous reaction associated with marked fibrosis.

- *Entamoeba histolytica*, an important cause of dysentery (Chapter 15), sometimes ascends to the liver through portal circulation and produces secondary foci of infection that can progress to large necrotic areas called amebic liver abscesses. Amebic abscesses are more common in the right lobe of the liver. The abscess cavity contains necrotic liver cells, but unlike pyogenic abscesses, neutrophils are absent.
- Liver fluke infection, most common in Southeast Asia, is associated with a high rate of cholangiocarcinoma. Responsible organisms include *Fasciola hepatica*, *Opisthorcis* species, and *Clonorchis sinensis*.
- Echinococcal infections may cause the formation of intrahepatic hydatid cysts that produce symptoms due to pressure on surrounding structures or following rupture.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic, progressive hepatitis with all the features of autoimmune diseases in general: genetic predisposition, association with other autoimmune diseases, the presence of autoantibodies, and therapeutic response to immunosuppression. Risk for autoimmune hepatitis is associated with certain HLA alleles, such as the DRB1* allele in Caucasians, but as in other autoimmune disorders the mechanistic basis for this relationship is unclear. Triggers for the immune reaction may include viral infections or drug or toxin exposures.

Clinicopathologic Features

The annual incidence is highest among white northern Europeans at 1.9 in 100,000, but all ethnic groups are susceptible. There is a female predominance (78%). Autoimmune hepatitis is classified into two types, based on the patterns of circulating antibodies.

- *Type 1,* more common in middle-age and older individuals, is characterized by the presence of antinuclear (ANA), anti–smooth muscle actin (SMA), antimitochondrial (AMA), and anti–soluble liver antigen/liver-pancreas antigen (anti-SLA/LP) antibodies.
- *Type 2,* usually seen in children and teenagers, is chararcterized by the presence of anti–liver kidney microsome-1 antibodies and anti–liver cytosol-1 antibodies.

MORPHOLOGY

Although autoimmune hepatitis shares patterns of injury with acute or chronic viral hepatitis, the time course of histologic progression differs. In viral hepatitis, fibrosis typically follows many years of slowly accumulating parenchymal injury, whereas in autoimmune hepatitis, there is an early phase of severe parenchymal destruction followed rapidly by scarring. For unclear reasons, this early wave of hepatocyte damage is often subclinical. The following features are typical of autoimmune hepatitis:

- **Necrosis and inflammation**, indicated by extensive interface hepatitis or foci of confluent (perivenular or bridging) necrosis or parenchymal collapse
- **Plasma cell predominance** in the mononuclear inflammatory infiltrates
- **Hepatocyte "rosettes"** in areas of marked activity

An acute clinical illness is a common presentation (40%); sometimes the disease is fulminant, progressing to hepatic encephalopathy within 8 weeks of onset. Mortality for patients with severe untreated autoimmune hepatitis is approximately 40% within 6 months of diagnosis, and cirrhosis develops in at least 40% of survivors. Hence, diagnosis and intervention are imperative. Immunosuppressive therapy is usually effective, leading to remission in 80% of patients and enabling long-term survival. End-stage disease is an indication for liver transplantation. The 10-year survival rate after liver transplant is 75%, but recurrence in the transplanted organ occurs in 20% of cases.

SUMMARY

- There are two primary types of autoimmune hepatitis:
  - Type 1 autoimmune hepatitis is most often seen in middle-age women and is characteristically associated with antinuclear and anti–smooth muscle antibodies.
  - Type 2 autoimmune hepatitis is most often seen in children or teenagers and is associated with anti–liver kidney microsomal autoantibodies.
- Autoimmune hepatitis may either develop with a rapidly progressive acute disease or follow a more indolent path; if untreated, both are likely to lead to liver failure.
- Plasma cells are a prominent and characteristic component of the inflammatory infiltrate in biopsy specimens showing autoimmune hepatitis.

DRUG- AND TOXIN-INDUCED LIVER INJURY

As the major drug metabolizing and detoxifying organ in the body, the liver is subject to injury from an enormous array of therapeutic and environmental chemicals. Injury may result from direct toxicity, may occur through hepatic conversion of a xenobiotic compound to an active toxin, or may be produced by immune mechanisms, such as by the drug or a metabolite acting as a hapten to convert a cellular protein into an immunogen. A diagnosis of drug- or toxin-induced liver injury may be made on the basis of a temporal association of liver damage with drug or toxin exposure, recovery (usually) upon removal of the inciting agent, and exclusion of other potential causes. Exposure to a toxin or therapeutic agent should always be included in the differential diagnosis of any form of liver disease.

Principles of drug and toxic injury are discussed in Chapter 8. Here it suffices to note that drug reactions may be *predictable* (intrinsic) or *unpredictable* (idiosyncratic).

Table 16.3 Patterns of Injury in Drug- and Toxin-Induced Hepatic Injury

Pattern of Injury	Morphologic Findings	Examples of Associated Agents
Cholestatic	Bland hepatocellular cholestasis, without inflammation	Contraceptive and anabolic steroids, antibiotics, HAART
Cholestatic hepatitis	Cholestasis with lobular necrosis and inflammation; may show bile duct destruction	Antibiotics, phenothiazines, statins
Hepatocellular necrosis	Spotty hepatocyte necrosis	Methyldopa, phenytoin
	Massive necrosis	Acetaminophen, halothane
	Chronic hepatitis	Isoniazid
Fatty liver disease	Large and small droplet fat	Ethanol, corticosteroids, methotrexate, total parenteral nutrition
	"Microvesicular steatosis" (diffuse small droplet fat)	Valproate, tetracycline, aspirin (Reye syndrome), HAART
	Steatohepatitis with Mallory-Denk bodies	Ethanol, amiodarone
Fibrosis and cirrhosis	Periportal and pericellular fibrosis	Alcohol, methotrexate, enalapril, vitamin A and other retinoids
Granulomas	Noncaseating epithelioid granulomas	Sulfonamides, amiodarone, isoniazid
	Fibrin ring granulomas	Allopurinol
Vascular lesions	Sinusoidal obstruction syndrome (veno-occlusive disease): obliteration of central veins	High-dose chemotherapy, bush teas
	Budd-Chiari syndrome	Oral contraceptives
	Peliosis hepatis: blood-filled cavities, not lined by endothelial cells	Anabolic steroids, tamoxifen

HAART, Highly active anti-retroviral therapy
Adapted from Washington K: Metabolic and toxic conditions of the liver. In Iacobuzio-Donahue CA, Montgomery EA, editors: *Gastrointestinal and liver pathology,* Philadelphia, 2005, Churchill Livingstone.

Predictable drug or toxin reactions affect all individuals in a dose-dependent fashion. Unpredictable reactions depend on idiosyncrasies of the host, particularly the propensity to mount an immune response to the antigenic stimulus or the rate at which the agent can be metabolized. Both classes of injury may be immediate or take weeks to months to develop (Table 16.3).

- A classic, predictable hepatotoxin is *acetaminophen,* now the most common cause of acute liver failure necessitating transplantation in the United States. The toxic agent is not acetaminophen itself but rather toxic metabolites produced by the cytochrome P-450 system. The damage begins in centrilobular hepatocytes but extends to encompass entire lobules in the most severe cases.
- Examples of drugs that can cause *idiosyncratic reactions* include *chlorpromazine,* an agent that causes cholestasis in patients who are slow to metabolize it, and *halothane and its derivatives,* which can cause a fatal immune-mediated hepatitis after repeated exposure.

ALCOHOLIC AND NONALCOHOLIC FATTY LIVER DISEASE

Alcohol is a well-known cause of fatty liver disease in adults and can manifest histologically as steatosis, steatohepatitis, and cirrhosis. In recent years, it has become evident that another entity, so-called "nonalcoholic fatty liver disease (NAFLD)," can mimic the entire spectrum of hepatic changes associated with alcohol abuse. Since the morphologic changes of alcoholic and NAFLD are indistinguishable, they are discussed together, followed by the pathogenesis and distinctive clinical features of each entity.

MORPHOLOGY

Three types of liver alterations are observed in fatty liver disease: steatosis (fatty change), hepatitis (alcoholic or steatohepatitis), and fibrosis.

Hepatocellular steatosis. Hepatocellular fat accumulation typically begins in centrilobular hepatocytes. The lipid droplets range from small (microvesicular) to large (macrovesicular), the largest filling and expanding the cell and displacing the nucleus. As steatosis becomes more extensive, the lipid accumulation spreads outward from the central vein to hepatocytes in the midlobule and then the periportal regions (Fig. 16.16).

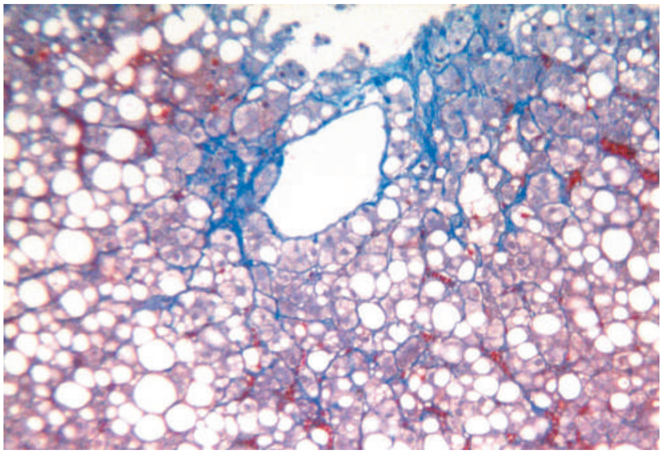

Fig. 16.16 Fatty liver disease associated with chronic alcohol use. A mix of small and large fat droplets (seen as clear vacuoles) is most prominent around the central vein and extends outward to the portal tracts. Some fibrosis *(stained blue)* is present in a characteristic perisinusoidal "chicken wire fence" pattern (Masson trichrome stain). *(Courtesy of Dr. Elizabeth Brunt, Washington University, St. Louis, Missouri.)*

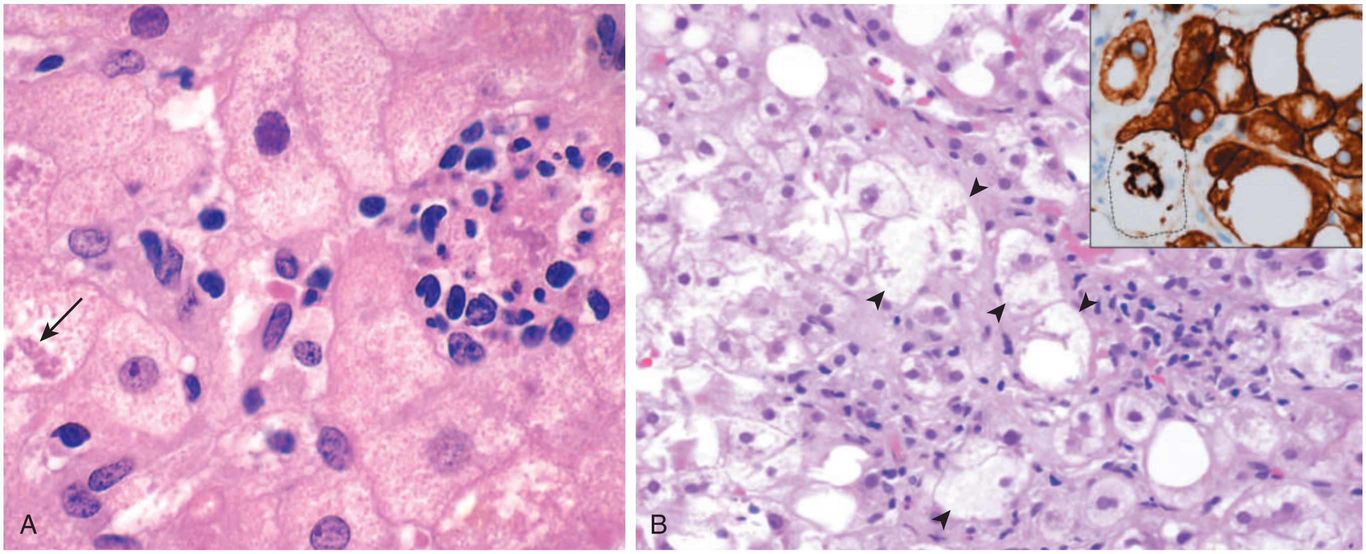

Fig. 16.17 Hepatocyte injury in fatty liver disease associated with chronic alcohol use. (A) Clustered inflammatory cells marking the site of a necrotic hepatocyte. A Mallory-Denk body is present in another hepatocyte *(arrow)*. (B) "Ballooned" hepatocytes *(arrowheads)* associated with clusters of inflammatory cells. The inset stained for keratins 8 and 18 *(brown)* shows a ballooned cell *(dotted line)* in which keratins have been ubiquitinylated and have collapsed into an immunoreactive Mallory-Denk body, leaving the cytoplasm "empty." *(Courtesy of Dr. Elizabeth Brunt, Washington University, St. Louis, Missouri.)*

Macroscopically, fatty livers with widespread steatosis are large (weighing 4–6 kg or more), soft, yellow, and greasy.

Steatohepatitis. These changes typically are more pronounced with alcohol use than in NAFLD, but can be seen in either:

- **Hepatocyte ballooning.** Single or scattered foci of cells undergo swelling and necrosis; as with steatosis, these features are most prominent in the centrilobular regions (Fig. 16.17A).
- **Mallory-Denk bodies.** These consist of tangled skeins of intermediate filaments (including ubiquitinylated keratins 8 and 18) and are visible as eosinophilic cytoplasmic inclusions in degenerating hepatocytes (see Fig. 16.17B).
- **Neutrophil infiltration.** Predominantly neutrophilic infiltration may permeate the lobule and accumulate around degenerating hepatocytes, particularly those containing Mallory-Denk bodies. Lymphocytes and macrophages also may be seen in portal tracts or parenchyma.

Steatofibrosis. Fatty liver disease of all kinds has a distinctive pattern of scarring. Like other changes, fibrosis appears first in the centrilobular region as **central vein sclerosis.** Perisinusoidal scarring appears next in the space of Disse of the centrilobular region and then spreads outward, encircling individual or small clusters of hepatocytes in a **chicken wire fence pattern** (see Fig. 16.16). Tendrils of fibrosis eventually link to portal tracts and then condense to create **central portal fibrous septa.** As these become more prominent, the liver takes on a nodular, cirrhotic appearance. Because in most cases the underlying cause persists, the continual subdivision of established nodules by new, perisinusoidal scarring leads to a classic **micronodular** or **Laennec cirrhosis.** Early in the course, the liver is yellow-tan, fatty, and enlarged, but with persistent damage over the course of years the liver is transformed into a brown, shrunken, nonfatty organ composed of cirrhotic nodules that are usually less than 0.3 cm in diameter—smaller than is typical for most chronic viral hepatitis. The end-stage cirrhotic liver may enter into a "burned-out" phase devoid of fatty change and other typical features. A majority of cases of **cryptogenic cirrhosis,** without clear etiology, are now recognized as "burned-out" NAFLD.

Alcoholic Liver Disease

Excessive ethanol consumption causes more than 60% of chronic liver disease in Western countries and accounts for 40% to 50% of deaths due to cirrhosis. Among the most important adverse effects of chronic alcohol consumption are the overlapping forms of alcohol-related fatty liver disease already discussed: (1) hepatic steatosis, (2) alcoholic hepatitis, and (3) fibrosis and cirrhosis, collectively referred to as *alcoholic liver disease* (Fig. 16.18).

Between 90% and 100% of heavy drinkers develop fatty liver (i.e., hepatic steatosis), and of those, 10% to 35% develop alcoholic hepatitis, whereas only 8% to 20% of chronic alcoholics develop cirrhosis. Steatosis, alcoholic hepatitis, and fibrosis may develop sequentially or independently, so they do not necessarily represent a sequential continuum of changes. Hepatocellular carcinoma arises in 10% to 20% of patients with alcoholic cirrhosis.

Pathogenesis

Short-term ingestion of as much as 80 g of ethanol per day (5–6 beers or 8–9 ounces of 80-proof liquor) generally produces mild reversible hepatic changes, such as fatty liver. Chronic intake of 40 to 80 g/day is considered a borderline risk factor for severe injury. For reasons that may relate to decreased gastric metabolism of ethanol and differences in body composition, women are more susceptible than men to hepatic injury. It seems that how often and what one drinks may affect the risk for liver disease development. For example, binge drinking causes more

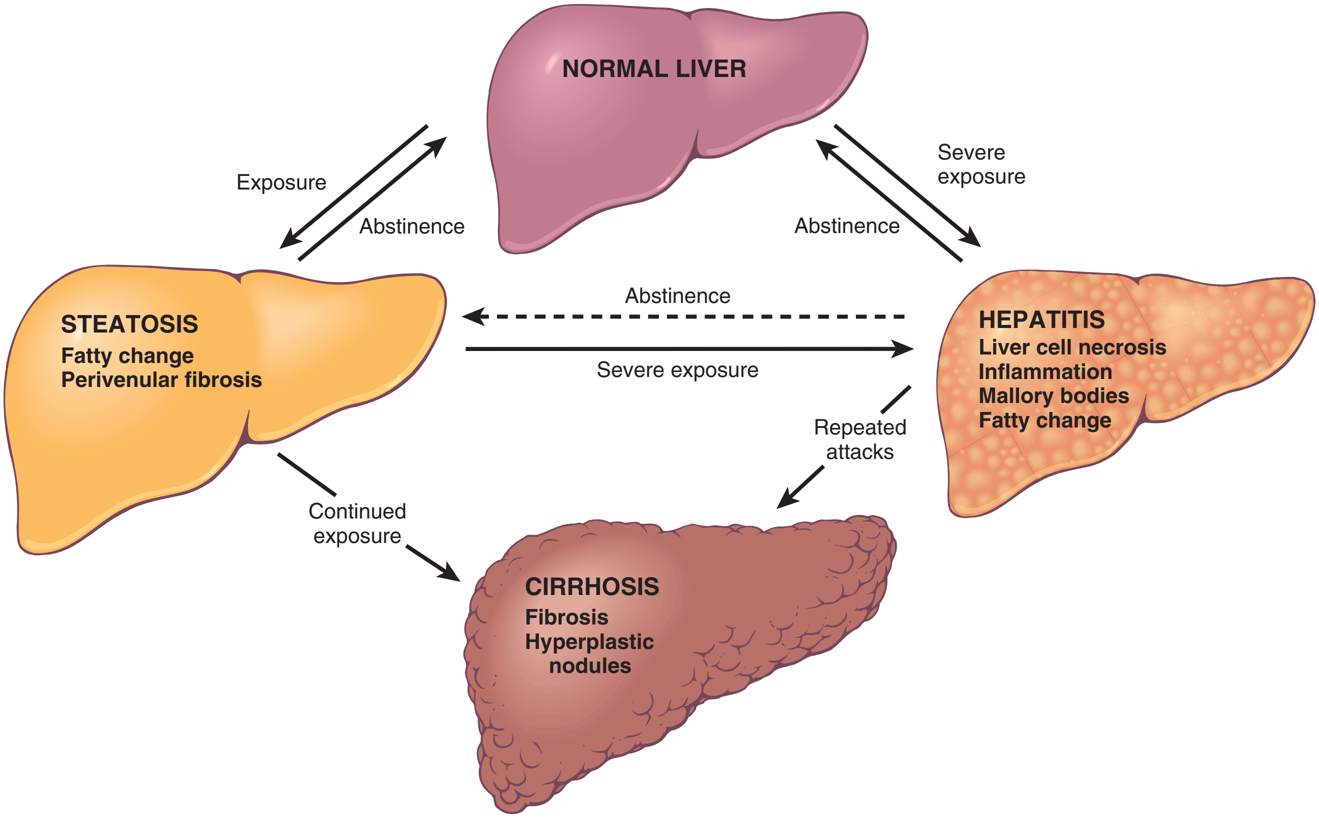

Fig. 16.18 Alcoholic liver disease. The interrelationships among hepatic steatosis, alcoholic hepatitis, and alcoholic cirrhosis are shown and key morphologic features are listed. As discussed in the text, steatosis, alcoholic hepatitis, and steatofibrosis may all develop independently and not along a continuum.

liver injury than that associated with steady, lower-level consumption. Since not everyone who drinks gets all the listed complications, individual, possibly genetic, risk factors must exist, but no reliable markers of susceptibility are known. In the absence of a clear understanding of the factors that influence liver damage, it is difficult to state what constitutes a safe level of alcohol consumption.

Hepatocellular steatosis is caused by alcohol through several mechanisms. First, metabolism of ethanol by alcohol dehydrogenase and acetaldehyde dehydrogenase generates large amounts of nicotinamide-adenine dinucleotide (NADH), which increases shunting of substrates away from catabolism and toward lipid biosynthesis. Second, ethanol impairs the assembly and secretion of lipoproteins. The net effect is to cause the accumulation of intracellular lipids.

The cause of *alcoholic hepatitis* is uncertain, but it may stem from one or more of the following toxic byproducts of ethanol and its metabolites:

- *Acetaldehyde* (a major metabolite of ethanol) induces lipid peroxidation and acetaldehyde-protein adduct formation, which may disrupt cytoskeleton and membrane function.
- *Alcohol* directly affects mitochondrial function and membrane fluidity.
- *Reactive oxygen species* generated during oxidation of ethanol by the microsomal ethanol oxidizing system react with and damage membranes and proteins. Reactive oxygen species also are produced by neutrophils, which infiltrate areas of hepatocyte necrosis.

Because generation of acetaldehyde and free radicals is maximal in the centrilobular region, this region is most susceptible to toxic injury. Pericellular and sinusoidal fibrosis develop first in this area of the lobule. Concurrent viral hepatitis, particularly hepatitis C, is a major accelerator of liver disease in alcoholics. The prevalence of hepatitis C among individuals with alcoholic liver disease is about 30% (and vice versa).

For unknown reasons, *cirrhosis* develops in only a small fraction of chronic alcoholics. With complete abstinence, at least partial regression of scarring occurs, and the micronodular liver transforms though parenchymal regeneration into a macronodular cirrhotic organ (see Figure 16.6); rarely, there is regression of cirrhosis altogether.

Clinical Features

Alcoholic steatosis may be innocuous or give rise to hepatomegaly with mild elevations of serum bilirubin and alkaline phosphatase. Severe hepatic compromise is unusual. Alcohol withdrawal and the provision of an adequate diet are sufficient treatment.

It is estimated that 15 to 20 years of excessive drinking are necessary to develop *alcoholic cirrhosis,* but *alcoholic hepatitis* can occur after just weeks or months of alcohol abuse. The onset is typically acute and often follows a bout of particularly heavy drinking. Symptoms and laboratory abnormalities range from minimal to severe. Most patients present with malaise, anorexia, weight loss, upper-abdominal discomfort, tender hepatomegaly, and fever. Typical findings include hyperbilirubinemia, elevated

serum alkaline phosphatase levels, and neutrophilic leukocytosis. Serum alanine and aspartate aminotransferases are elevated but usually remain below 500 U/mL. The outlook is unpredictable; each bout of alcoholic hepatitis carries a 10% to 20% risk for death. With repeated bouts, cirrhosis appears in about one-third of patients within a few years.

The manifestations of alcoholic cirrhosis are similar to those of other forms of cirrhosis. In chronic alcoholics, ethanol may be the major source of calories in the diet, displacing other nutrients and leading to malnutrition and vitamin deficiencies (e.g., thiamine, vitamin B_{12}). Compounding these effects is impaired digestive function, primarily related to chronic gastric and intestinal mucosal damage and pancreatitis.

The long-term outlook for alcoholic patients with liver disease is variable. The most important aspect of treatment is abstinence from alcohol. The 5-year survival rate approaches 90% in abstainers who are free of jaundice, ascites, and hematemesis, but drops to 50% to 60% in individuals who continue to imbibe. Among those with end-stage alcoholic liver disease, the immediate causes of death are as follows:

- Hepatic failure
- Massive gastrointestinal hemorrhage
- Intercurrent infection (to which affected individuals are predisposed)
- Hepatorenal syndrome
- Hepatocellular carcinoma (3%–6% of cases)

SUMMARY

ALCOHOLIC LIVER DISEASE

- Alcoholic liver disease has three main manifestations, hepatic steatosis, alcoholic hepatitis, and cirrhosis, which may occur alone or in combination.
- Cirrhosis typically develops after more than 10 years of heavy drinking, but only occurs in a small proportion of chronic alcoholics; alcoholic cirrhosis has similar clinical signs and symptoms as cirrhosis caused by viral hepatitis.
- The multiple pathologic effects of alcohol include changes in lipid metabolism, decreased export of lipoproteins, and cell injury caused by reactive oxygen species and metabolites of alcohol.

Nonalcoholic Fatty Liver Disease

NAFLD is a common condition in which fatty liver disease develops in individuals who do not drink alcohol. The liver can show any of the three types of changes discussed earlier (steatosis, steatohepatitis, and cirrhosis), though on average inflammation is less prominent than in alcoholic liver disease. The term *nonalcoholic steatohepatitis (NASH)* is used to describe overt clinical features of liver injury, such as elevated transaminases, and the histologic features of hepatitis already discussed. NAFLD is consistently associated with insulin resistance and the metabolic syndrome (Chapter 8). Other commonly associated abnormalities are as follows:

- Type 2 diabetes (or family history of the condition)
- Obesity, primarily central obesity (body mass index >30 kg/m^2 in whites and >25 kg/m^2 in Asians)
- Dyslipidemia (hypertriglyceridemia, low high-density lipoprotein cholesterol, high low-density lipoprotein cholesterol)
- Hypertension

Pathogenesis

The key initiating events in NAFLD appear to be the development of obesity and insulin resistance, the latter within both adipose tissue and the liver. These factors combine to increase the mobilization of free fatty acids from adipose tissue, which are taken up by hepatocytes, and to stimulate the synthesis of fatty acids within hepatocytes. It is estimated that over half of the lipid found in hepatocytes in NAFLD is derived from adipose tissue, with most of the remainder coming from de novo synthesis in liver cells. Precisely how the accumulation of lipid in hepatocytes predisposes to the development of NASH is not known and may involve several interrelated mechanisms. Excessive intrahepatic lipids and their metabolic intermediates enhance insulin resistance in the liver and sensitize hepatocytes to the toxic effects of inflammatory cytokines, which are produced in increased amounts in the setting of the metabolic syndrome. In addition, hepatocytes in patients with NASH show evidence of inflammasome activation, possibly due to direct or indirect effects of particular lipids, leading to local release of the pro-inflammatory cytokine IL-1. Other products of lipid metabolism appear to be directly toxic to hepatocytes; proposed mechanisms include increased production of reactive oxygen species, induction of ER stress, and disruption of mitochondrial function. Liver injury resulting from these various insults causes stellate cell activation, collagen deposition, and hepatic fibrosis, which along with ongoing hepatocyte damage lead to full-blown NASH.

Clinical Features

NAFLD is the most common cause of incidental elevation of serum transaminases. Most individuals with steatosis are asymptomatic; patients with active steatohepatitis or fibrosis may also be asymptomatic, but some may have fatigue, malaise, right upper-quadrant discomfort, or more severe symptoms of chronic liver disease. Liver biopsy is required to identify NASH and distinguish it from uncomplicated NAFLD. Fortunately, the frequency of progression from steatosis to active steatohepatitis and then from active steatohepatitis to cirrhosis is low (Fig. 16.19). Nevertheless, NAFLD is considered to be a significant contributor to the pathogenesis of "cryptogenic" cirrhosis. Because they share common risk factors, the incidence of coronary artery disease also is increased in patients with NAFLD.

Current therapy is directed toward obesity reduction and reversal of insulin resistance. Lifestyle modifications that lead to weight loss (diet and exercise) appear to be the most effective form of treatment.

Pediatric NAFLD is becoming an increasing problem as obesity and metabolic syndrome approach epidemic proportions. In children, the appearance of the histologic lesions is somewhat different, as inflammation and scarring tend to be more prominent in the portal tracts and periportal regions, and mononuclear infiltrates rather than neutrophilic infiltrates predominate.

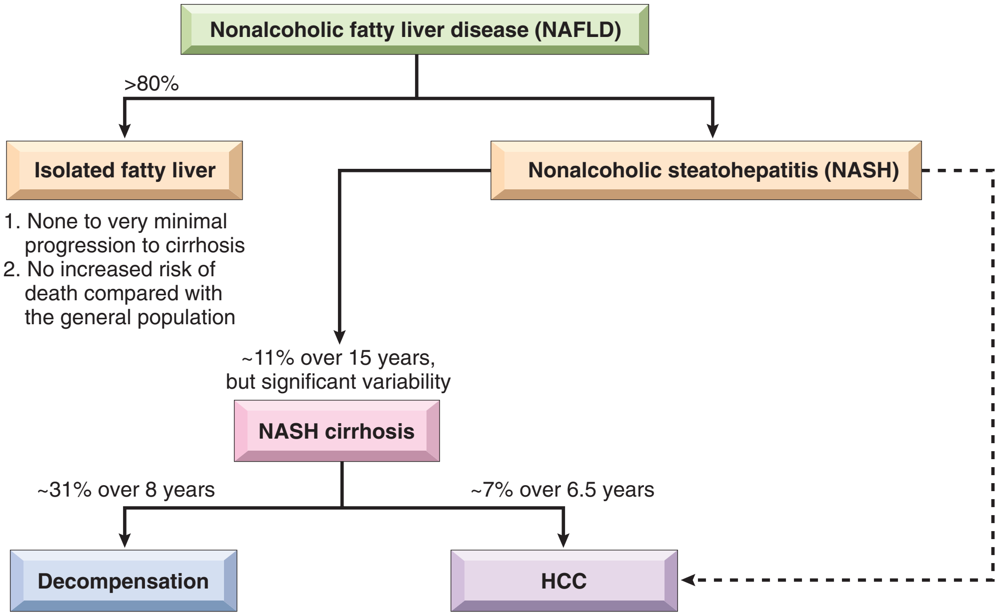

Fig. 16.19 Natural history of nonalcoholic fatty liver disease. Isolated fatty liver disease shows minimal risk for progression to cirrhosis or increased mortality, while nonalcoholic steatohepatitis shows increased overall mortality as well as increased risk for cirrhosis and hepatocellular carcinoma. *DM*, Diabetes mellitus.

SUMMARY

NONALCOHOLIC FATTY LIVER DISEASE

- Nonalcoholic fatty liver disease (NAFLD) is associated with the metabolic syndrome, obesity, type 2 diabetes, and dyslipidemia and/or hypertension.
- NAFLD may show all the changes associated with alcoholic liver disease: steatosis, nonalcoholic steatohepatitis (NASH), and cirrhosis, although the features of steatohepatitis (such as hepatocyte ballooning, Mallory-Denk bodies, and neutrophilic infiltration) often are less prominent than they are in alcohol-related injury.
- Pediatric NAFLD is increasingly being recognized as the obesity epidemic spreads to pediatric age groups, although its histologic pattern differs somewhat from that seen in adults.

INHERITED METABOLIC LIVER DISEASES

Although there are many inherited metabolic liver diseases, only some relatively common, pathogenically interesting entities are discussed here: hereditary hemochromatosis, Wilson disease, and alpha-1-anti-trypsin (α_1AT) deficiency.

Hemochromatosis

Hemochromatosis is caused by excessive absoprtion of iron, which is primarily deposited in parenchymal organs such as the liver and pancreas, as well as in the heart, joints, and endocrine organs. It results most commonly from an inherited disorder, *hereditary hemochromatosis.* When iron accumulation occurs as a consequence of parenteral administration of iron, usually in the form of transfusions, it is called *acquired hemochromatosis.* Secondary iron overload also can complicate diseases that are associated with persistent ineffective erythropoiesis, particularly thalassemia and myelodysplastic syndromes (Chapter 12).

As discussed in Chapter 12, the total body iron pool ranges from 2 to 6 gm in normal adults; about 0.5 gm is stored in hepatocytes. In severe hemochromatosis, total iron may exceed 50 gm, one-third of which accumulates in the liver. Fully developed cases exhibit (1) micronodular cirrhosis; (2) diabetes mellitus (up to 80% of patients); and (3) abnormal skin pigmentation (up to 80% of patients).

Pathogenesis

Because there is no regulated iron excretion from the body, the total body content of iron is tightly regulated by intestinal absorption. As discussed in Chapter 12, hepcidin is a circulating peptide hormone that acts as a key negative regulator of intestinal iron uptake. **Diverse mutations in several genes have been described in hereditary hemochromatosis, all of which lower hepcidin levels or diminish hepcidin function.** Whatever the underlying defect, the net result is an increase in intestinal absorption of dietary iron, leading to an accumulation of 0.5 to 1 gm of iron per year.

The most frequently mutated gene in patients with hereditary hemochromatosis is *HFE,* which is located on chromosome 6 close to the *HLA* gene cluster. *HFE* encodes an HLA class I–like molecule that regulates the synthesis of hepcidin in hepatocytes. The most common HFE mutation is a cysteine-to-tyrosine substitution at amino acid 282 (C282Y). This mutation, which inactivates the HFE protein, is present in over 70% of patients diagnosed with hereditary hemochromatosis and is most common in European populations. Several other mutations can also give rise to

hemochromatosis, including other mutations in HFE as well as mutations in transferrin receptor 2 and in hepcidin itself. The associated clinical condition is milder with some of these alternative mutations and more severe with others, sometimes manifesting in young adults or even during childhood.

Whatever the underlying cause, the onset of disease typically occurs after 20 gm of stored iron have accumulated. Excessive iron appears to be directly toxic to host tissues. Mechanisms of liver injury include the following:

- Lipid peroxidation via iron-catalyzed free radical reactions
- Stimulation of collagen formation by activation of hepatic stellate cells
- DNA damage by reactive oxygen species, leading to lethal cell injury or predisposition to HCC

The deleterious effects of iron on cells that are not fatally injured are reversible, and removal of excess iron with therapy promotes recovery of tissue function.

MORPHOLOGY

The morphologic changes in severe hemochromatosis are characterized principally by (1) **tissue deposition of hemosiderin** in the following organs (in decreasing order of severity): liver, pancreas, myocardium, pituitary gland, adrenal gland, thyroid and parathyroid glands, joints, and skin; (2) **cirrhosis**; and (3) **pancreatic fibrosis**. In the liver, iron becomes evident first as golden-yellow hemosiderin granules in the cytoplasm of periportal hepatocytes, which can be histochemically stained with Prussian blue (Fig. 16.20). With increasing iron load, there is progressive deposition in the rest of the lobule, the bile duct epithelium, and Kupffer cells. At this stage, the liver typically is slightly enlarged and chocolate brown. Fibrous septa develop slowly, linking portal tracts to each other and leading ultimately to **cirrhosis** in an intensely pigmented (very dark brown to black) liver.

The **pancreas** also becomes pigmented, acquires diffuse interstitial fibrosis, and may show parenchymal atrophy. Hemosiderin is found in the acinar and the islet cells and sometimes in the interstitial fibrous stroma. The **heart** often is enlarged, with hemosiderin granules within the myocardial fibers. The pigmentation may induce a striking brown coloration of the myocardium. A delicate interstitial fibrosis may appear. Although **skin pigmentation** is partially attributable to hemosiderin deposition in dermal macrophages and fibroblasts, most of the coloration results from increased epidermal melanin production. The combination of these pigments renders the skin slate-gray. With hemosiderin deposition in the joint synovial linings, an acute synovitis may develop. There is also excessive deposition of calcium pyrophosphate, which damages the articular cartilage and sometimes produces disabling polyarthritis, referred to as *pseudogout*. With the onset of cirrhosis, the testes may become atrophic.

Clinical Features

Symptoms usually appear earlier in men than in women since menstrual bleeding limits the accumulation of iron until menopause. This results in a male-to-female ratio of clinically significant iron overload of approximately 5:1 to 7:1. In the most common form caused by *HFE* mutations,

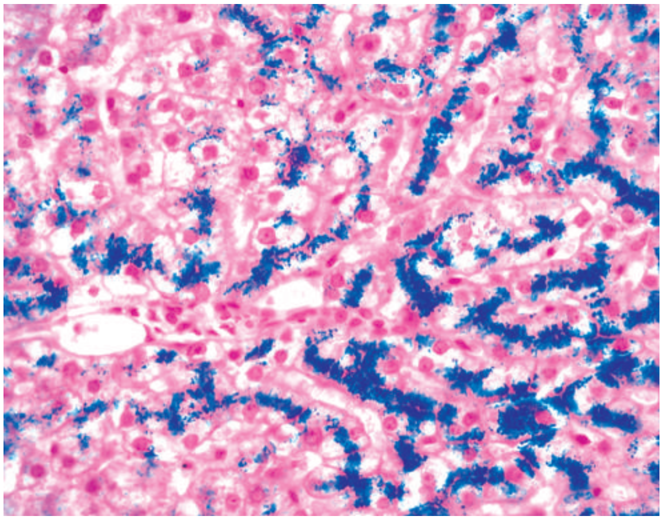

Fig. 16.20 Hereditary hemochromatosis. In this Prussian blue–stained section, hepatocellular iron appears blue. The parenchymal architecture is normal at this stage of disease, even with such abundant iron.

symptoms usually appear in the fifth and sixth decades of life in men and later in women. With population screening, it has become clear that homozygosity for the most common *HFE* mutation (C282Y) shows variable penetrance; thus disease development is not inevitable, presumably because other genetic and environmental factors influence the rate of iron accumulation.

The principal manifestations include hepatomegaly, abdominal pain, skin pigmentation (particularly in sun-exposed areas), deranged glucose homeostasis or frank diabetes mellitus due to destruction of pancreatic islets, cardiac dysfunction (arrhythmias, cardiomyopathy), and atypical arthritis. In some patients, the presenting complaint is hypogonadism (e.g., amenorrhea in the female, impotence and loss of libido in the male). As noted, clinically apparent disease is more common in males and rarely becomes evident before 40 years of age. Death may result from cirrhosis or cardiac disease. In those with untreated disease, the risk for HCC is increased 200-fold, presumably because of ongoing liver damage and the genotoxic effects of oxidants generated by iron in the liver.

Fortunately, hemochromatosis can be diagnosed long before irreversible tissue damage has occurred. Screening of family members of probands is important. Heterozygotes also accumulate excessive iron, but not to a level that causes significant tissue damage. Currently most patients with hemochromatosis are diagnosed in the subclinical, precirrhotic stage due to routine serum iron measurements (as part of another diagnostic workup). Regular phlebotomy results in steady removal of excess tissue iron, and with this simple treatment life expectancy is normal.

Wilson Disease

Wilson disease is an autosomal recessive disorder caused by mutation of the *ATP7B* gene, which results in impaired copper excretion into bile and a failure to incorporate copper into ceruloplasmin. This disorder is marked by the accumulation of toxic levels of copper in many tissues and organs, principally the liver, brain, and eye. Normally, 40%

to 60% of ingested copper (2–5 mg/day) is absorbed in the duodenum and proximal small intestine, from where it is transported complexed with albumin and histidine to the liver. Here, free copper dissociates and is taken up by hepatocytes, where copper is incorporated into enzymes and α_2-globulin (apoceruloplasmin) to form *ceruloplasmin,* which is secreted into the blood. Ceruloplasmin carries 90% to 95% of plasma copper. Circulating ceruloplasmin is eventually desialylated, endocytosed by the liver, and degraded within lysosomes, after which the released copper is excreted into bile. This degradation/excretion pathway is the primary route for copper elimination.

The *ATP7B* gene, located on chromosome 13, encodes a transmembrane copper-transporting ATPase that is expressed on the hepatocyte canalicular membrane. The overwhelming majority of patients with Wilson disease are compound heterozygotes with different loss-of-function mutations affecting each *ATP7B* allele. The overall frequency of mutated alleles is 1:100, and the prevalence of the disease is approximately 1:30,000 to 1:50,000. Loss of ATP7B protein function impairs the transport of copper into the bile and the incorporation of copper into ceruloplasmin, which is not secreted in its apoceruloplasmin form. These abnormalities lead to copper accumulation in the liver and a decrease in plasma ceruloplasmin. Accumulating copper causes liver injury through the production of reactive oxygen species by the Fenton reaction (Chapter 3). Eventually, non-ceruloplasmin–bound copper is released from injured hepatocytes into the circulation, causing red cell hemolysis and allowing copper to deposit in other tissues, such as the brain, corneas, kidneys, bones, joints, and parathyroid glands. Concomitantly, urinary excretion of copper increases markedly from its normal minuscule levels.

MORPHOLOGY

The liver often bears the brunt of injury. The hepatic changes are variable, ranging from relatively minor to massive and mimic many other disease processes. There may be mild to moderate **fatty change (steatosis)** associated with focal hepatocyte necrosis. **Acute, fulminant hepatitis** can mimic acute viral hepatitis. **Chronic hepatitis** in Wilson disease exhibits moderate to severe inflammation and hepatocyte necrosis, areas of fatty change, and features of steatohepatitis (hepatocyte ballooning with prominent Mallory-Denk bodies). In advanced cases, **cirrhosis** may be seen. Copper deposition in hepatocytes can be demonstrated by special stains (rhodamine stain for copper, orcein stain for copper-associated protein).

Toxic injury to the brain primarily affects the basal ganglia. Nearly all patients with neurologic involvement develop eye lesions called ***Kayser-Fleischer rings,*** green to brown deposits of copper in Desçemet membrane in the limbus of the cornea.

Clinical Features

The age at onset and the clinical presentation of Wilson disease are extremely variable. Symptoms usually appear between 6 and 40 years of age. Acute or chronic liver disease are common presenting features. Neuropsychiatric manifestations are the initial features in most of the remaining cases and stem from deposition of copper in the basal ganglia.

The diagnosis of Wilson disease is based on low levels of serum ceruloplasmin, an increase in hepatic copper content (the most sensitive test), and increased urinary excretion of copper (the most specific test). Hepatic copper content in excess of 250 μg per gram dry weight of liver is taken to be diagnostic, but is only about 80% sensitive. In those with lower liver copper levels, the diagnosis depends on other abnormalities, such as elevated urinary copper, low serum ceruloplasmin, and the presence of Kayser-Fleischer rings. Unlike hereditary hemochromatosis, where the limited number of genetic variants makes genetic testing fairly simple, the large number of different causative mutations in *ATP7B7* complicates the use of DNA sequencing as a diagnostic test. Serum copper levels also are of no diagnostic value, as they may be low, normal, or elevated, depending on the stage of the liver disease.

Early recognition and long-term copper chelation therapy (with D-penicillamine or Trientine) or zinc-based therapy (which inhibits copper uptake in the gut) has dramatically altered the usual progressive downhill course. Individuals with hepatitis or advanced cirrhosis require liver transplantation, which can be curative.

α_1-Anti-Trypsin Deficiency

α_1-Anti-trypsin deficiency is an autosomal recessive disorder marked by very low levels of circulating α_1-anti-trypsin (α_1AT) that is caused by mutations that lead to misfolding of α_1AT. The major function of α_1AT is to inhibit proteases, particularly neutrophil elastase, cathepsin G, and proteinase 3, which are released from neutrophils at sites of inflammation. α_1AT deficiency leads to the development of pulmonary emphysema because the activity of destructive proteases is not inhibited (Chapter 13). It also causes liver disease as a consequence of hepatocellular accumulation of the misfolded α_1AT protein.

α_1AT is a small 394–amino acid plasma glycoprotein synthesized predominantly by hepatocytes. The gene, located on chromosome 14, is very polymorphic. At least 75 α_1AT variants have been identified, denoted alphabetically by their relative migration on an isoelectric gel. The general notation is "Pi" for "protease inhibitor" and an alphabetic letter for the position on the gel; two letters denote the genotype of the two alleles. The most common genotype is PiMM, occurring in 90% of individuals (the "wild-type").

The most common clinically significant mutation is PiZ; PiZZ homozygotes have circulating α_1AT levels that are only 10% of normal. These individuals are at high risk for developing clinical disease. Variant alleles are codominant, and, consequently, PiMZ heterozygotes have intermediate plasma levels of α_1AT. Among individuals of northern European descent, the PiZZ state affects 1 in 1800 live births. Because of the early presentation of the liver disease, α_1AT deficiency is the most commonly diagnosed genetic hepatic disorder in infants and children.

Pathogenesis

The PiZ polypeptide is prone to misfolding and aggregation due to a single amino acid glutamine-to-lysine

substitution at residue 342 (E342K). This in turn creates endoplasmic reticulum stress and triggers the unfolded protein response, which ultimately leads to apoptosis. It is worth emphasizing that the liver damage is caused by protein misfolding, whereas lung damage leading to emphysema stems from the loss of α_1AT function and excessive protease activity. Although all individuals with the PiZZ genotype accumulate α_1AT-Z in the endoplasmic reticulum of hepatocytes, only 10% to 15% develop overt clinical liver disease; thus, other genetic factors or environmental factors must also play a role in the development of liver disease.

MORPHOLOGY

α_1-Anti-trypsin deficiency is characterized by the presence of round-to-oval cytoplasmic **globular inclusions** in hepatocytes that are strongly periodic acid–Schiff (PAS) positive and diastase resistant (Fig. 16.21). Periportal hepatocytes are most affected in early and in mild forms of the disease, with central lobular hepatocytes being affected later or in more severe disease. Other pathologic features vary, ranging from hepatitis to fibrosis to full-blown cirrhosis.

Clinical Features

Neonatal hepatitis with cholestatic jaundice appears in 10% to 20% of newborns with α_1AT deficiency. In adolescence, presenting symptoms may be related to hepatitis or cirrhosis. Attacks of hepatitis may subside with apparent complete recovery, or they may become chronic and lead progressively to cirrhosis. Alternatively, the disease may remain silent until cirrhosis appears in middle to later adult life. HCC develops in 2% to 3% of PiZZ adults, usually in the setting of cirrhosis. The definitive treatment, for severe hepatic disease is liver transplantation. In patients with pulmonary disease, avoidance of cigarette smoking is crucial, because smoking results in accumulation of neutrophils and release of elastase in the lung that is not inactivated because of lack of α_1AT. The unopposed action of neutrophil derived proteases destroys elastic fibers in alveolar walls, leading to emphysema (Chapter 13).

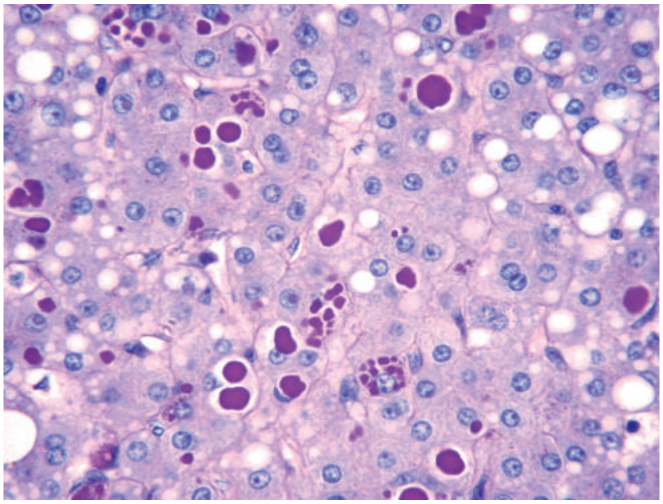

Fig. 16.21 α_1-Anti-trypsin deficiency. Periodic acid–Schiff (PAS) stain after diastase digestion of the liver, highlights the characteristic magenta cytoplasmic granules.

SUMMARY

INHERITED METABOLIC LIVER DISEASE

- Hemochromatosis is most commonly caused by mutations in the *HFE* gene and less commonly by mutations in other genes, all of which result in decreased hepcidin levels or function and increased intestinal iron uptake. It is characterized by accumulation of iron in the liver, pancreas, and other tissues.
- Wilson disease is caused by loss-of-function mutations in the metal ion transporter ATP7B, which results in accumulation of copper in the liver, brain (particularly basal ganglia), and eyes (Kayser-Fleischer rings).
- Wilson disease effects on the liver are protean, showing changes ranging from acute massive hepatic necrosis, to fatty liver disease, to chronic hepatitis and cirrhosis.
- α_1AT deficiency is a disease in which mutations in α_1AT lead to its misfolding, causing liver toxicity and a functional deficit of α_1AT in the plasma. This deficiency places affected individuals at high risk for emphysema, particularly smokers, due to the unopposed effects of proteases released from neutrophils.

CHOLESTATIC SYNDROMES

Hepatic bile serves two major functions: (1) the emulsification of dietary fat in the lumen of the gut through the detergent action of bile salts, and (2) the elimination of bilirubin, excess cholesterol, xenobiotics, and other waste products that are insufficiently water-soluble to be excreted into urine. Processes that interfere with excretion of bile lead to *jaundice* and *icterus* due to retention of bilirubin, and to *cholestasis* (discussed later).

Jaundice may occur in settings of increase bilirubin production (e.g., extravascular red cell hemolysis), hepatocyte dysfunction (e.g., hepatitis), or obstruction of the flow of bile (e.g., an impacted gallstone), any of which can disturb the equilibrium between bilirubin production and clearance (summarized in Table 16.4). The metabolism of bilirubin by the liver occurs in four steps: uptake from the circulation; intracellular storage; conjugation with glucuronic acid; and biliary excretion. These are discussed next.

Bilirubin and Bile Formation

Bilirubin is the end product of heme degradation (Fig. 16.22). Approximately 85% of daily production (0.2–0.3 gm) is derived from the breakdown of senescent red cells by macrophages in the spleen, liver, and bone marrow. The remainder is derived from the turnover of hepatic heme or hemoproteins (e.g., the P-450 cytochromes) and from destruction of red cell precursors in the bone marrow (Chapter 12). Whatever the source, intracellular heme oxygenase oxidizes heme to biliverdin (step 1 in Fig. 16.22),

Table 16.4 Major Causes of Jaundice

Predominantly Unconjugated Hyperbilirubinemia
Excess Production of Bilirubin
Hemolytic anemias Resorption of blood from internal hemorrhage (e.g., alimentary tract bleeding, hematomas) Ineffective erythropoiesis (e.g., pernicious anemia, thalassemia)
Reduced Hepatic Uptake
Drug interference with membrane carrier systems
Impaired Bilirubin Conjugation
Physiologic jaundice of the newborn Diffuse hepatocellular disease (e.g., viral or drug-induced hepatitis, cirrhosis)
Predominantly Conjugated Hyperbilirubinemia
Decreased Hepatocellular Excretion
Drug-induced canalicular membrane dysfunction (e.g., oral contraceptives, cyclosporine) Hepatocellular damage or toxicity (e.g., viral or drug-induced hepatitis, total parenteral nutrition, systemic infection)
Impaired Intrahepatic or Extrahepatic Bile Flow
Inflammatory destruction of intrahepatic bile ducts (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, graft-versus-host disease, liver transplantation) Gallstones External compression (e.g., carcinoma of the pancreas)

which is immediately reduced to bilirubin by biliverdin reductase. Bilirubin thus formed is released and binds to serum albumin (step 2), which is critical since bilirubin is virtually insoluble in aqueous solutions at physiologic pH and also highly toxic to tissues. Albumin carries bilirubin to the liver, where bilirubin is taken up into hepatocytes (step 3) and conjugated with one or two molecules of glucuronic acid by bilirubin uridine diphosphate (UDP)–glucuronyltransferase (UGT1A1, step 4) in the endoplasmic reticulum. Water-soluble, nontoxic bilirubin glucuronides are then excreted into the bile. Most bilirubin glucuronides are deconjugated in the gut lumen by bacterial β-glucuronidases and degraded to colorless urobilinogens (step 5). The urobilinogens and the residue of intact pigment are largely excreted in feces. Approximately 20% of the urobilinogens formed are reabsorbed in the ileum and colon, returned to the liver, and reexcreted into bile. A small amount of reabsorbed urobilinogen is excreted in the urine.

Two-thirds of the organic materials in bile are bile salts, which are formed by the conjugation of bile acids with taurine or glycine. Bile acids, the major catabolic products of cholesterol, are a family of water-soluble sterols with carboxylated side chains. The primary human bile acids are cholic acid and chenodeoxycholic acid. Bile acids are highly effective detergents. Their primary physiologic role is to solubilize water-insoluble lipids secreted by hepatocytes into bile, and also to solubilize dietary lipids in the gut lumen. Ninety-five percent of secreted bile acids, conjugated or unconjugated, are reabsorbed from the gut lumen and recirculate to the liver *(enterohepatic circulation),* thus helping to maintain a large endogenous pool of bile acids for digestive and excretory purposes.

Pathophysiology of Jaundice

Both unconjugated bilirubin and conjugated bilirubin (bilirubin glucuronides) may accumulate systemically. As discussed earlier, unconjugated bilirubin is virtually insoluble and tightly bound to albumin. As a result, it cannot be excreted in the urine, even when blood levels are high. Normally, a very small amount of unconjugated bilirubin is present as a free anion in plasma. If unconjugated bilirubin levels rise, this unbound fraction may diffuse into tissues, particularly the brain in infants, and produce toxic injury. The unbound plasma fraction increases in severe hemolytic disease or when protein-binding drugs displace bilirubin from albumin. Hence, hemolytic disease of the newborn (erythroblastosis fetalis) may lead to accumulation of unconjugated bilirubin in the brain, which can cause severe neurologic damage, referred to as *kernicterus*

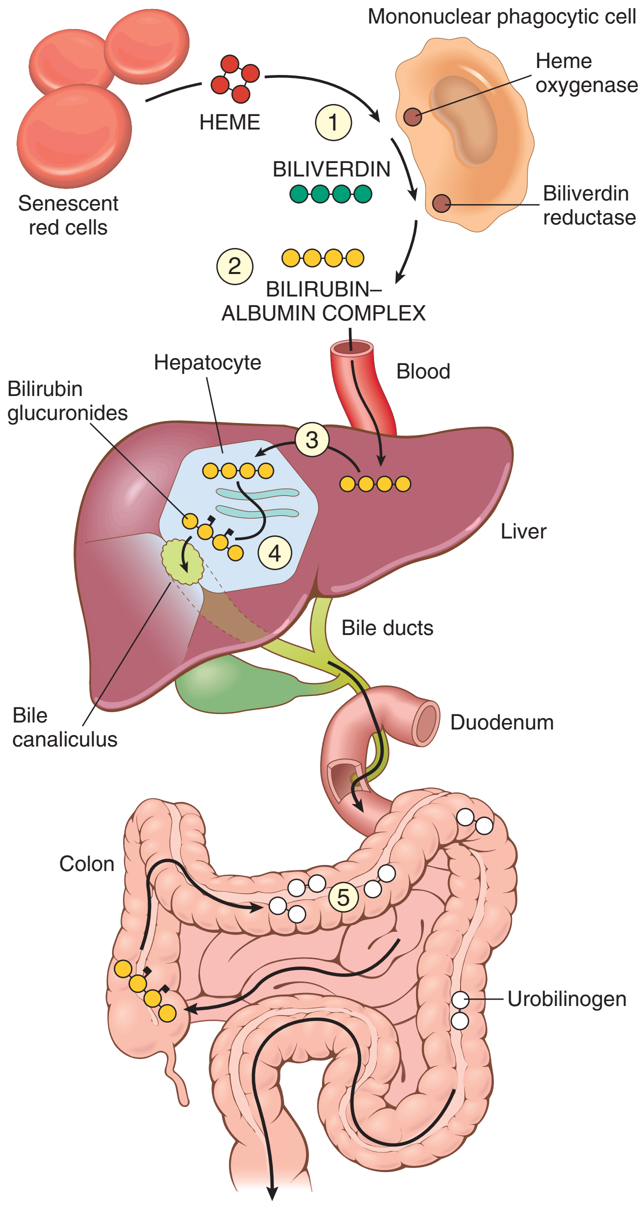

Fig. 16.22 Bilirubin metabolism and elimination.

(Chapter 7). In contrast, conjugated bilirubin is water-soluble, nontoxic, and only loosely bound to albumin. Because of its solubility and weak association with albumin, excess conjugated bilirubin in plasma can be excreted in urine.

Serum bilirubin levels in the normal adult vary between 0.3 and 1.2 mg/dL. Jaundice becomes evident when the serum bilirubin levels rise above 2 to 2.5 mg/dL; levels as high as 30 to 40 mg/dL can occur with severe disease. Causes of conjugated and unconjugated hyperbilirubinemia differ, and so measurement of both forms is of value in evaluating a patient with jaundice.

Defects in Hepatocellular Bilirubin Metabolism

Neonatal Jaundice

Because the hepatic machinery for conjugating and excreting bilirubin does not fully mature until about 2 weeks of age, almost every newborn develops transient and mild unconjugated hyperbilirubinemia, termed *neonatal jaundice* or *physiologic jaundice of the newborn*. This may be exacerbated by breastfeeding, due to the action of bilirubin-deconjugating enzymes in breast milk. Nevertheless, sustained jaundice in the newborn is abnormal and is discussed later in the "Neonatal Cholestasis" section.

Hereditary Hyperbilirubinemias

Jaundice also may result from inborn errors of metabolism, including the following:

- *Gilbert syndrome* is a common (7% of the population) inherited condition that manifests as fluctuating unconjugated hyperbilirubinemia of variable severity. The primary cause is mildly decreased hepatic levels of glucuronosyltransferase attributed to a mutation in the encoding gene, *UGT1A1;* polymorphisms in the gene may play a role in the variable expression of this disorder. Gilbert syndrome is not associated with any morbidity. By contrast, severe glucuronosyltransferase deficiency causes a rare disorder called *Crigler-Najjar Syndrome Type 1* that is fatal in infancy.
- *Dubin-Johnson syndrome* results from an autosomal recessive defect in the transport protein responsible for hepatocellular excretion of bilirubin glucuronides across the canalicular membrane. Affected individuals exhibit conjugated hyperbilirubinemia. Other than having a darkly pigmented liver (from polymerized epinephrine metabolites, not bilirubin) and hepatomegaly, patients are normal.

Cholestasis

Cholestasis is a condition caused by extrahepatic or intrahepatic obstruction of bile channels or by defects in hepatocyte bile secretion. Patients may have jaundice, pruritus, skin xanthomas (focal accumulation of cholesterol), or symptoms related to intestinal malabsorption, including nutritional deficiencies of the fat-soluble vitamins A, D, or K. A characteristic laboratory finding is elevated serum alkaline phosphatase and γ-glutamyl transpeptidase (GGT), enzymes that are present on the apical membranes of hepatocytes and cholangiocytes.

MORPHOLOGY

The morphologic features of cholestasis depend on its severity, duration, and underlying cause. Common to both obstructive and nonobstructive cholestasis is the accumulation of bile pigment within the hepatic parenchyma (Fig. 16.23). Elongated green-brown plugs of bile are visible in dilated bile canaliculi. Rupture of canaliculi leads to extravasation of bile, which is quickly phagocytosed by Kupffer cells. Droplets of bile pigment also accumulate within hepatocytes, which can take on a fine, foamy appearance referred to as ***feathery degeneration***. Occasional apoptotic hepatocytes also may be seen.

Bile Duct Obstruction and Ascending Cholangitis

The most common cause of bile duct obstruction in adults is extrahepatic cholelithiasis (gallstones, discussed

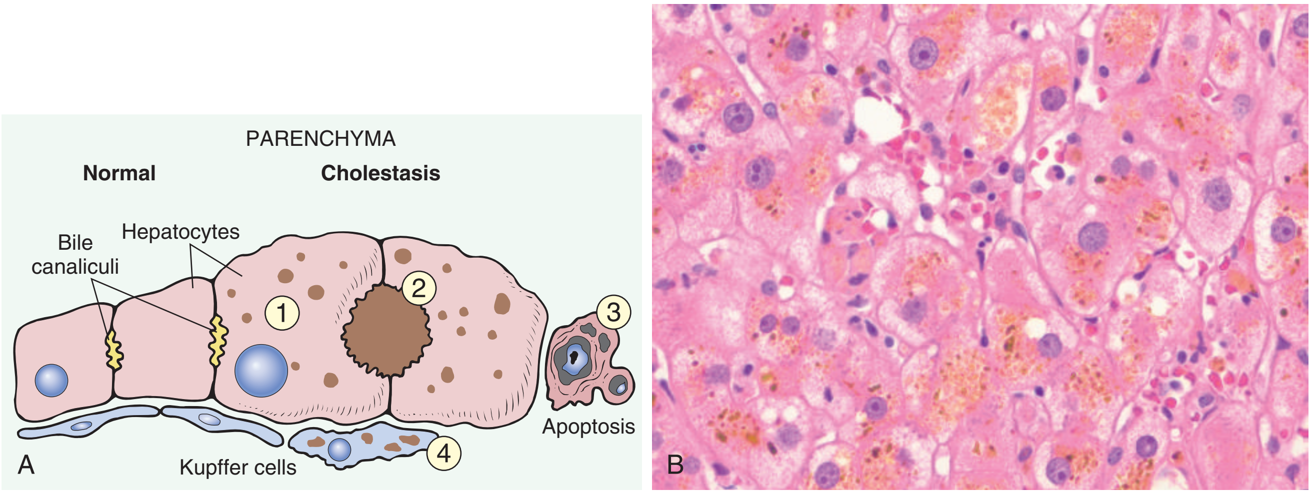

Fig. 16.23 Cholestasis. (A) Morphologic features of cholestasis *(right)* and comparison with normal liver *(left)*. Cholestatic hepatocytes (1) are enlarged and are associated with dilated canalicular spaces (2). Apoptotic cells (3) may be seen, and Kupffer cells (4) frequently contain regurgitated bile pigments. (B) Cholestasis, showing the characteristic accumulation of bile pigments in the cytoplasm.

later), followed by malignant obstructions, and postsurgical strictures. Obstructive conditions in children include biliary atresia, cystic fibrosis, choledochal cysts (a cystic anomaly of the extrahepatic biliary tree), and syndromes in which there are insufficient intrahepatic bile ducts (paucity of bile duct syndromes). The initial morphologic features of cholestasis have been discussed and are entirely reversible with correction of the obstruction. Prolonged obstruction can lead to biliary cirrhosis, discussed later.

Ascending cholangitis, secondary bacterial infection of the biliary tree, may complicate duct obstruction. Enteric organisms such as coliforms and enterococci are common culprits. Cholangitis usually presents with fever, chills, abdominal pain, and jaundice. The most severe form of cholangitis is *suppurative cholangitis,* in which purulent bile fills and distends bile ducts. Since sepsis rather than cholestasis tends to dominate this potentially grave process, prompt diagnostic evaluation and intervention are imperative.

Since extrahepatic biliary obstruction is frequently amenable to surgical treatment, correct and prompt diagnosis is imperative. In contrast, cholestasis due to diseases of the intrahepatic biliary tree or hepatocellular secretory failure (collectively termed *intrahepatic cholestasis*) is not benefited by surgery (short of transplantation), and the patient's condition may be worsened by an operative procedure. It is thus important to establish the underlying basis for jaundice and cholestasis.

MORPHOLOGY

Acute biliary obstruction, either intrahepatic or extrahepatic, causes distention of upstream bile ducts, which often become dilated. In addition, **ductular reactions** appear at the portal-parenchymal interface along with stromal edema and neutrophils. The hallmark of superimposed infection **(ascending cholangitis)** is the influx of periductular neutrophils into the bile duct epithelium and lumen (Fig. 16.24).

Left uncorrected, the inflammation and ductular reactions resulting **from chronic biliary obstruction** initiate periportal fibrosis, eventually generating **secondary or obstructive biliary cirrhosis** (Fig. 16.25). Cholestatic features in the parenchyma may be prominent. These take the form of extensive **feathery degeneration of periportal hepatocytes**, a type of cytoplasmic swelling often associated with **Mallory-Denk bodies** and **bile infarcts** caused by the detergent effects of extravasated bile.

Neonatal Cholestasis

Prolonged conjugated hyperbilirubinemia in the neonate, termed *neonatal cholestasis* (as opposed to the already discussed neonatal jaundice) affects approximately 1 in 2500 live births. The major conditions causing it are (1) cholangiopathies, primarily *biliary atresia* (discussed later), and (2) a variety of disorders causing conjugated hyperbilirubinemia in the neonate, collectively referred to as *neonatal hepatitis*.

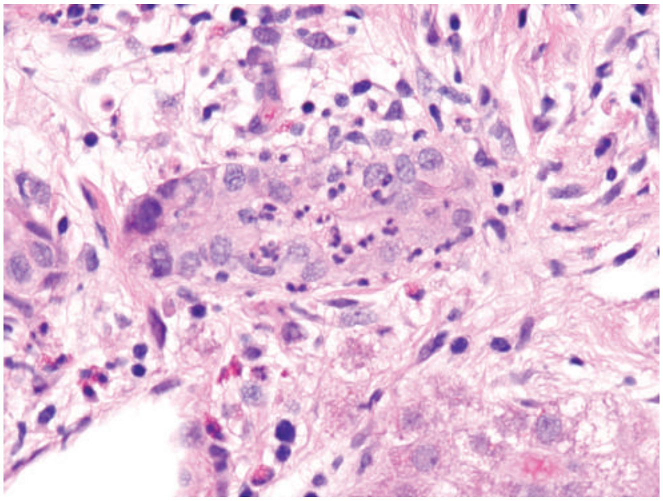

Fig. 16.24 Acute large-duct obstruction with ascending cholangitis. Superimposed on features of duct obstruction (edema, ductular reaction) is an infiltrate of neutrophils involving the bile duct, the hallmark of ascending cholangitis.

Neonatal hepatitis is not a specific entity, nor does it necessarily have an inflammatory basis. Rather it is an indication to conduct a diligent search for recognizable toxic, metabolic, and infectious liver diseases, as greater than 85% of cases have identifiable causes.

Differentiation of biliary atresia from nonobstructive neonatal cholestasis is very important, since definitive treatment of biliary atresia requires surgical intervention (Kasai procedure), whereas surgery may adversely affect a child with other disorders. Fortunately, discrimination can be made on the basis of clinical data in about 90% of cases. In 10% of cases, liver biopsy may be necessary to distinguish neonatal hepatitis from an identifiable cholangiopathy. Affected infants have jaundice, dark urine, light or acholic stools, and hepatomegaly. Variable degrees of hepatic synthetic dysfunction may be identified, such as hypoprothrombinemia.

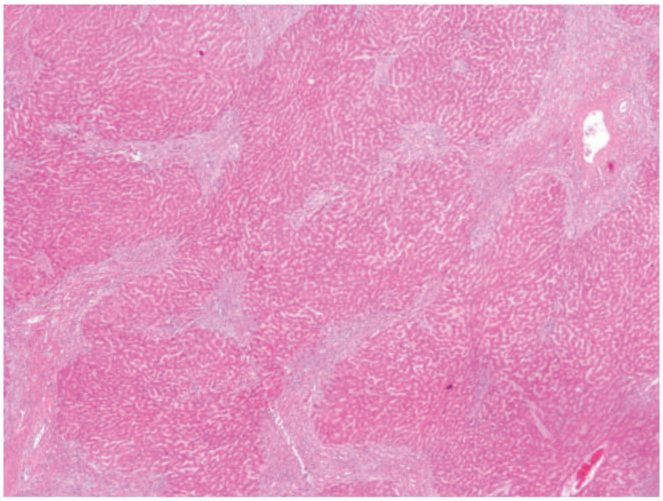

Fig. 16.25 Cirrhosis secondary to primary biliary cholangitis.

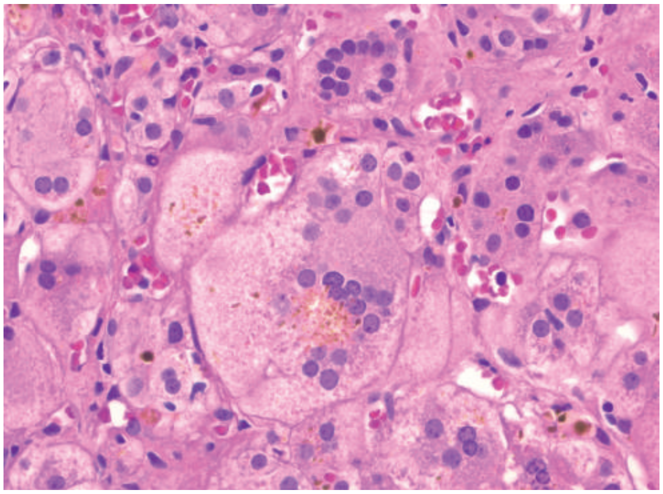

Fig. 16.26 Neonatal hepatitis. Note the multinucleated giant hepatocytes.

MORPHOLOGY

The morphologic features of neonatal hepatitis (Fig. 16.26) include striking giant-cell transformation of hepatocytes, associated with lobular disarray, focal liver cell apoptosis and prominent hepatocellular and canalicular cholestasis. In some cases, this parenchymal pattern of injury also is accompanied by ductular reaction and fibrosis of portal tracts.

Biliary Atresia

Biliary atresia is defined as a complete or partial obstruction of the extrahepatic biliary tree that occurs within the first 3 months of life. It underlies approximately one-third of cases of neonatal cholestasis and is the single most frequent cause of death from liver disease in early childhood. Approximately 50% to 60% of children referred for liver transplantation have biliary atresia.

Pathogenesis

Two major forms of biliary atresia are recognized; these are based on the presumed timing of luminal obliteration.

- The *fetal form* accounts for as many as 20% of cases and is commonly associated with other developmental anomalies involving the thoracic and abdominal organs, including malrotation of abdominal viscera, interrupted inferior vena cava, polysplenia, and congenital heart disease.
- Much more common is the *perinatal form* of biliary atresia, in which an apparently normally developed biliary tree is injured and obstructed following birth. The etiology of perinatal biliary atresia is unknown; viral infection and toxic exposures are considered prime suspects.

MORPHOLOGY

The salient features of biliary atresia include **inflammation and fibrosing stricture of the hepatic or common bile ducts;** in some individuals, periductular inflammation also extends into the intrahepatic bile ducts, leading to progressive destruction of the intrahepatic biliary tree as well. When biliary atresia is unrecognized or uncorrected, cirrhosis develops within 3 to 6 months of birth.

There is considerable variability in the pattern of biliary atresia. When the disease is limited to the common duct or right and/or left hepatic bile ducts with patent intrahepatic branches, the disease is surgically correctable (**Kasai procedure**). Unfortunately, in 90% of patients the obstruction also involves bile ducts at or above the porta hepatis. These cases are not correctable, since there are no patent bile ducts amenable to surgical anastomosis.

Clinical Features

Infants with biliary atresia present with neonatal cholestasis, but exhibit normal birth weight and postnatal weight gain. There is a slight female predominance. Initially stools are normal, but they become acholic as the disease progresses. Ascending cholangitis and/or intrahepatic progression of the disease may impede attempts at surgical resection of the obstruction and bypass of the biliary tree. Transplantation of a donor liver and its accompanying bile ducts is the primary hope for saving these young patients. Without surgical intervention, death usually occurs within 2 years of birth.

Autoimmune Cholangiopathies

Autoimmune cholangiopathies comprise two distinct immunologically-mediated disorders that involve intrahepatic bile ducts: primary biliary cholangitis and primary sclerosing cholangitis. The salient features of these are listed in Table 16.5.

Primary Biliary Cholangitis

Primary biliary cholangitis (PBC) is an autoimmune disease whose primary feature is nonsuppurative, inflammatory destruction of small- and medium-sized intrahepatic bile ducts. Large intrahepatic ducts and the extrahepatic biliary tree are not involved. Previously, this disease was known as primary biliary cirrhosis, but most patients do not progress to this stage, and the name primary biliary cholangitis is now preferred.

PBC is primarily a disease of middle-age women, with a female-to-male ratio of 6:1. Its peak incidence is between 40 and 50 years of age. The disease is most prevalent in Northern European countries (England and Scotland) and the Northern United States (Minnesota), where the prevalence is as high as 400 per 1 million cases. Recent increases in incidence and prevalence along with geographic clustering suggest that both environmental and genetic factors are important in its pathogenesis. Family members of PBC patients have an increased risk for developing the disease.

Pathogenesis

PBC is thought to be an autoimmune disorder, but as with other autoimmune diseases the triggers that initiate PBC are unknown. **Anti-mitochondrial antibodies are the most**

Table 16.5 Main Features of Primary Biliary Cholangitis and Primary Sclerosing Cholangitis

Parameter	Primary Biliary Cholangitis	Primary Sclerosing Cholangitis
Age	Median age 50 years	Median age 30 years
Gender	90% female	70% male
Clinical course	Progressive	Unpredictable, but progressive
Associated conditions	Sjögren syndrome (70%)	Inflammatory bowel disease (70%)
	Scleroderma (5%)	Pancreatitis (≤25%)
	Thyroid disease (20%)	Idiopathic fibrosing diseases (retroperitoneal fibrosis)
Serology	95% AMA-positive	0%–5% AMA-positive (low titer)
	20% ANA-positive	6% ANA-positive
	40% ANCA-positive	65% ANCA-positive
Radiology	Normal	Strictures and beading of large bile ducts; pruning of smaller ducts
Duct lesion	Florid duct lesions and loss of small ducts only	Inflammatory destruction of extrahepatic and large intrahepatic ducts; fibrotic obliteration of medium and small intrahepatic ducts

AMA, Anti-mitochondrial antibody; *ANA*, anti-nuclear anti-body; *ANCA*, anti-neutrophil cytoplasmic antibody.

characteristic finding in PBC. T cells specific for certain mitochondrial enzymes are another feature of the disease, supporting the notion of an immune-mediated process. Other findings suggestive of altered immunity include aberrant expression of MHC class II molecules on bile duct epithelial cells, accumulation of autoreactive T cells around bile ducts, and the frequent presence of other autoantibodies against nuclear pore proteins centromeric proteins, and other cellular components.

MORPHOLOGY

Interlobular bile ducts are actively destroyed by lymphoplasmacytic inflammation with or without granulomas (the *florid duct lesion*) (Fig. 16.27). Some biopsy specimens, however, do not have active lesions and only show the absence of bile ducts in portal tracts. The disease is quite patchy in distribution; it is common to see a single bile duct under immune attack in one level of a biopsy specimen, while other nearby ducts, are unaffected. **Ductular reactions** follow on this duct injury, and these in turn participate in the development of **portal-portal septal fibrosis.**

In the absence of treatment, the disease follows one of two paths to end-stage disease. In the first, most classic pathway, there is increasingly widespread duct loss, slowly leading to established cirrhosis and eventually to profound cholestasis. Alternatively, some patients eventually developed prominent portal hypertension rather than severe cholestasis. Fortunately, both of these outcomes are now rarely seen.

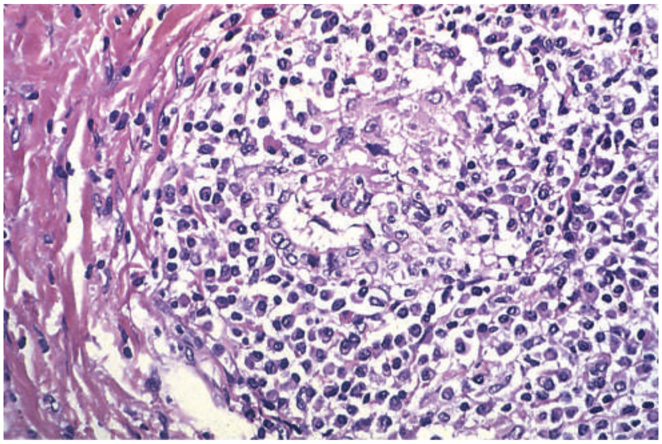

Fig. 16.27 Primary biliary cirrhosis. A portal tract is markedly expanded by an infiltrate of lymphocytes and plasma cells. Note the granulomatous reaction to the bile duct undergoing destruction (the "florid duct lesion").

Clinical Features

Most patients are diagnosed while asymptomatic following a workup triggered by the identification of an elevated serum alkaline phosphatase level or severe itching. Hypercholesterolemia is common. Anti-mitochondrial antibodies are present in 90% to 95% of patients. They are highly characteristic of PBC, although other autoantibodies may be seen in a small number of cases. The disease is confirmed by liver biopsy, which is considered diagnostic if a florid duct lesion is present. When symptoms appear, their onset is insidious, with patients typically complaining of slowly increasing fatigue and pruritus.

In recent years, early treatment with oral ursodeoxycholic acid has dramatically improved outcomes by slowing disease progression. Its mechanism of action remains unclear, but is presumably related to the ability of ursodeoxycholate to enter the bile acid pool and alter the biochemical composition of bile.

With time, even with treatment, secondary features may emerge, including skin hyperpigmentation, xanthelasmas, steatorrhea, and vitamin D malabsorption–related osteomalacia and/or osteoporosis. Individuals with PBC may also have extrahepatic manifestations of autoimmunity, including the sicca complex of dry eyes and mouth (Sjögren syndrome), systemic sclerosis, thyroiditis, rheumatoid arthritis, Raynaud phenomenon, and celiac disease. Liver transplantation is the best treatment for individuals with advanced liver disease.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is characterized by inflammation and obliterative fibrosis of intrahepatic and extrahepatic bile ducts, leading to dilation of preserved segments. Irregular biliary strictures and dilations cause the characteristic "beading" of the intrahepatic and extrahepatic biliary tree seen by MRI. Inflammatory bowel disease (Chapter 15), most commonly ulcerative colitis, coexists in approximately 70% of individuals with PSC. Conversely, the prevalence of PSC in individuals with ulcerative colitis is about 4%. Like inflammatory bowel disease, PSC tends to occur in the third through fifth decades of life and has a 2:1 male predominance (see Table 16.5).

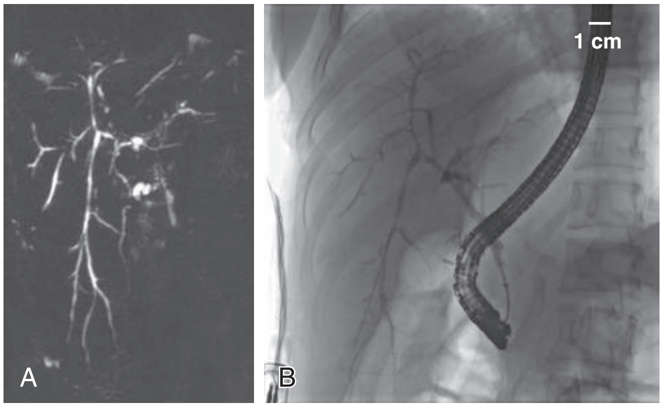

Fig. 16.28 Imaging studies of a patient with primary sclerosing cholangitis. (A) Magnetic resonance cholangiography of the bile ducts shows focal dilation in some ducts *(bright, broad areas)* and stricturing of others *(thinning or absence).* (B) Endoscopic retrograde cholangiography of the same patient shows nearly identical features as in *A. (Courtesy of Dr. M. Edwyn Harrison, MD, Mayo Clinic, Scottsdale, Arizona.)*

Pathogenesis

Several features of PSC suggest immunologically mediated injury to bile ducts. T cells in the periductal stroma, the presence of autoantibodies, an association with HLA-B8 and other MHC alleles, and clinical linkage to ulcerative colitis all support an underlying, immunologic process. First-degree relatives of patients with PSC are at increased risk for developing the disease, suggesting that genetic factors also contribute.

In one model, it is proposed that T cells activated in the damaged mucosa of patients with ulcerative colitis migrate to the liver, where they recognize a cross-reacting bile duct antigen and initiate an autoimmune assault on bile ducts. Autoantibody profiles in PSC are not as characteristic as in PBC, but atypical perinuclear anti-neutrophil cytoplasmic antibodies (pANCA) that recognize a nuclear envelope protein are found in up to 80% of patients. The pathogenic relationship of pANCA to PSC is unknown.

MORPHOLOGY

Morphologic changes differ between large ducts (intrahepatic and extrahepatic) and smaller intrahepatic ducts. **Large duct inflammation** resembles that seen in ulcerative colitis, taking the form of neutrophils infiltrating into the epithelium superimposed on a chronic inflammatory background. Inflamed areas develop strictures as scarring narrows the lumen. The **smaller ducts,** however, often have little inflammation and show a striking **circumferential, "onion skin" fibrosis** around an atrophic duct lumen (Fig. 16.29), which eventually is obliterated, leaving a "tombstone" scar. Because the likelihood of sampling small-duct lesions on a random needle biopsy is small, diagnosis depends on radiologic imaging of the extrahepatic and large intrahepatic ducts. As the disease progresses, the liver becomes markedly cholestatic, culminating in cirrhosis. Biliary intraepithelial neoplasia often appear in the setting of chronic inflammation and cholangiocarcinoma develops in up to 7% of patients, usually with a fatal outcome.

Clinical Features

Patients may come to attention only because of persistent elevation of serum alkaline phosphatase, particularly in those with ulcerative colitis who are being routinely screened. Alternatively, progressive fatigue, pruritus, and jaundice may develop. Acute bouts of ascending cholangitis may also signal the presence or progression of PSC. Chronic pancreatitis and chronic cholecystitis due to involvement of the pancreatic ducts and gallbladder are also seen. In some patients, sclerosing cholangitis is associated with autoimmune pancreatitis. In such cases PSC may be one manifestation of IgG4 related chronic disease (Chapter 5).

PSC follows a protracted course of 5 to 17 years, and severely afflicted patients have symptoms typical of chronic cholestatic liver disease, including steatorrhea. Unlike with PBC, there is no satisfactory medical treatment. A variety of immunosuppressive agents have been tried, but none has been proven to alter the disease course. Endoscopic dilation with sphincterotomy or stenting is used to relieve obstruction. Liver transplantation is the only definitive treatment for individuals with end-stage liver disease.

SUMMARY
CHOLESTATIC DISEASES

- **Cholestasis** occurs with impaired excretion of bile, leading to jaundice and accumulation of bile pigment in the hepatic parenchyma. Causes include mechanical or inflammatory obstruction or destruction of the bile ducts or metabolic defects in hepatocyte bile secretion.
- **Large bile duct obstruction** is most commonly associated with gallstones and malignancies involving the head of the pancreas. Chronic obstruction can lead to cirrhosis.
- **Neonatal cholestasis** is not a specific entity; it is variously associated with cholangiopathies such as *biliary atresia* and a variety of disorders causing conjugated hyperbilirubinemia in the neonate, collectively referred to as *neonatal hepatitis.*
- **Primary biliary cholangitis** is an autoimmune disease with progressive, inflammatory, often granulomatous, destruction of

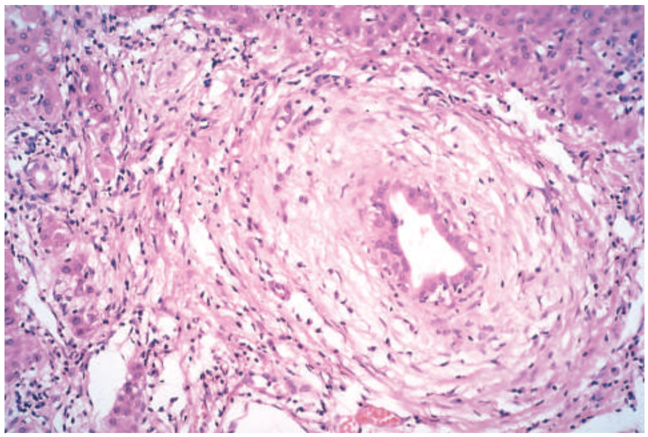

Fig. 16.29 Primary sclerosing cholangitis. A bile duct undergoing degeneration is entrapped in a dense, "onion-skin" concentric scar.

small to medium intrahepatic bile ducts. It most often occurs in middle-age women and is associated with anti-mitochondrial antibodies and often with other autoimmune diseases, such as Sjögren syndrome and Hashimoto thyroiditis.
- **Primary sclerosing cholangitis** is an autoimmune disease with progressive inflammatory and sclerosing destruction of intrahepatic and extrahepatic bile ducts of all sizes. Diagnosis is made by radiologic imaging of the biliary tree. It most often occurs in younger men and has a strong association with inflammatory bowel disease, particularly ulcerative colitis.

CIRCULATORY DISORDERS

Hepatic circulatory disorders can be grouped according to whether the disorder leads to abnormalities in the inflow, flow-through, or outflow of blood (Fig. 16.30).

Impaired Blood Flow Into the Liver

Hepatic Artery Compromise

Liver infarcts are rare, thanks to the double blood supply to the liver. Nonetheless, thrombosis or obstruction of an intrahepatic branch of the hepatic artery by embolism (Fig. 16.31), neoplasia, or an inflammatory process such as polyarteritis nodosa (Chapter 10) may produce an infarct, which may either be pale or hemorrhagic if suffused with blood from the portal circulation. Blockage of the main hepatic artery may not produce ischemic necrosis of the organ, particularly if the liver is otherwise normal, as retrograde arterial flow through accessory vessels and the portal venous supply is usually sufficient to sustain the liver parenchyma.

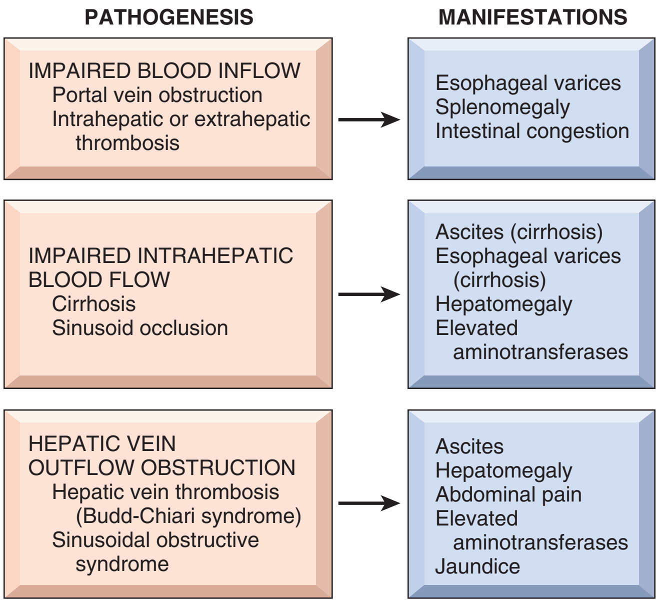

Fig. 16.30 Hepatic circulatory disorders. Forms and clinical manifestations of compromised hepatic blood flow.

Fig. 16.31 Liver infarct. A thrombus is lodged in a peripheral branch of the hepatic artery (*arrow*) and compresses the adjacent portal vein; the distal hepatic tissue is pale, with a hemorrhagic margin.

Portal Vein Obstruction and Thrombosis

Blockage of the extrahepatic portal vein may cause only vague symptoms or may be a catastrophic and potentially lethal event; most cases fall somewhere in between. Occlusive disease of the portal vein or its major radicles typically produces abdominal pain and other manifestations of portal hypertension, principally esophageal varices that are prone to rupture. Ascites is not common (because the block is presinusoidal), but, when present, is often massive and intractable.

Extrahepatic portal vein obstruction may be idiopathic (approximately one-third of cases) or may arise from a number of conditions. Some of the most common settings for development of extrahepatic portal vein obstruction include the following:
- *Cirrhosis,* which is associated with portal vein thrombosis in 25% of patients, some of whom have other risk factors as well
- *Hypercoagulable states,* including myeloproliferative neoplasms such as polycythemia vera (Chapter 12), inherited thrombophilias such as factor V Leiden (Chapter 4), and miscellaneous hypercoagulable conditions such as paroxysmal nocturnal hemoglobinuria and antiphospholipid antibody syndrome
- *Inflammatory processes* involving the splenic vein or portal vein, such as pancreatitis and intraabdominal sepsis
- *Trauma*, surgical or otherwise

Obstruction of intrahepatic portal vein radicles may be caused by acute thrombosis. The thrombosis does not cause ischemic infarction but instead results in a sharply demarcated area of red-blue discoloration called *infarct of Zahn*. There is no necrosis, only severe hepatocellular atrophy and marked congestion of distended sinusoids. The most common cause of small portal vein branch obstruction is *schistosomiasis;* the eggs of the parasites lodge in and obstruct the smallest portal vein branches. The other

disorders producing this pattern of injury are now collectively referred to as *obliterative portal venopathy,* which often presents as noncirrhotic portal hypertension. Causes of obliterative portal venopathy are not well understood. It occurs in both untreated and treated HIV disease, and may in some instances be a complication of anti-retroviral therapy.

Impaired Blood Flow Through the Liver

The most common intrahepatic cause of blood flow obstruction is cirrhosis, as discussed earlier. In addition, physical occlusion of the sinusoids occurs in *sickle cell disease, disseminated intravascular coagulation, eclampsia*, and *intrasinusoidal metastasis* of solid tumors. If severe and unabated, all of these disorders may produce sufficient obstruction of blood flow to cause massive necrosis of hepatocytes and fulminant hepatic failure.

Hepatic Venous Outflow Obstruction

Hepatic Vein Thrombosis

Occlusive events can occur in any caliber of hepatic vein branches. If it occurs in the smallest intrahepatic branches, it produces *sinusoidal obstruction syndrome* (formally known as *veno-occlusive disease*). A rare, but well-known cause of this syndrome is consumption of pyrrolizidine alkaloid–containing Jamaican bush tea, but it now occurs primarily following allogeneic hematopoietic stem cell transplantation, usually within the first 3 weeks, or in cancer patients receiving chemotherapy, in whom it can have as high as 30% mortality.

The obstruction of two or more major hepatic veins produces liver enlargement, pain, and ascites, a condition known as *Budd-Chiari syndrome.* Obstruction of a single main hepatic vein by thrombosis is clinically silent. Hepatic damage is the consequence of increased intrahepatic blood pressure. Hepatic vein thrombosis is associated with the same hypercoagulable states as portal vein thrombosis as well as intraabdominal cancers, particularly HCC. As is often the case in those afflicted with various thrombotic disorders, Budd-Chiari syndrome often occurs in patients with several risk factors, such as pregnancy or oral contraceptive use combined with an underlying thrombophilic disorder.

MORPHOLOGY

In Budd-Chiari syndrome, the liver is swollen and red-purple and has a tense capsule (Fig. 16.32). There may be areas of hemorrhagic collapse alternating with areas of preserved or regenerating parenchyma, depending on which small and large hepatic veins are obstructed. Microscopically, the affected hepatic parenchyma reveals severe centrilobular congestion and necrosis. Centrilobular fibrosis develops in instances in which the thrombosis is more slowly developing. The major veins may contain fresh occlusive thrombi or, in chronic cases, organized adherent thrombi.

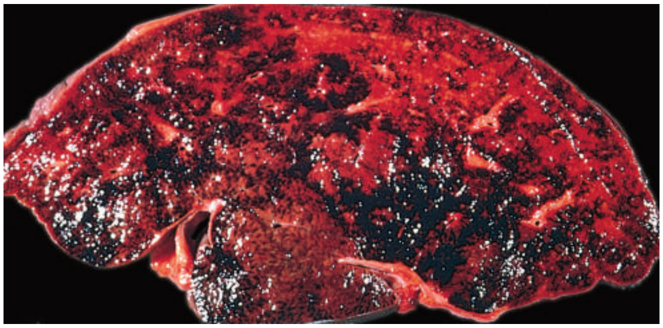

Fig. 16.32 Budd-Chiari syndrome. Thrombosis of the major hepatic veins has caused severe hepatic congestion.

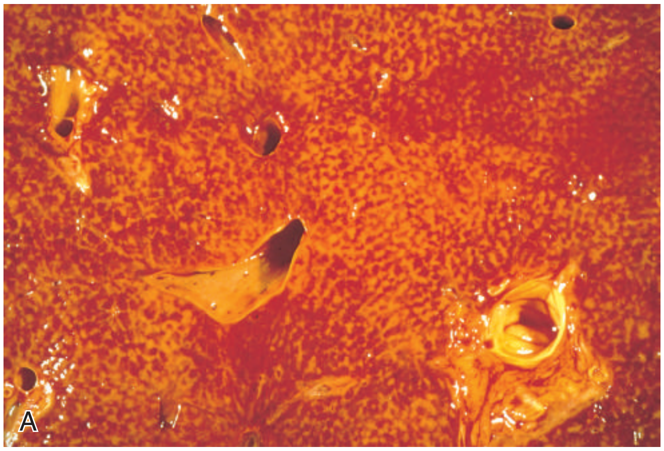
The mortality of untreated acute hepatic vein thrombosis is high. The condition is rare, and treatments are largely empiric. They include anti-coagulation to prevent clot propagation; angioplasty to restore the patency of occluded veins; thrombolysis; and creation of portovenous shunts, using either invasive radiologic approaches or surgery, in order to decompress the liver. The chronic form is far less lethal, and more than two-thirds of patients are alive after 5 years.



Passive Congestion and Centrilobular Necrosis

These hepatic manifestations of systemic circulatory compromise—passive congestion and centrilobular necrosis—are considered together because they represent a morphologic continuum. Both changes are commonly seen at autopsy, as there is an element of preterminal circulatory failure in virtually every nontraumatic death.

MORPHOLOGY

Right-sided cardiac decompensation leads to passive congestion of the liver. The liver is slightly enlarged, tense, and cyanotic, with rounded edges. Microscopically there is congestion of **centrilobular sinusoids.** With time, centrilobular hepatocytes become atrophic, resulting in markedly attenuated liver cell plates. Left-sided cardiac failure or shock may lead to hepatic hypoperfusion and hypoxia, causing ischemic coagulative necrosis of hepatocytes in the central region of the lobule (**centrilobular necrosis**).

The combination of hypoperfusion and retrograde congestion acts synergistically to cause **centrilobular hemorrhagic necrosis.** The liver takes on a variegated mottled appearance, reflecting hemorrhage and necrosis in the centrilobular regions (Fig. 16.33A). This finding is known as **nutmeg liver** due to its resemblance to the cut surface of a nutmeg. There typically is a sharp demarcation between viable periportal and necrotic or atrophic pericentral regions that are suffused with blood (see Fig. 16.33B). Uncommonly, with sustained chronic severe congestive heart failure, centrilobular fibrosis (**cardiac sclerosis**) or even cirrhosis develops.

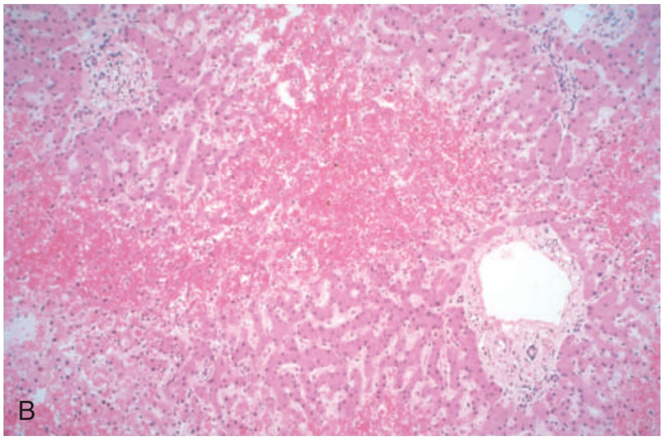


Fig. 16.33 Acute passive congestion ("nutmeg liver"). (A) The cut liver section, in which major blood vessels are visible, is notable for a variegated mottled red appearance, representing congestion and hemorrhage in the centrilobular regions of the parenchyma. (B) On microscopic examination, the centrilobular region is suffused with red blood cells, and atrophied hepatocytes are not easily seen. Portal tracts and the periportal parenchyma are intact.

SUMMARY

CIRCULATORY DISORDERS

- Circulatory disorders of the liver can be caused by impaired blood inflow, defects in intrahepatic blood flow, and obstruction of blood outflow.
- Portal vein obstruction by intrahepatic or extrahepatic thrombosis may cause portal hypertension, esophageal varices, and ascites.
- The most common cause of impaired intrahepatic blood flow is cirrhosis.
- Obstructions of blood outflow include hepatic vein thrombosis (Budd-Chiari syndrome) and sinusoidal obstruction syndrome, previously known as *veno-occlusive disease.*

NODULES AND TUMORS

Hepatic masses come to attention for a variety of reasons. They may generate epigastric fullness and discomfort or be detected by routine physical examination or radiographic studies for other indications. Hepatic masses include nodular hyperplasias and true neoplasms.

Focal Nodular Hyperplasia

Solitary or multiple hyperplastic hepatocellular nodules that may develop in the noncirrhotic liver are called *focal nodular hyperplasias.* These lesions arise from local alterations in hepatic parenchymal blood supply, such as arteriovenous malformations or inflammatory or posttraumatic obliteration of portal vein radicles and compensatory augmentation of arterial blood supply.

MORPHOLOGY

Focal nodular hyperplasia appears as a well-demarcated, poorly encapsulated nodule ranging up to many centimeters in diameter (Fig. 16.34A). It presents as a mass lesion in an otherwise normal liver, most frequently in young to middle-age adults. Typically, there is a central gray-white, depressed stellate

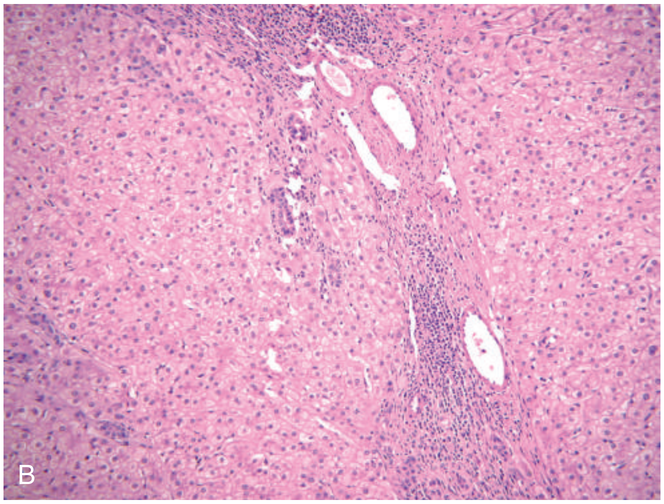

Fig. 16.34 Focal nodular hyperplasia. (A) Resected specimen showing lobulated contours and a central stellate scar. (B) Low-power photomicrograph showing a broad fibrous scar with mixed hepatic arterial and bile duct elements and chronic inflammation within hepatic parenchyma that lacks normal architecture due to hepatocyte regeneration.

scar from which fibrous septa radiate to the periphery (see Fig. 16.34B).

Microscopically, the central scar contains large abnormal vessels and ductular reactions along the spokes of scar. A vascular lesion is probably the initiating insult, as it is believed that hypoperfused parenchyma collapses to produce the septa, whereas hyperperfused regions undergo hyperplasia. The hyperplastic regions are composed of normal hepatocytes separated by thickened sinusoidal plates.

Benign Neoplasms

Cavernous hemangiomas are the most common benign liver tumors (Chapter 10). The chief clinical significance of cavernous hemangiomas is that they must be distinguished radiographically or intraoperatively from metastatic tumors.

Hepatocellular Adenomas

Benign neoplasms developing from hepatocytes are called hepatocellular adenomas (Fig. 16.35). They may be detected incidentally as a hepatic mass on abdominal imaging or when they cause symptoms. The most common symptom is pain, which may be caused by pressure placed on the liver capsule by the expanding mass or hemorrhagic necrosis of the tumor as it outstrips its blood supply. Hepatocellular adenomas occasionally rupture, an event that may lead to life-threatening intraabdominal bleeding.

Hepatic adenomas can be subclassified molecularly into tumors at low, intermediate, and high risk for malignant transformation. Sex hormone exposure (e.g., oral contraceptive pills, anabolic steroids) markedly increases the frequency of all types of hepatic adenoma, and cessation of exposure to sex hormones often—but not always—leads to tumor regression, clearly linking sex hormones to the growth and survival of tumor cells in some cases.

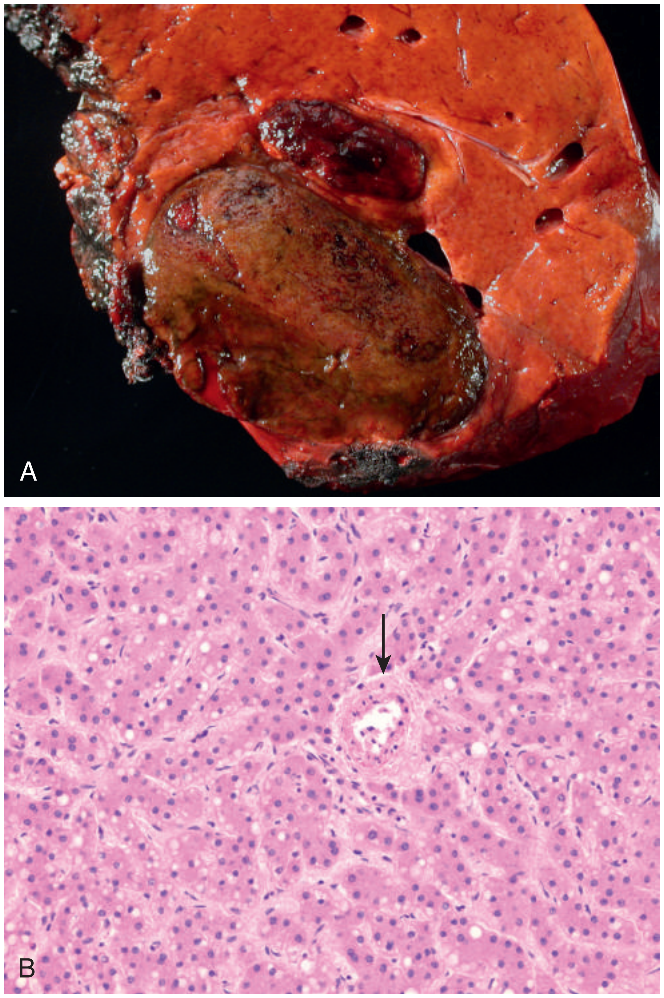

Fig. 16.35 Liver cell adenoma. (A) Resected specimen of the liver mass. (B) Microscopic view showing cords of hepatocytes, with an arterial vascular supply *(arrow)* and no portal tracts.

Malignant Neoplasms

Malignant tumors occurring in the liver can be primary or metastatic. The latter are far more common. Our discussion here is focused on primary hepatic tumors. Most primary liver cancers arise from hepatocytes and are termed *hepatocellular carcinoma (HCC)*. Much less common are cancers of bile duct origin, *cholangiocarcinomas*. Other types of primary liver cancers, such as *hepatoblastoma* (a childhood hepatocellular tumor) and *angiosarcoma,* are too rare to merit further discussion.

Hepatocellular Carcinoma (HCC)

Globally, HCC, also erroneously known as *hepatoma,* accounts for approximately 5.4% of all cancers, but its incidence varies widely in different parts of the world. More than 85% of cases occur in countries with high rates of chronic HBV infection. The incidence of HCC is highest in Asia (southeast China, Korea, Taiwan) and sub-Saharan Africa, areas in which HBV is transmitted vertically and, as already discussed, the carrier state starts in infancy. Moreover, many of these populations are exposed to aflatoxin, which when combined with HBV infection increases the risk for HCC dramatically. The peak incidence of HCC in these areas is between 20 and 40 years of age and, in almost 50% of cases, the tumor appears in the absence of cirrhosis.

In Western counties, the incidence of HCC is rapidly rising, largely owing to the increased prevalence of hepatitis C. The number of new HCC cases tripled in the United States in recent decades, but its incidence is still 8-fold to 30-fold lower than in some Asian countries. It is hoped that new, effective treatments for hepatitis C infection will stem the rising tide of HCC in the United States. In Western populations, HCC rarely manifests before 60 years of age, and in almost 90% of cases the malignancy emerges after cirrhosis becomes established. There is a pronounced male predominance throughout the world, about 3:1 in low-incidence areas and as high as 8:1 in high-incidence areas.

Pathogenesis

Chronic liver diseases are the most common setting for emergence of HCC. While usually identified in a background of cirrhosis, cirrhosis is not required for hepatocarcinogenesis. Rather, progression to cirrhosis and to hepatocellular cancer take place in parallel over many years to decades.

The most important underlying factors in hepatocarcinogenesis are viral infections (HBV, HCV) and toxic injuries (aflatoxin, alcohol). Thus, where HBV and HCV are endemic, there is a very high incidence of HCC. Coinfection further increases risk. *Aflatoxin* is a mycotoxin produced by *Aspergillus* species that contaminates staple food crops in Africa and Asia. Aflatoxin metabolites are present in the urine of individuals who consume these foods, as are aflatoxin-albumin adducts in serum. These biomarkers identify populations at risk and have helped to confirm the importance of aflatoxin in hepatocarcinogenesis. As discussed earlier, aflatoxin synergizes with HBV (and perhaps also with HCV) to increase risk further.

Other HCC risk factors all share the ability to cause chronic liver injury associated with varying degrees of inflammation. These factors include:

- *Alcohol consumption,* which synergistically increases risk with HBV, HCV, and possibly even cigarette smoking.
- *Inherited disorders,* particularly hereditary hemochromatosis and α_1AT deficiency, and to a lesser degree Wilson disease
- *Metabolic syndrome* and its attendant obesity, diabetes mellitus, and NAFLD, all of which increase the risk for HCC.

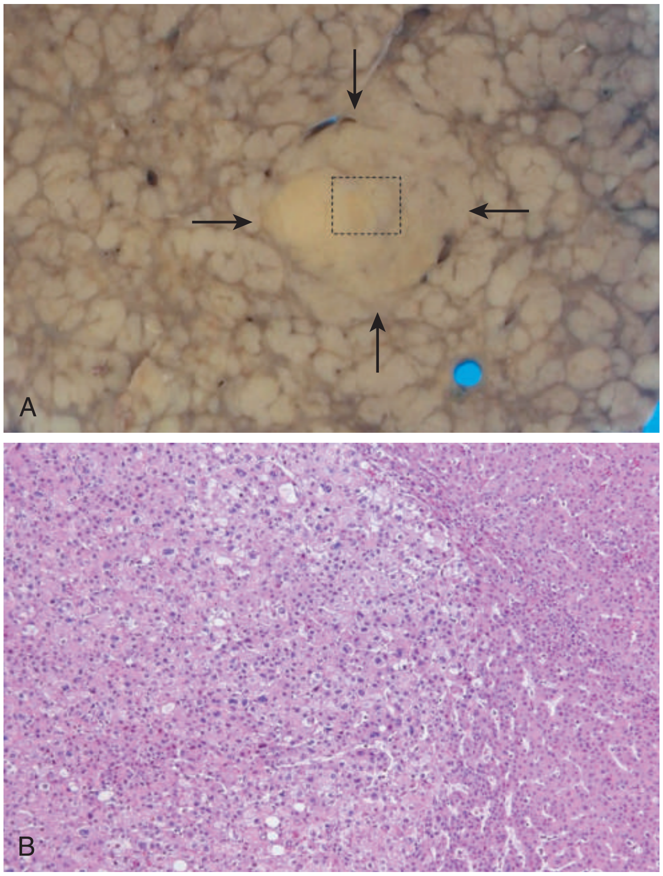

Fig. 16.36 (A) Hepatitis C–related cirrhosis with a distinctively large dysplastic nodule *(arrows)*. Nodule-in-nodule growth suggests an evolving cancer. (B) Histologically the region within the box in *A* shows a well-differentiated hepatocellular carcinoma *(right side)* and a subnodule of moderately differentiated hepatocellular carcinoma within it *(center, left)*. *(Courtesy of Dr. Masamichi Kojiro, Kurume University, Kurume, Japan.)*

As with all cancers, HCC is induced by acquired driver mutations in oncogenes and tumor suppressor genes. No single, universal sequence of molecular or genetic alterations leads to emergence of HCC. Gain of function mutations in beta-catenin and loss of function mutations in p53 are the two most common driver mutations. Beta-catenin mutations are identified in up to 40% of HCCs. These tumors are more likely to be unrelated to HBV and to demonstrate genomic instability. Inactivation of *TP53* is present in up to 60% of HCCs. These tumors are strongly associated with exposure to aflatoxin, which appears in many cases to be directly responsible for the causative *TP53* mutations.

HCC often appears to arise from premalignant precursors lesions. *Hepatic adenoma* has already been discussed, some of which carry beta-catenin–activating mutations. Chronic liver disease is associated with cellular dysplasias called *large-cell change* and *small-cell change*. These may be found at any stage of chronic liver disease, before or after development of cirrhosis, and serve to indicate which patients need more aggressive cancer surveillance. *Dysplastic nodules* are usually found in cirrhosis, either radiologically or in resected specimens (including explants). *Low-grade dysplastic nodules* may or may not undergo transformation to higher-grade lesions, but they indicate a higher risk for HCC. *High-grade dysplastic nodules* are probably the most important precursor of HCC in viral hepatitis and alcoholic liver disease. Overt HCC is often found in high-grade dysplastic nodules in biopsy or resection specimens.

MORPHOLOGY

HCC may appear grossly as (1) a unifocal (usually large) mass (Fig. 16.37); **(2) multifocal, widely distributed nodules of variable size; or (3) a diffusely infiltrative cancer,** permeating widely and sometimes involving the entire liver. Sometimes HCCs arise within dysplastic nodules (Fig. 16.37), eventually overgrowing these precursor lesions. Intrahepatic metastases by either vascular invasion or direct extension become more likely once tumors reach 3 cm in size. These metastases are usually small, satellite tumor nodules around a larger primary mass. Vascular invasion is also the most likely route for extrahepatic metastasis, especially by the hepatic venous system, usually only in advanced cases. Occasionally, long, snakelike masses of tumor invade the portal vein (causing portal hypertension) or inferior vena cava; in the latter instance, the tumor may extend all the way up into the right ventricle. Lymph node metastases are less common.

HCCs range from well differentiated to highly anaplastic lesions. Well-differentiated HCCs are composed of cells that look like normal hepatocytes and grow as thick trabeculae (recapitulating liver cell plates) or in pseudoglandular patterns that recapitulate poorly formed, ectatic bile canaliculi (see Fig. 16.37).

Clinical Features

The clinical manifestations of HCC are varied and in Western populations are often masked by symptoms related to underlying cirrhosis or chronic hepatitis. In areas of high incidence, such as tropical Africa where aflatoxin exposure is common, patients usually have no

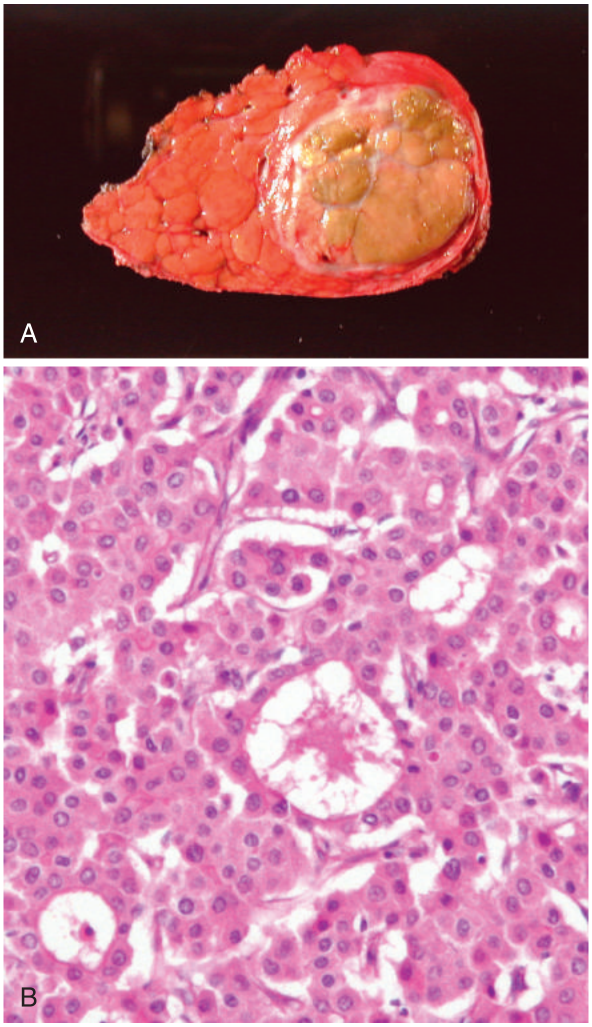

Fig. 16.37 Hepatocellular carcinoma. (A) Liver removed at autopsy showing a unifocal, massive neoplasm replacing most of the right hepatic lobe in a noncirrhotic liver. (B) Malignant hepatocytes growing in distorted versions of normal architecture: large pseudoacinar spaces, essentially malformed, dilated bile canaliculi, and thickened hepatocyte trabeculae.

clinical history of liver disease (although cirrhosis may be detected at autopsy). In both populations, most patients have ill-defined upper-abdominal pain, malaise, fatigue, weight loss, and sometimes awareness of an abdominal mass or abdominal fullness. Jaundice, fever, and gastrointestinal or esophageal variceal bleeding are inconstant findings.

Laboratory studies may provide clues but are rarely conclusive. Elevated serum levels of *α-fetoprotein* are found in 50% of individuals with advanced HCC, but this is neither a sensitive nor specific marker for premalignant or early well-differentiated cancers. Better tests for detection of small tumors are imaging studies, such as ultrasonography, computed tomography, and magnetic resonance imaging. Increasing arterialization during the development and progression of HCC can be identified by imaging and is so characteristic that its detection can be diagnostic, precluding the need for tissue biopsy.

The natural history of HCC involves the progressive enlargement of the primary mass until it disturbs hepatic function or metastasizes, most commonly to the lungs. Death usually occurs from (1) cachexia, (2) gastrointestinal or esophageal variceal bleeding, (3) liver failure with hepatic coma, or rarely (4) rupture of the tumor with fatal hemorrhage. The 5-year survival of large tumors is dismal, and the majority of patients die within 2 years of diagnosis.

With implementation of screening procedures and advances in imaging, the detection of HCCs less than 2 cm in diameter has increased in countries where such facilities are available. These small tumors can be removed surgically or ablated (e.g., through embolization, microwave radiation, or freezing) with good outcomes. If relatively small HCCs arise in the setting of advanced stage (cirrhotic) chronic liver disease, liver transplantation is a better option and may be curative. Radiofrequency ablation and chemoembolization are used for local control of unresectable tumors. The kinase inhibitor sorafenib can prolong the life of individuals with advanced-stage HCC.

Cholangiocarcinoma

Cholangiocarcinoma (CCA), the second most common primary malignant tumor of the liver after HCC, arises from intrahepatic and extrahepatic bile ducts. It accounts for 3% of gastrointestinal cancers in the United States, where there are approximately 2000 to 3000 new cases each year. However, in some regions of southeast Asia such as northeastern Thailand, Laos, and Cambodia where infestation with liver flukes is endemic, cholangiocarcinoma is much more common, occurring at rates 30 to 40 times higher than in areas of Asia without liver fluke infestation.

All risk factors for cholangiocarcinoma cause chronic inflammation and cholestasis, which presumably promote occurrence of somatic mutations or epigenetic alterations in cholangiocytes. The risk factors include infestation by liver flukes (particularly *Opisthorchis* and *Clonorchis* species), chronic inflammatory disease of the large bile ducts (such as primary sclerosing cholangitis), hepatolithiasis, and fibropolycystic liver disease. As with HCC, rates of cholangiocarcinoma also are elevated in patients with hepatitis B and C and NAFLD.

MORPHOLOGY

Extrahepatic cholangiocarcinomas are generally small lesions at the time of diagnosis, as they cause obstruction of the biliary tract early in their course. Most tumors appear as firm, gray nodules within the bile duct wall; some may be diffusely infiltrative, while others are papillary or polypoid. **Intrahepatic cholangiocarcinomas** occur in noncirrhotic livers (Fig. 16.38A) and may track along the intrahepatic portal tract system or produce a single massive tumor.

Cholangiocarcinomas are typical mucin-producing adenocarcinomas. Most are well to moderately differentiated, growing as glandular/tubular structures lined by malignant epithelial cells (see Fig. 16.38B). They typically incite marked desmoplasia. Lymphovascular invasion and perineural invasion are both common and often lead to extensive intrahepatic and extrahepatic metastases.

Tsui, Caritas Medical Centre, Hong Kong.)*

SUMMARY

LIVER TUMORS

- The liver is the most common site of metastatic cancers from primary tumors of the colon, lung, and breast.
- **Hepatocellular adenomas** are benign tumors of hepatocytes. Most can be subclassified on the basis of molecular changes with varying degrees of malignant potential. They are associated with use of oral contraceptives and androgens.
- The two main types of malignant tumors are **hepatocellular carcinomas and cholangiocarcinomas**; HCCs are much more common.
  - HCC is a common tumor in regions of Asia and Africa, and its incidence is increasing in the United States.
  - The main etiologic agents for HCC are hepatitis B and C, alcoholic cirrhosis, hemochromatosis, and exposure to aflatoxins. In the Western population, about 90% of HCCs develop in cirrhotic livers; in Asia, almost 50% of cases develop in noncirrhotic livers.
  - The chronic inflammation and cellular regeneration associated with viral hepatitis are predisposing factors for the development of carcinomas.
  - HCC may be unifocal or multifocal, tends to invade blood vessels, and recapitulates normal liver architecture to varying degrees.
  - Cholangiocarcinoma is a tumor of intrahepatic or extrahepatic bile ducts that is relatively common in areas where liver flukes, such as *Opisthorchis* and *Clonorchis* species, are endemic.

Gallbladder

GALLSTONE DISEASE

Gallstones afflict 10% to 20% of adults residing in Western countries in the Northern Hemisphere, 20% to 40% in Latin American countries, and only 3% to 4% in Asian countries. In the United States, about 1 million new cases of gallstones are diagnosed annually, and two-thirds of individuals so affected undergo surgery, resulting in the removal of as much as 25 to 50 million tons of stones per year! There are two main types of gallstones: *cholesterol stones,* containing crystalline cholesterol monohydrate (80% of stones in Western countries), and *pigment stones,* made of bilirubin calcium salts.

Pathogenesis

Bile formation is the only significant pathway for elimination of excess cholesterol from the body, either as free cholesterol or as bile salts. Cholesterol is rendered water-soluble by aggregation with bile salts and lecithins. When cholesterol concentrations exceed the solubilizing capacity of bile (supersaturation), cholesterol can no longer remain dispersed and crystallizes out of solution. Cholesterol gallstone formation is enhanced by *hypomobility of the gallbladder* (stasis), which promotes nucleation, and by *mucus hypersecretion,* with consequent trapping of the crystals, thereby enhancing their aggregation into stones.

Pigment stones form when the bile contains a high concentration of unconjugated bilirubin in the biliary tree, as may occur in patients with chronic extravascular red cell hemolysis or with certain infections of the biliary tract, such as liver flukes. The precipitates are primarily insoluble calcium bilirubinate salts.

Prevalence and Risk Factors

The major risk factors for gallstones are listed in Table 16.6. In up to 80% of individuals with gallstones, the only identifiable risk factors are age and gender. Some elaboration on these risk factors follows:

- *Age and gender.* The prevalence of gallstones increases throughout life. In the United States, less than 5% to 6% of the population younger than 40 years of age has stones, in contrast with 25% to 30% of those older than

Table 16.6 Risk Factors for Gallstones

Cholesterol Stones
Demography: Northern Europeans, North and South Americans, Native Americans, Mexican Americans
Advancing age
Female sex hormones
Female gender
Oral contraceptives
Pregnancy
Obesity and insulin resistance
Rapid weight reduction
Gallbladder stasis
Inborn disorders of bile acid metabolism
Dyslipidemia syndromes
Pigment Stones
Demography: Asian more than Western, rural more than urban
Chronic hemolysis (e.g., sickle cell anemia, hereditary spherocytosis)
Biliary infection
Gastrointestinal disorders: ileal disease (e.g., Crohn disease), ileal resection or bypass, cystic fibrosis with pancreatic insufficiency

80 years of age. The prevalence in women of all ages is about twice as high as in men.

- *Ethnic and geographic.* Cholesterol gallstone prevalence approaches 50% to 75% in certain Native American populations (Pima, Hopi, and Navajo), whereas pigment stones are rare. The high prevalence in these populations seems to be related to biliary cholesterol hypersecretion.
- *Heredity.* In addition to ethnicity, a positive family history imparts increased risk, as do a variety of inborn errors of metabolism, such as those associated with impaired bile salt synthesis and secretion.
- *Environment.* Estrogens increase hepatic cholesterol uptake and synthesis, leading to excess biliary secretion of cholesterol. These effects explain the increased risk for gallstone disease with oral contraceptive use and with pregnancy. Obesity, rapid weight loss, and treatment with the hypocholesterolemic agent clofibrate also are strongly associated with increased biliary cholesterol secretion and risk for gallstone disease.
- *Acquired disorders.* Any condition in which gallbladder motility is reduced predisposes to gallstones, such as pregnancy, rapid weight loss, and spinal cord injury. In most cases, however, gallbladder hypomotility is present without obvious cause.

MORPHOLOGY

Cholesterol stones arise exclusively in the gallbladder and consist of 50% to 100% cholesterol. Pure cholesterol stones are pale yellow; increasing proportions of calcium carbonate, phosphates, and bilirubin impart gray-white to black discoloration (Fig. 16.39). They are ovoid and firm; they can occur singly, but most often there are several, with faceted surfaces resulting from their apposition. Most cholesterol stones are radiolucent, although as many as 20% may contain sufficient calcium carbonate to be radiopaque.

Pigment stones may arise anywhere in the biliary tree and are classified into black and brown stones. In general, black pigment stones are found in sterile gallbladder bile, while brown stones are found in infected intrahepatic or extrahepatic ducts. The stones contain calcium salts of unconjugated bilirubin and lesser amounts of other calcium salts, mucin glycoproteins, and cholesterol. Black stones are usually small, numerous, and fragile to the touch (Fig. 16.40). Brown stones tend to be single or few in number and to have a soft, greasy, soaplike consistency owing to the presence of fatty acid salts released from biliary lecithins by bacterial phospholipases. Because of calcium carbonates and phosphates, 50% to 75% of black stones are radiopaque. Brown stones, which contain calcium soaps, are radiolucent.

Fig. 16.39 Cholesterol gallstones. The wall of the gallbladder is thickened and fibrotic due to chronic cholecystitis.

Clinical Features

Gallstones may be present for decades without causing any symptoms, and 70% to 80% of individuals with gallstones remain asymptomatic throughout life. In an unfortunate minority, however, the symptoms are striking. There is usually right upper-quadrant or epigastric pain, often excruciating, which may be constant or, less

Fig. 16.40 Pigment gallstones. Several faceted black gallstones are present in this otherwise unremarkable gallbladder from a patient with a mechanical mitral valve prosthesis, leading to chronic intravascular hemolysis.

commonly, spasmodic. Such "biliary" pain is caused by gallbladder or biliary tree obstruction or by inflammation of the gallbladder itself. More severe complications include empyema, perforation, fistulas, inflammation of the biliary tree, obstructive cholestasis and pancreatitis. The larger the stone, the less likely it is to enter the cystic or common ducts to produce obstruction; thus, the very small stones, or "gravel," are dangerous. Occasionally a large stone may erode directly into an adjacent loop of small bowel, generating intestinal obstruction *(gallstone ileus).*

CHOLECYSTITIS

Inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic, and almost always occurs in association with gallstones. In the United States, cholecystitis is one of the most common indications for abdominal surgery. Its epidemiologic distribution closely parallels that of gallstones.

Acute Calculous Cholecystitis

Acute inflammation of a gallbladder that contains stones is termed *acute calculous cholecystitis* and is precipitated in 90% of cases by obstruction of the gallbladder neck or cystic duct. It is the most common major complication of gallstones and the most frequent indication for emergency cholecystectomy. Manifestations of obstruction may appear with remarkable suddenness and constitute a surgical emergency. In some cases, however, symptoms may be mild and resolve without intervention.

Acute calculous cholecystitis initially results from chemical irritation and inflammation of the gallbladder wall due to obstruction of bile outflow. Gallbladder injury in the setting of bile obstruction stems from several sources, including: phospholipases derived from the mucosa hydrolyze biliary lecithin to lysolecithin, which is toxic to the mucosa; the normally protective glycoprotein mucous layer is disrupted, exposing the mucosal epithelium to the detergent action of bile salts.; prostaglandins released within the wall of the distended gallbladder enhance mucosal and mural inflammation; and distention and increased intraluminal pressure may compromise blood flow to the mucosa. All of these effects occur in the absence of bacterial infection, which may be superimposed later.

Acute Acalculous Cholecystitis

Between 5% and 12% of gallbladders removed for acute cholecystitis contain no gallstones. Most cases occur in seriously ill patients. Some of the most common predisposing insults are as follows:

- Major surgery
- Severe trauma (e.g., from motor vehicle crashes)
- Severe burns
- Sepsis

Other contributing factors include dehydration, gallbladder stasis and sludging, vascular compromise, and bacterial contamination.

Chronic Cholecystitis

Chronic cholecystitis may be the sequel to repeated bouts of acute cholecystitis, but in most instances it develops without any antecedent history of acute attacks. Like acute cholecystitis, it is almost always associated with gallstones. However, gallstones do not seem to be an essential part of the initiation of inflammation or the development of pain, because chronic acalculous cholecystitis causes symptoms and morphologic alterations similar to those seen in the calculous form. Rather, supersaturation of bile appears to predispose to both chronic inflammation and, in most instances, stone formation. Microorganisms, usually *E. coli* and enterococci, can be cultured from the bile in only about one-third of cases. Unlike acute calculous cholecystitis, obstruction of gallbladder outflow by stones is not requisite in chronic cholecystitis. Most gallbladders removed at elective surgery for gallstones show features of chronic cholecystitis, making it likely that biliary symptoms emerge after long-term coexistence of gallstones and low-grade inflammation.

MORPHOLOGY

In **acute cholecystitis,** the gallbladder usually is enlarged and tense, and has a bright red or blotchy, violaceous color, the latter imparted by subserosal hemorrhages. The serosa frequently is covered by a fibrinous or, in severe cases, a fibrinopurulent exudate. In 90% of cases, stones are present, often obstructing the neck of the gallbladder or the cystic duct. The gallbladder lumen is filled with cloudy or turbid bile that may contain fibrin, blood, and pus. When the contained exudate is mostly pus, the condition is referred to as ***empyema of the gallbladder.*** In mild cases, the gallbladder wall is thickened, edematous, and hyperemic. In more severe cases, the gallbladder wall is green-black and necrotic—a condition termed ***gangrenous cholecystitis.*** On histologic examination, the inflammatory reactions are not distinctive and consist of some combination of the usual patterns of acute inflammation (i.e., edema, leukocytic infiltration, vascular congestion, abscess formation, gangrenous necrosis).

The morphologic changes in **chronic cholecystitis** are extremely variable and sometimes subtle. The mere presence of stones within the gallbladder, even in the absence of acute inflammation, often is taken as sufficient justification for a diagnosis. The gallbladder may be contracted, of normal size, or enlarged. Mucosal ulcerations are infrequent; the submucosa and subserosa often are thickened from fibrosis. In the absence of superimposed acute cholecystitis, collections of lymphocytes in the wall are the only sign of inflammation (Fig. 16.41A). Outpouchings of mucosal epithelium through the wall of the gallbladder (Rokitansky-Aschoff sinuses) may be quite prominent (see Fig. 16.41B).

Clinical Features

Acute calculous cholecystitis presents with biliary pain that lasts for more than 6 hours. The pain is severe, usually steady, upper abdominal in location, and often radiates to the right shoulder. Fever, nausea, leukocytosis, and prostration are classic; the presence of conjugated hyperbilirubinemia suggests obstruction of the common bile duct. The right subcostal region is markedly tender and rigid as a result of spasm of the abdominal muscles; occasionally a

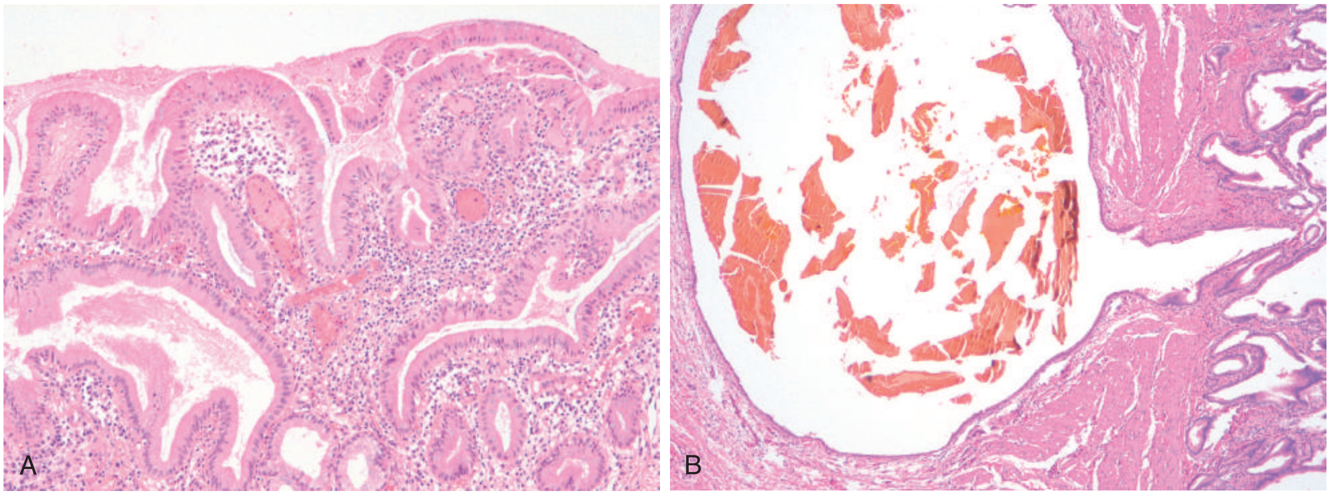

Fig. 16.41 Chronic cholecystitis. (A) The gallbladder mucosa is infiltrated by chronic inflammatory cells. (B) A Rokitansky-Aschoff sinus containing a fragmented bile pigment stone.

tender, distended gallbladder can be palpated. Mild attacks usually subside spontaneously over 1 to 10 days; however, recurrence is common. Approximately 25% of symptomatic patients are sufficiently ill to require surgical intervention.

The diagnosis of acute cholecystitis usually is based on the detection of gallstones by ultrasonography, typically accompanied by evidence of a thickened gallbladder wall. Attention to this disorder is important because of the potential for the following serious complications:

- Bacterial superinfection leading to cholangitis or sepsis
- Gallbladder perforation and local abscess formation
- Gallbladder rupture leading to diffuse peritonitis
- Biliary enteric (cholecystenteric) fistula, with drainage of bile into adjacent organs, entry of air and bacteria into the biliary tree, and potentially gallstone-induced intestinal obstruction (ileus)
- Aggravation of preexisting medical illness, with cardiac, pulmonary, renal, or liver decompensation

Symptoms arising from *acute acalculous cholecystitis* usually are obscured by another serious medical or surgical condition, which sets the stage for the development of cholecystitis. The diagnosis therefore rests on a high index of suspicion. *Chronic cholecystitis* lacks the striking manifestations of the acute forms and is usually characterized by recurrent attacks of steady epigastric or right upper-quadrant pain. Nausea, vomiting, and intolerance for fatty foods are frequent accompaniments. Chronic cholecystitis is a pathologic diagnosis based on the examination of the resected gallbladder. Beyond signs and symptoms mentioned above, its principal importance may lie in the association of gallstones and chronic inflammation with carcinoma of the gallbladder (discussed next).

CARCINOMA OF THE GALLBLADDER

Carcinoma of the gallbladder is the most common malignancy of the extrahepatic biliary tract. It is slightly more common in women and occurs most frequently in the seventh decade of life. The incidence in the United States is 1 in 50,000. Only rarely is it discovered at a resectable stage, and the mean 5-year survival rate has remained unchanged at about 5% to 12% over the past many years. The most important risk factor associated with gallbladder carcinoma is gallstones (cholelithiasis), which are present in 95% of cases. Presumably, gallbladders containing stones or infectious agents develop cancer as a result of chronic inflammation, a known enabler of malignancy in several organs (Chapter 6). Carcinogenic derivatives of bile acids also are suspected to play a role. Primary sclerosing cholangitis is also a risk factor.

MORPHOLOGY

Carcinomas of the gallbladder show two patterns of growth: **infiltrating** and **exophytic.** The infiltrating pattern is more common and usually appears as a poorly defined area of diffuse wall thickening and induration. The exophytic pattern grows into the lumen as an irregular, cauliflower mass, but at the same time invades the underlying wall (Fig. 16.42). Most carcinomas of the gallbladder are adenocarcinomas. About 5% are squamous cell carcinomas or have adenosquamous differentiation.

Clinical Features

Preoperative diagnosis of carcinoma of the gallbladder is the exception rather than the rule, occurring in fewer than 20% of patients. Presenting symptoms are insidious and typically indistinguishable from those associated with cholelithiasis: abdominal pain, jaundice, anorexia, nausea and vomiting. There is no satisfactory treatment of gall bladder cancer due to the advanced stage at the time of diagnosis. Only 10% are diagnosed at a stage that is early enough to attempt curative surgery.

SUMMARY

GALLBLADDER DISEASES

- Gallbladder diseases include cholelithiasis and acute and chronic cholecystitis, and gall bladder cancer.

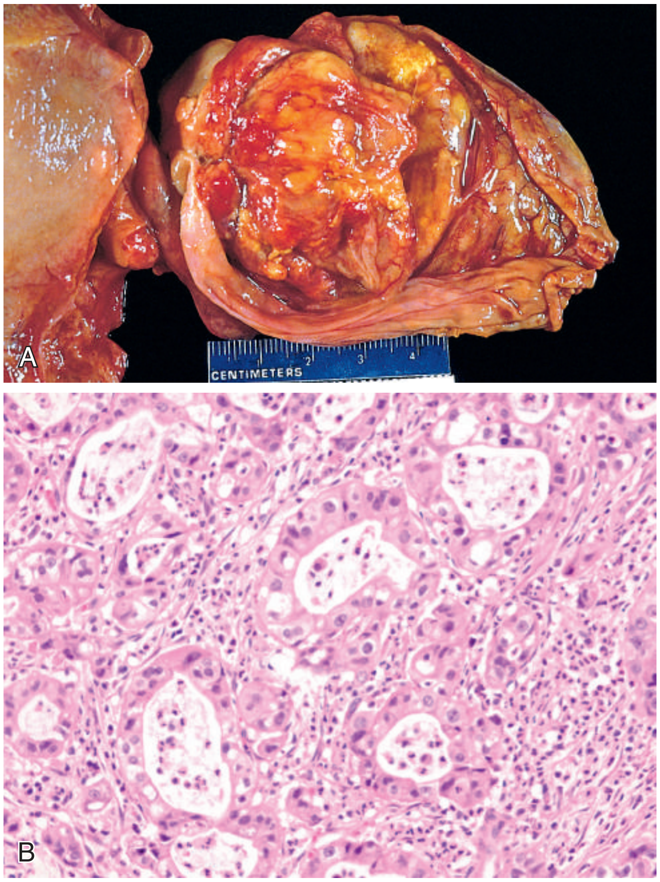

Fig. 16.42 Gallbladder adenocarcinoma. (A) The opened gallbladder contains a large, exophytic tumor that virtually fills the lumen. (B) Microscopically, the tumor has the same appearance as that of intrahepatic cholangiocarcinoma.

- Gallstone formation is a common condition in Western countries. The great majority of the gallstones are cholesterol stones. Pigmented stones containing bilirubin and calcium are most common in Asian countries, due to the higher incidence of chronic hemolytic disorders and liver fluke infestations in these locales.
- Risk factors for the development of cholesterol stones are advancing age, female gender, estrogen use, obesity, and heredity.
- Cholecystitis almost always occurs in association with cholelithiasis, although in about 10% of cases it occurs in the absence of gallstones.
- Acute calculous cholecystitis is the most common reason for emergency cholecystectomy.
- Gall bladder cancer is almost always associated with gall stones. Because of the advanced stage at diagnosis, it has a very poor prognosis.

CHAPTER 17

Pancreas

CHAPTER OUTLINE

The pancreas is a transversely oriented retroperitoneal organ extending from the so-called "C loop" of the duodenum to the hilum of the spleen. Although the pancreas does not have well-defined anatomic subdivisions, adjacent vessels and ligaments serve to demarcate the organ into a head, body, and tail.

The pancreas is really two organs packaged into one. The islets of Langerhans scattered in the pancreas serve critical endocrine functions, and the exocrine portion that makes up the bulk of this organ is a major source of enzymes that are essential for digestion. Diseases affecting the pancreas can be the source of significant morbidity and mortality. Unfortunately, the retroperitoneal location of the pancreas and the generally vague nature of signs and symptoms associated with its injury or with dysfunction of the exocrine portion allow many pancreatic diseases to progress undiagnosed for extended periods of time; thus, recognition of pancreatic disorders requires a high degree of suspicion.

The pancreas gets its name from the Greek *pankreas,* meaning "all flesh," and is a complex lobulated organ. The endocrine portion constitutes only 1% to 2% of the pancreas and is composed of about 1 million cell clusters, the islets of Langerhans; these cells secrete insulin, glucagon, and somatostatin. The most significant disorders of the *endocrine pancreas* are diabetes mellitus and neoplasms; these are discussed in detail in Chapter 20 and are not discussed further here.

The *exocrine pancreas* is composed of *acinar cells* and the ductules and ducts that convey their secretions to the duodenum. The acinar cells are responsible for the synthesis of digestive enzymes, which are mostly made as inactive pro-enzymes that are stored in *zymogen granules.* When acinar cells are stimulated to secrete, the granules fuse with the apical plasma membrane and release their contents into the central acinar lumen. These secretions are transported to the duodenum through a series of anastomosing ducts.

The epithelial cells lining the ducts also are active participants in pancreatic secretion: The cuboidal cells that line the smaller ductules secrete bicarbonate-rich fluid, while the columnar cells lining the larger ducts produce mucin. The epithelial cells of the ducts also express the *cystic fibrosis transmembrane conductance regulator (CFTR);* aberrant function of this membrane protein affects the biochemical content and viscosity of pancreatic secretions. CFTR has a fundamental role in the pathophysiology of pancreatic disease in individuals with cystic fibrosis (Chapter 7).

As discussed later, autodigestion of the pancreas (e.g., in pancreatitis) can be a catastrophic event. A number of "fail-safe" mechanisms have evolved to minimize the risk for occurrence of this phenomenon:

- A majority of pancreatic enzymes are synthesized as inactive pro-enzymes and sequestered in membrane-bound zymogen granules, as mentioned earlier.
- Activation of pro-enzymes requires conversion of trypsinogen to trypsin by duodenal enteropeptidase (also called *enterokinase*).
- Trypsin inhibitors (e.g., SPINK1, also known as *pancreatic secretory trypsin inhibitor*) also are secreted by acinar and ductal cells.
- Trypsin cleaves and inactivates itself, a negative feedback mechanism that normally puts a limit on local levels of activated trypsin.
- Acinar cells are remarkably resistant to the action of activated enzymes such as trypsin, chymotrypsin, and phospholipase A_2.

Diseases of the exocrine pancreas include cystic fibrosis, congenital anomalies, acute and chronic pancreatitis, and

The contributions of those who authored this chapter in previous editions of this book are gratefully acknowledged.

neoplasms. Cystic fibrosis is discussed in detail in Chapter 7; the other pathologic processes are discussed in this chapter.

CONGENITAL ANOMALIES

Pancreatic development is a complex process involving fusion of dorsal and ventral primordia; subtle deviations in this process frequently give rise to congenital variations in pancreatic anatomy. While most of these do not cause clinical disease, variants (especially in ductal anatomy) can present challenges to the endoscopist and the surgeon. For example, failure to recognize idiosyncratic anatomy could result in inadvertent severing of a pancreatic duct during surgery, resulting in pancreatitis.

Agenesis

Very rarely, the pancreas may be totally absent, a condition usually (but not invariably) associated with additional severe malformations that are incompatible with life. *Pancreatic duodenal homeobox 1* (*PDX1*) is a homeodomain transcription factor critical for normal pancreatic development, and germline mutations of this gene have been associated with pancreatic agenesis.

Pancreas Divisum

Pancreas divisum is the most common congenital anomaly of the pancreas, with an incidence of 3% to 10%. In most individuals, the main pancreatic duct (the duct of Wirsung) joins the common bile duct just proximal to the papilla of Vater, and the accessory pancreatic duct (the duct of Santorini) drains into the duodenum through a separate minor papilla. Pancreas divisum is caused by a failure of fusion of the fetal duct systems of the dorsal and ventral pancreatic primordia. As a result, the bulk of the pancreas (formed by the dorsal pancreatic primordium) drains into the duodenum through the small-caliber minor papilla. The duct of Wirsung in individuals with divisum drains only a small portion of the head of the gland through the papilla of Vater. More than 95% of individuals are asymptomatic. The remaining 5% develop acute or chronic pancreatitis, possibly related to inadequate drainage of pancreatic secretions through the minor papilla.

Annular Pancreas

Annular pancreas is a relatively uncommon variant of pancreatic fusion in which a ring of pancreatic tissue completely encircles the duodenum. It can manifest with signs and symptoms of duodenal obstruction such as gastric distention and vomiting.

Ectopic Pancreas

Aberrantly situated, or *ectopic,* pancreatic tissue occurs in about 2% of the population; favored sites are the stomach and duodenum, followed by the jejunum, Meckel diverticulum, and ileum. These embryologic rests typically are small (ranging from millimeters to centimeters in diameter) and are located in the submucosa; they are composed of normal pancreatic acini with occasional islets. Though usually incidental and asymptomatic, ectopic pancreas may become inflamed, leading to pain, or—rarely—can cause mucosal bleeding. Approximately 2% of pancreatic neuroendocrine tumors (Chapter 20) arise in ectopic pancreatic tissue.

Congenital Cysts

Congenital cysts result from anomalous development of the pancreatic ducts. In *polycystic disease,* the kidneys, liver, and pancreas may all contain cysts (Chapter 14). Congenital cysts generally are unilocular and range from microscopic to 5 cm in diameter. They are lined by either uniform cuboidal or flattened epithelium and are enclosed in a thin, fibrous capsule. These benign cysts contain clear *serous* fluid—an important point of distinction from pancreatic cystic neoplasms, which often are *mucinous* (discussed later).

PANCREATITIS

Inflammatory disorders of the pancreas are divided into acute and chronic forms. In *acute pancreatitis,* function can return to normal if the underlying cause of inflammation is removed. By contrast, *chronic pancreatitis* causes irreversible destruction of exocrine pancreas.

Acute Pancreatitis

Acute pancreatitis is a reversible inflammatory disorder that varies in severity, from focal edema and fat necrosis to widespread hemorrhagic necrosis. This is a relatively common condition, with an annual incidence of 10 to 20 per 100,000 people in the Western world.

Etiology

The most common cause of acute pancreatitis in the United States is the impaction of gallstones within the common bile duct, impeding the flow of pancreatic enzymes through the ampulla of Vater ("gallstone pancreatitis"); this is closely followed by pancreatitis secondary to excessive alcohol intake. *Overall, gallstones and alcoholism account for greater than 80% of acute pancreatitis cases,* with the remaining caused by a multitude of factors (Table 17.1). These include the following:

- *Non–gallstone-related obstruction* of the pancreatic ducts (e.g., due to pancreatic cancer or other periampullary neoplasms, pancreas divisum, biliary "sludge," or parasites, particularly *Ascaris lumbricoides* and *Clonorchis sinensis*)
- *Medications* including anti-convulsants, cancer chemotherapeutic agents, thiazide diuretics, estrogens, and more than 85 others in clinical use
- *Infections* with mumps virus or coxsackievirus, which can directly infect pancreatic exocrine cells
- *Metabolic disorders,* including hypertriglyceridemia, hyperparathyroidism, and other hypercalcemic states

*Most common causes in the United States.

- *Ischemia* due to vascular thrombosis, embolism, vasculitis, or shock
- *Trauma,* both blunt force and iatrogenic during surgery or endoscopy
- *Germline mutations* involving genes encoding pancreatic enzymes or their inhibitors. For example, *hereditary pancreatitis* is a rare autosomal dominant disease with 80% penetrance that is characterized by recurrent attacks of severe pancreatitis, usually beginning in childhood. It is caused by mutations in the *PRSS1* gene, which encodes trypsinogen, the proenzyme of pancreatic trypsin. The pathogenic mutations alter the site through which trypsin cleaves and inactivates itself, abrogating an important negative feedback mechanism. This defect leads not only to the hyperactivation of trypsin, but also to the hyperactivation of many other digestive enzymes that require trypsin cleavage for their activation. As a result of this unbridled protease activity, the pancreas is prone to autodigestion and injury. Loss-of-function mutations in genes that encode protease inhibitors such as *SPINK1* are less commonly associated with hereditary pancreatitis.

Of note, 10% to 20% of cases of acute pancreatitis have no identifiable cause *(idiopathic pancreatitis),* although a growing body of evidence suggests that many may have an underlying genetic basis. For example, a subset of these so-called *idiopathic pancreatitis* patients has underlying germ line mutations of the *CFTR* gene with symptoms predominantly restricted to the pancreas (Chapter 7).

Pathogenesis

Acute pancreatitis appears to be caused by autodigestion of the pancreas by inappropriately activated pancreatic enzymes. As discussed earlier, once activated trypsin is capable of converting other zymogen forms of pancreatic enzymes to their active forms. Premature activation of trypsin within the substance of the pancreas can unleash these proenzymes (e.g., phospholipases and elastases), leading to tissue injury and inflammation. Trypsin also converts prekallikrein to its activated form, thus sparking the kinin system, and, by activation of factor XII (Hageman factor), also sets in motion the clotting and complement systems (Chapter 4). Three pathways can incite the initial enzyme activation that may lead to acute pancreatitis (Fig. 17.1):

- *Pancreatic duct obstruction.* Impaction of a gallstone or biliary sludge, or extrinsic compression of the ductal system by a mass blocks ductal flow, increases intraductal pressure, and allows accumulation of an enzyme-rich interstitial fluid. Since lipase is secreted in an active form, local fat necrosis may result. Injured tissues, periacinar myofibroblasts, and leukocytes then release pro-inflammatory cytokines that promote local inflammation and interstitial edema through a leaky microvasculature. Edema further compromises local blood flow, causing vascular insufficiency and ischemic injury to acinar cells.
- *Primary acinar cell injury.* This pathogenic mechanism comes into play in acute pancreatitis caused by ischemia, viral infections (e.g., mumps), drugs, and direct trauma to the pancreas.
- *Defective intracellular transport of proenzymes within acinar cells.* In normal acinar cells, digestive enzymes intended for zymogen granules (and eventually extracellular release) and hydrolytic enzymes destined for lysosomes are transported in discrete pathways after synthesis in the endoplasmic reticulum. However, at least in some animal models of metabolic injury, pancreatic proenzymes and lysosomal hydrolases become packaged together. This results in proenzyme activation, lysosomal rupture (action of phospholipases), and local release of activated enzymes. The role of this mechanism in human acute pancreatitis is not clear.

Alcohol consumption may cause pancreatitis by several mechanisms. Alcohol transiently increases pancreatic exocrine secretion and contraction of the sphincter of Oddi (the muscle regulating the flow of pancreatic juice through papilla of Vater). Alcohol also has direct toxic effects on acinar cells, including induction of oxidative stress in acinar cells, which leads to membrane damage (discussed later). Finally, chronic alcohol ingestion results in the secretion of protein-rich pancreatic fluid, which leads to the deposition of inspissated protein plugs and obstruction of small pancreatic ducts.

MORPHOLOGY

The basic alterations in acute pancreatitis are **(1) microvascular leakage causing edema, (2) necrosis of fat by lipases, (3) an acute inflammatory reaction, (4) proteolytic destruction of pancreatic parenchyma, and (5) destruction of blood vessels leading to interstitial hemorrhage.**

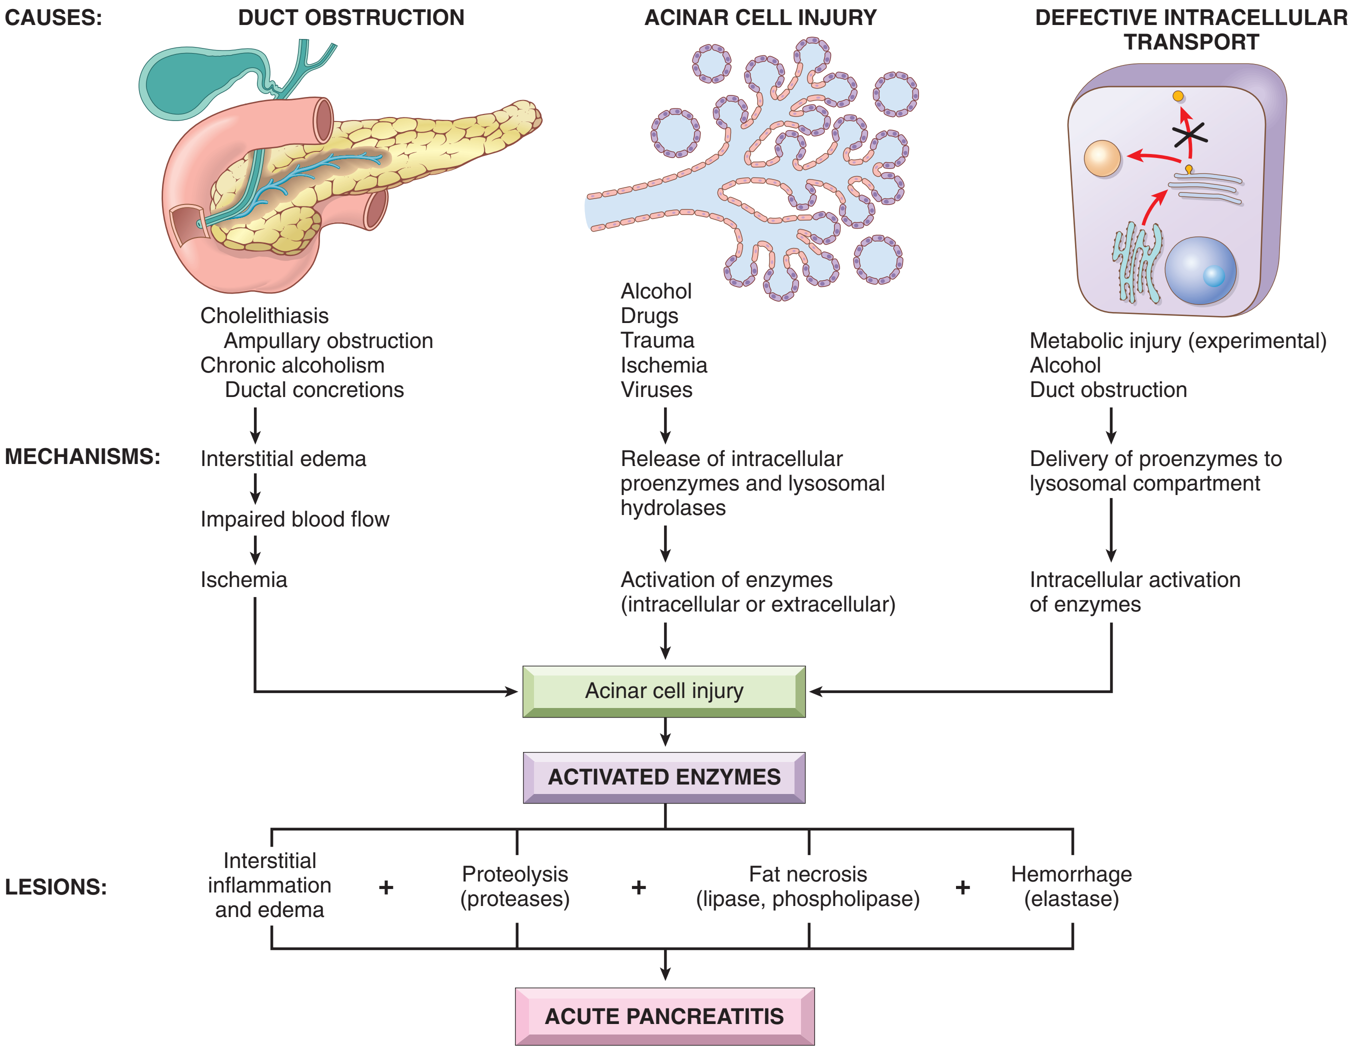

Fig. 17.1 Proposed pathogenesis of acute pancreatitis.

In mild forms, there is interstitial edema and focal areas of fat necrosis in the pancreas and peripancreatic fat (Fig. 17.2A). Fat necrosis results from enzymatic destruction of fat cells; the released fatty acids combine with calcium to form insoluble salts that precipitate in situ.

In more severe forms, such as **acute necrotizing pancreatitis,** the damage also involves acinar and ductal cells, the islets of Langerhans, and blood vessels. Macroscopically, the pancreas exhibits red-black hemorrhagic areas interspersed with foci of yellow-white, chalky **fat necrosis** (Fig. 17.2B). Fat necrosis also can occur in extrapancreatic fat, including the omentum and bowel mesentery, and even outside the abdominal cavity (e.g., in subcutaneous fat). In most cases, the peritoneum contains a serous, slightly turbid, brown-tinged fluid with globules of fat (derived from enzymatically digested adipose tissue). In the most severe form, **hemorrhagic pancreatitis,** extensive parenchymal necrosis is accompanied by diffuse hemorrhage within the substance of the gland.

Clinical Features

Abdominal pain is the cardinal manifestation of acute pancreatitis. Its severity varies from mild and uncomfortable to severe and incapacitating. Acute pancreatitis is diagnosed primarily by the presence of elevated plasma levels of amylase and lipase and the exclusion of other causes of abdominal pain. In 80% of cases, acute pancreatitis is mild and self-limiting; the remaining 20% develop severe disease.

Full-blown acute pancreatitis is a medical emergency of the first order. Affected individuals usually experience the sudden calamitous onset of an "acute abdomen" with pain, guarding, and the ominous absence of bowel sounds. Characteristically, the pain is constant, intense and referred to the upper back; it must be differentiated from pain of other causes such as perforated peptic ulcer, biliary colic, acute cholecystitis with rupture, and occlusion of mesenteric vessels with infarction of the bowel.

The manifestations of severe acute pancreatitis are attributable to systemic release of digestive enzymes and

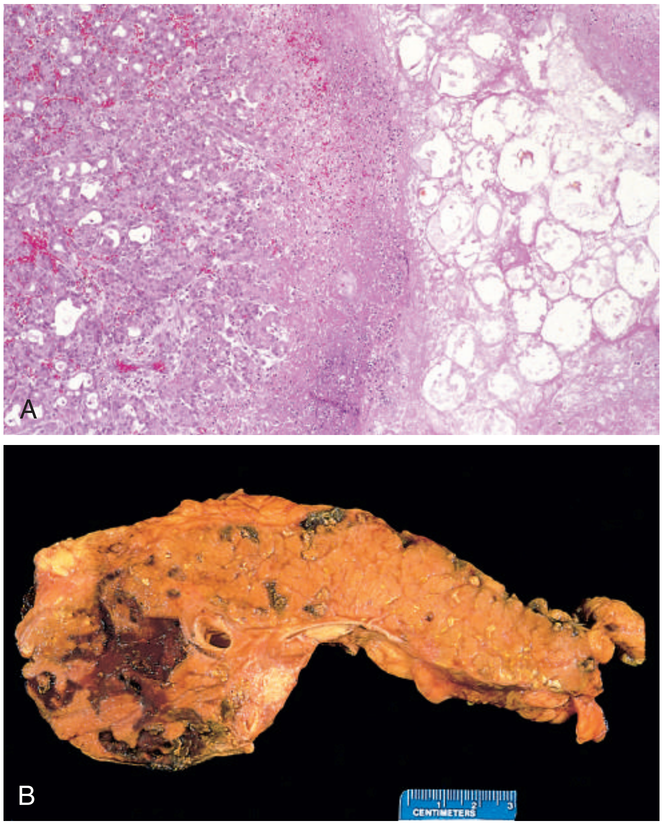

Fig. 17.2 Acute pancreatitis. (A) The microscopic field shows a region of fat necrosis *(right)* and focal pancreatic parenchymal necrosis *(center)*. (B) The pancreas has been sectioned longitudinally to reveal dark areas of hemorrhage in the pancreatic substance and a focal area of pale fat necrosis in the peripancreatic fat *(upper left)*.

explosive activation of the inflammatory response. The initial clinical evaluation may reveal leukocytosis, disseminated intravascular coagulation (Chapter 12), acute respiratory distress syndrome (due to diffuse alveolar damage) (Chapter 13), and diffuse fat necrosis. Peripheral vascular collapse (shock) can rapidly ensue as a result of increased microvascular permeability and resultant hypovolemia, compounded by endotoxemia (from breakdown of the barriers between gastrointestinal flora and the bloodstream), and renal failure due to acute tubular necrosis (Chapter 14).

Laboratory findings include markedly elevated serum amylase during the first 24 hours, followed (within 72–96 hours) by rising serum lipase levels. Hypocalcemia can result from precipitation of calcium in areas of fat necrosis; if persistent, it is a poor prognostic sign. The enlarged inflamed pancreas can be visualized by computed tomography (CT) or magnetic resonance imaging (MRI).

The crux of the management of acute pancreatitis is supportive therapy (e.g., maintaining blood pressure and alleviating pain) and "resting" the pancreas by total restriction of oral food and fluids. In 40% to 60% of cases of acute necrotizing pancreatitis, the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary tract, further complicating the clinical course. Although most individuals with acute pancreatitis eventually recover, some 5% die from shock during the first week of illness; acute respiratory distress syndrome and acute renal failure are ominous complications. In surviving patients, sequelae include sterile or infected *pancreatic "abscesses"* or *pancreatic pseudocysts.*

Pancreatic Pseudocysts

A common sequela of acute pancreatitis (and in particular, alcoholic pancreatitis) is a *pancreatic pseudocyst.* Liquefied areas of necrotic pancreatic tissue become walled off by fibrous tissue to form a cystic space, lacking an epithelial lining (hence the designation *pseudo*). The cyst contents are rich in pancreatic enzymes, and a laboratory assessment of the cyst aspirate can be diagnostic. Pseudocysts account for approximately 75% of all pancreatic cysts. While many pseudocysts spontaneously resolve, they can become secondarily infected, and larger pseudocysts can compress or even perforate into adjacent structures.

MORPHOLOGY

Pseudocysts usually are solitary; they commonly are attached to the surface of the gland and involve peripancreatic tissues such as the lesser omental sac or the retroperitoneum between the stomach and transverse colon or liver (Fig. 17.3A). They can range in diameter from 2 cm to 30 cm. Since pseudocysts form by walling off areas of hemorrhagic fat necrosis, they typically are composed of necrotic debris encased by walls of granulation tissue and fibroblasts lacking an epithelial lining (see Fig. 17.3B). If they get infected, a pancreatic abscess is formed.

Chronic Pancreatitis

Chronic pancreatitis is characterized by long-standing inflammation that leads to irreversible destruction of the exocrine pancreas, followed eventually by loss of the islets of Langerhans. Of note, recurrent bouts of acute pancreatitis regardless of etiology can evolve over time into chronic pancreatitis. The prevalence of chronic pancreatitis is difficult to determine but probably ranges between 0.04% and 5% of the U.S. population.

Etiology

By far **the most common cause of chronic pancreatitis is long-term alcohol abuse.** Middle-aged men constitute the bulk of patients in this etiologic group. Less common causes of chronic pancreatitis include the following:

- *Duct Obstruction.* Long-standing obstruction of pancreatic duct e.g., by pseudocysts, calculi, neoplasms, or pancreas divisum.
- *Tropical pancreatitis,* a poorly characterized heterogeneous disorder seen in Africa and Asia, with a subset of cases having a hereditary basis.
- *Hereditary pancreatitis* due to mutations in the pancreatic trypsinogen gene *(PRRS1)*, or the *SPINK1* gene encoding a trypsin inhibitor (see Table 17.1).
- *Chronic pancreatitis associated with CFTR mutations.* The pathophysiology of chronic pancreatitis in cystic fibrosis is discussed in detail in Chapter 7.
- *Autoimmune pancreatitis* is a pathogenically distinct form of chronic pancreatitis that is associated with the

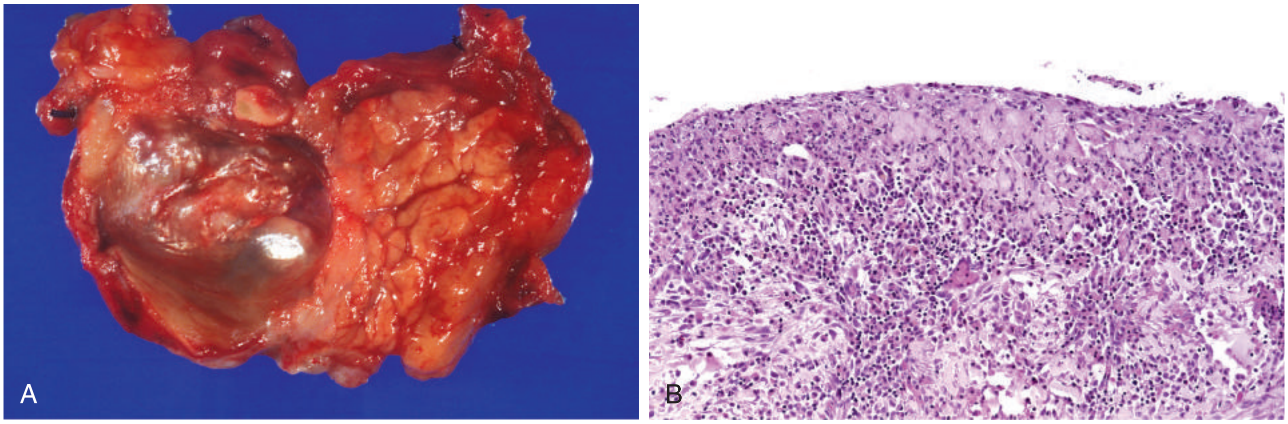

Fig. 17.3 Pancreatic pseudocyst. (A) Cross-section revealing a poorly defined cyst with a necrotic brownish wall. (B) Histologically, the cyst lacks an epithelial lining and instead is lined by fibrin and granulation tissue, with typical changes of chronic inflammation.

presence of IgG4-secreting plasma cells in the pancreas. Autoimmune pancreatitis is one manifestation of IgG-related disease (Chapter 5), which may involve multiple tissues. It is important to recognize because it responds to steroid therapy.

As many as 40% of individuals with chronic pancreatitis have no recognizable predisposing factors. As with acute pancreatitis, however, a growing number of these "idiopathic" cases are associated with inherited mutations in genes, such as *CFTR,* that are important for normal pancreatic exocrine function. Recent studies have also identified polymorphisms in genes encoding exocrine pancreatic enzymes, including carboxypeptidase A1 *(CPA1)* and lipase *(CEL)*, that may confer increased susceptibility to chronic pancreatitis.

Pathogenesis

Although the pathogenesis of chronic pancreatitis is not well defined, several hypotheses are proposed:

- *Ductal obstruction by concretions.* Many of the inciting agents in chronic pancreatitis (e.g., alcohol) increase the protein concentration of pancreatic secretions, and these proteins can form ductal plugs.
- *Toxic-metabolic.* Toxins, including alcohol and its metabolites, can exert a direct toxic effect on acinar cells, leading to lipid accumulation, acinar cell loss, and eventually parenchymal fibrosis.
- *Oxidative stress.* Alcohol-induced oxidative stress may generate free radicals in acinar cells, leading to membrane damage (Chapter 2), and subsequent expression of chemokines like interleukin-8 (IL-8), which recruits inflammatory cells. Oxidative stress also promotes the fusion of lysosomes and zymogen granules with resulting acinar cell necrosis, inflammation, and fibrosis.
- *Inappropriate activation of pancreatic enzymes* due to mutations affecting genes mentioned earlier.

In contrast to acute pancreatitis, a variety of profibrogenic cytokines, such as transforming growth factor-β (TGF-β), connective tissue growth factor, and platelet-derived growth factor, are secreted in chronic pancreatitis by infiltrating immune cells such as macrophages. These cytokines induce the activation and proliferation of periacinar myofibroblasts ("pancreatic stellate cells"), which deposit collagen and give rise to fibrosis.

MORPHOLOGY

Chronic pancreatitis is characterized by **parenchymal fibrosis, reduced number and size of acini, and variable dilation of the pancreatic ducts;** there is a relative sparing of the islets of Langerhans initially (Fig. 17.4A). **Acinar loss** is a constant feature, usually with a chronic inflammatory infiltrate around remaining lobules and ducts. The ductal epithelium may be atrophied or hyperplastic or exhibit squamous metaplasia, and ductal concretions may be noted (Fig. 17.4B). The remaining islets of Langerhans become embedded in the sclerotic tissue and may fuse and appear enlarged; eventually they also disappear. On gross evaluation, the gland is hard, sometimes with extremely dilated ducts and visible calcified concretions.

Autoimmune pancreatitis (AIP) is a distinct form of chronic pancreatitis that is characterized by striking infiltration of the pancreas by lymphocytes and plasma cells, many of which are positive for IgG4, accompanied by a "swirling" fibrosis and venulitis **(lymphoplasmacytic sclerosing pancreatitis).**

Clinical Features

Chronic pancreatitis manifests as repeated bouts of jaundice, vague indigestion, or persistent or recurrent abdominal and back pain, or it may be entirely silent until pancreatic insufficiency and diabetes mellitus develop (the latter as a consequence of islet destruction). Attacks can be precipitated by alcohol abuse, overeating (which increases demand on pancreatic secretions), or opiates or other drugs that increase the muscle tone of the sphincter of Oddi.

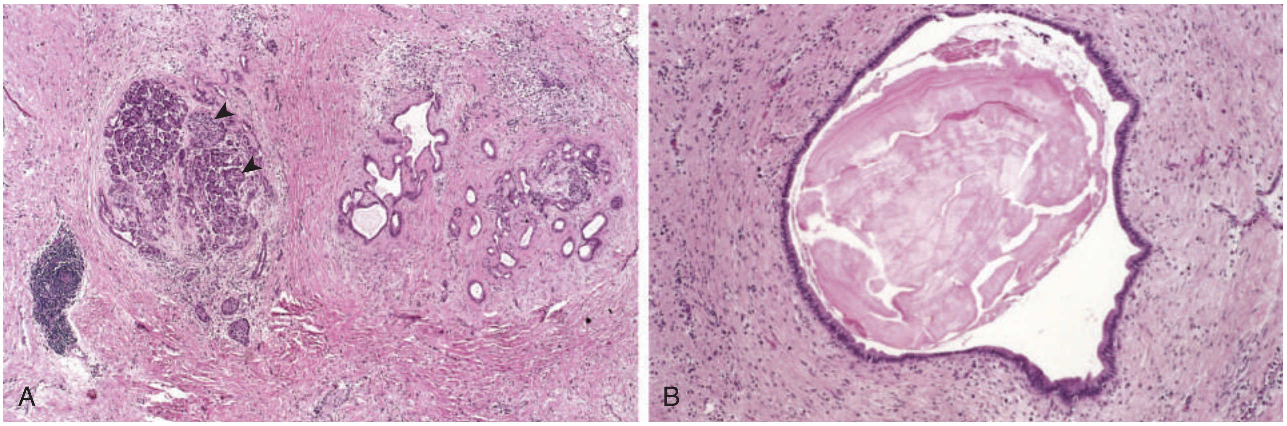

Fig. 17.4 Chronic pancreatitis. (A) Extensive fibrosis and atrophy have left only residual islets *(left)* and ducts *(right)*, with a sprinkling of chronic inflammatory cells and acinar tissue. (B) A higher-power view demonstrating dilated ducts with inspissated eosinophilic concretions in a patient with alcoholic chronic pancreatitis.

The diagnosis of chronic pancreatitis requires a high degree of clinical suspicion. During an attack of abdominal pain, there may be mild fever and modest elevations of serum amylase. In end-stage disease, however, acinar destruction may be so advanced that enzyme elevations are absent. Gallstone-induced obstruction may manifest as jaundice or elevated levels of serum alkaline phosphatase. A very helpful finding is visualization of calcifications within the pancreas by CT or ultrasonography. Weight loss and hypoalbuminemic edema from malabsorption caused by pancreatic exocrine insufficiency can also point to the disease.

Although chronic pancreatitis is usually not acutely life-threatening, the long-term outlook is poor, with a 50% mortality rate over 20 to 25 years. The most common long-term sequelae of chronic pancreatitis is insufficiency of pancreatic exocrine enzymes, with consequent malabsorption and deficiency of fat-soluble vitamins (Chapter 8). Exocrine insufficiency typically predates endocrine dysfunction, and patients with severe loss of islets can develop diabetes mellitus (Chapter 20). In other patients, *severe chronic pain* may dominate the clinical picture. *Pancreatic pseudocysts* (discussed earlier) develop in about 10% of patients. The most feared long-term complication of chronic pancreatitis is pancreatic cancer. The risk for malignant transformation in adult-onset disease is modest, with no more than 5% of patients developing cancer at 20 years. In contrast, chronic pancreatitis that begins in childhood, such as hereditary pancreatitis secondary to *PRSS1* mutations, confers a 40% to 55% lifetime risk for pancreatic cancer. It is not unusual for patients with *PRSS1* mutations to undergo prophylactic pancreatectomy.

SUMMARY

PANCREATITIS

- *Acute pancreatitis* is characterized by inflammation and reversible parenchymal damage that ranges from focal edema and fat necrosis to widespread parenchymal necrosis and hemorrhage; the clinical presentation varies widely, from mild abdominal pain to rapidly fatal vascular collapse.
- *Chronic pancreatitis* is characterized by irreversible parenchymal damage and scar formation; clinical presentations include chronic malabsorption (due to pancreatic exocrine insufficiency) and diabetes mellitus (due to islet cell loss).
- Both entities share similar pathogenic mechanisms, and indeed recurrent acute pancreatitis can result in chronic pancreatitis. *Ductal obstruction* and *long-term alcohol abuse* are the most common causes in both forms. Inappropriate activation of pancreatic digestive enzymes (due to mutations in genes encoding trypsinogen or trypsin inhibitors) and primary acinar injury (due to toxins, infections, ischemia, or trauma) also cause pancreatitis.

PANCREATIC NEOPLASMS

Pancreatic exocrine neoplasms can be cystic or solid. Some tumors are benign, while others are among the most lethal of all malignancies.

Cystic Neoplasms

Cystic neoplasms are diverse tumors that range from harmless benign cysts to invasive, potentially lethal, cancers. Approximately 5% to 15% of all pancreatic cysts are neoplastic; these constitute less than 5% of all pancreatic neoplasms. Some of these are almost always benign (e.g., serous cystadenoma); others, such as mucinous cystic neoplasms, can be benign or malignant.

Serous cystadenomas account for approximately 25% of all pancreatic cystic neoplasms; they are composed of glycogen-rich cuboidal cells surrounding small cysts containing clear, straw-colored fluid (Fig. 17.5). The tumors typically manifest in the seventh decade of life with nonspecific symptoms such as abdominal pain; the female-to-male ratio is 2:1. These tumors are almost uniformly benign, and surgical resection is curative in the vast majority of patients. Most serous

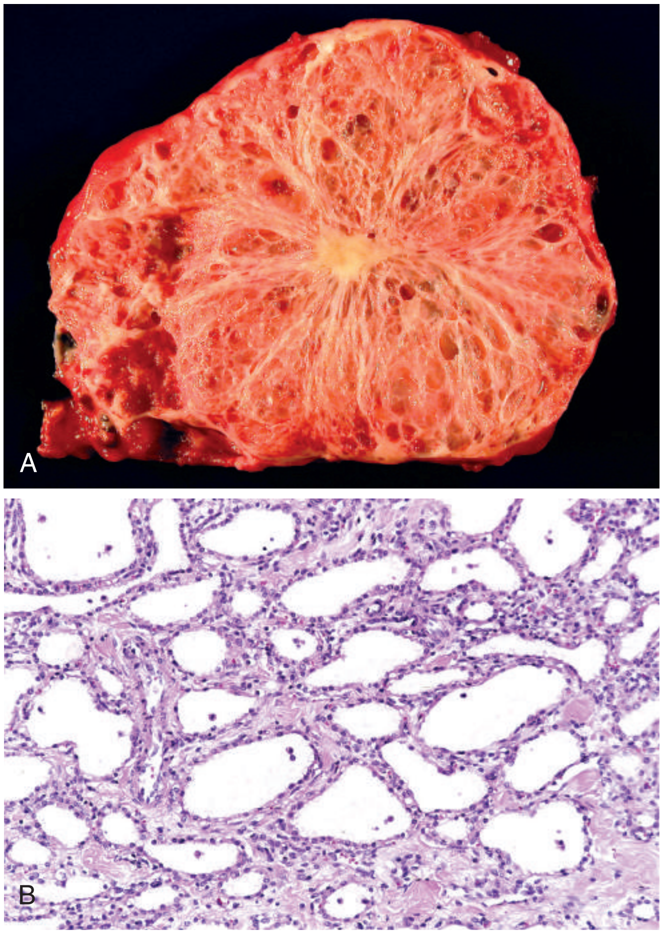

Fig. 17.5 Serous cystadenoma. (A) Cross-section through a serous cystadenoma. Only a thin rim of normal pancreatic parenchyma remains. The cysts are relatively small and contain clear, straw-colored fluid. (B) The cysts are lined by cuboidal epithelium without atypia.

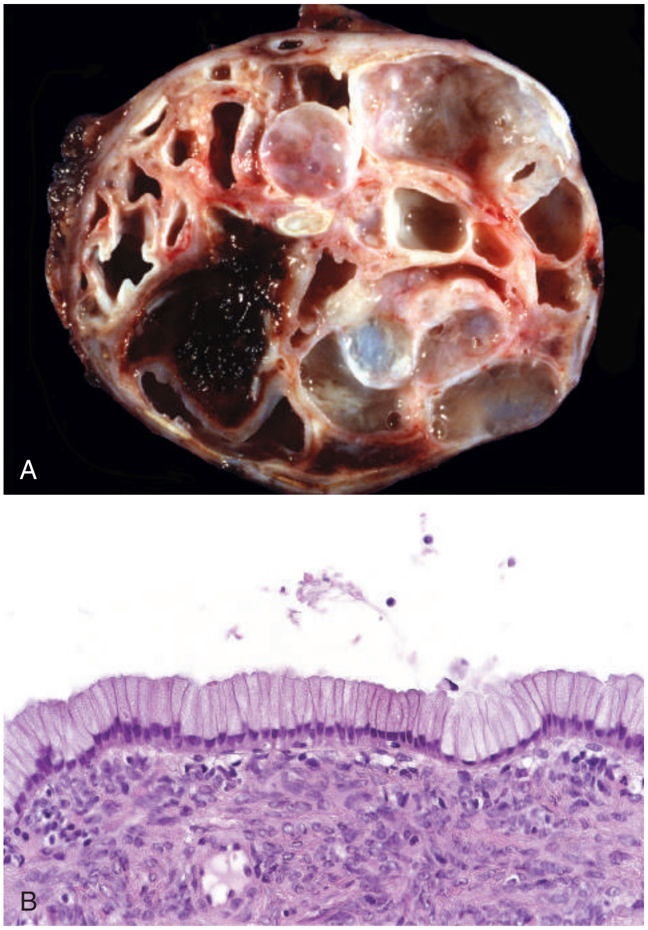

Fig. 17.6 Mucinous cystic neoplasm. (A) Cross-section through a mucinous multiloculated cyst in the tail of the pancreas. The cysts are large and filled with tenacious mucin. (B) The cysts are lined by columnar mucinous epithelium, with a densely cellular "ovarian" stroma.

cystadenomas carry somatic loss of function mutations of the von Hippel-Lindau *(VHL)* tumor suppressor gene, which you will recall is a negative regulator of hypoxia-inducible factor 1 alpha (HIF-1-alpha) (Chapter 6).

In contrast to serous cystic tumors, **close** *to 95% of mucinous cystic neoplasms arise in women, usually in the body or tail of the pancreas, and manifest as painless, slow-growing masses.* The cystic spaces are filled with thick, tenacious mucin, and the cysts are lined by a columnar mucinous epithelium with an associated densely cellular stroma resembling that of the ovary (Fig. 17.6). Based on the degree of cytologic and architectural atypia in the epithelial lining, noninvasive mucinous cystic neoplasms are classified as harboring *low-grade, moderate,* or *severe* dysplasia. Up to one-third of these cysts can be associated with an invasive adenocarcinoma, another important difference from the serous tumors. Distal pancreatectomy for noninvasive mucinous cysts typically is curative, even in the setting of severe dysplasia.

Intraductal Papillary Mucinous Neoplasms

In contrast with mucinous cystic neoplasms, intraductal papillary mucinous neoplasms (IPMNs) occur more frequently in men than in women and more frequently involve the head of the pancreas. IPMNs arise in the main pancreatic ducts, or one of its major branch ducts, and lack the cellular stroma seen in mucinous cystic neoplasms (Fig. 17.7). As with mucinous cystic neoplasms, the epithelia of noninvasive IPMNs harbor various grades of dysplasia, and a subset of lesions is associated with invasive adenocarcinoma. In particular, "colloid" carcinomas of the pancreas, which are adenocarcinomas associated with abundant extracellular mucin production, nearly always represent malignant transformation of an IPMN. Up to two-thirds of IPMNs harbor oncogenic mutations of *GNAS* on chromosome 20q13, which encodes the alpha subunit of a stimulatory G-protein, G_s (Chapter 20). Constitutive activation of this G-protein is predicted to result in an intracellular cascade that promotes cell proliferation.

Pancreatic Carcinoma

Infiltrating ductal adenocarcinoma of the pancreas (more commonly referred to as *pancreatic cancer*) is the third leading cause of cancer deaths in the United States, preceded only by lung and colon cancers. Although it is substantially less common than the other two malignancies, pancreatic carcinoma is near the top of the list of killers because it carries one of the highest mortality rates. Close to 49,000 Americans were diagnosed with pancreatic cancer

in 2015, and virtually all will die in a short period after diagnosis; the 5-year survival rate is a dismal 8%.

Pathogenesis

Like all cancers, pancreatic cancer arises as a consequence of inherited and acquired mutations in cancer-associated genes. In a pattern analogous to that seen in the multistep progression of colon cancer (Chapter 6), there is a progressive accumulation of genetic changes in pancreatic epithelium as it proceeds from nonneoplastic, to noninvasive precursor lesions, to invasive carcinoma (Fig. 17.8). While both intraductal papillary mucinous neoplasms and mucinous cystic neoplasms can progress to invasive adenocarcinoma, **the most common antecedent lesions of pancreatic cancer arise in small ducts and ductules, and are called pancreatic intraepithelial neoplasias (PanINs).** Evidence in favor of the precursor relationship of PanINs to frank malignancy includes the observations that these microscopic lesions often are found adjacent to infiltrating carcinomas and the two share a number of genetic alterations. Moreover, the epithelial cells in PanINs show dramatic telomere shortening, potentially predisposing these lesions to pathogenic chromosomal abnormalities that may contribute to acquisition of the full spectrum of cancer hallmarks.

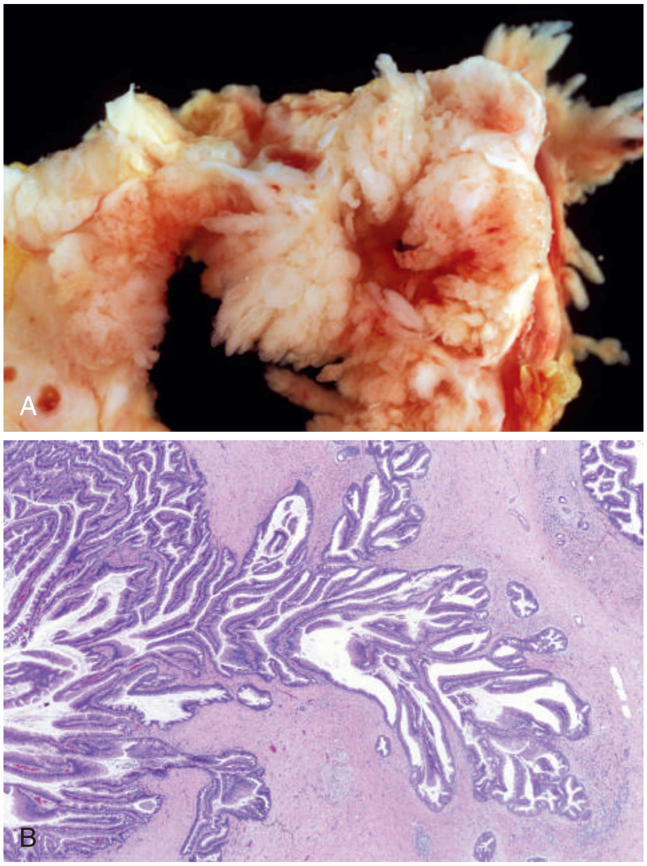

Fig. 17.7 Intraductal papillary mucinous neoplasm. (A) Cross-section through the head of the pancreas showing a prominent papillary neoplasm distending the main pancreatic duct. (B) The papillary mucinous neoplasm involves the main pancreatic duct *(left)* and is extending down into the smaller ducts and ductules *(right)*.

The recent sequencing of the pancreatic cancer genome has confirmed that **four genes are most commonly affected by somatic mutations in this neoplasm: *KRAS, CDKN2A/p16, SMAD4*, and *TP53*:**

- *KRAS* is the most frequently altered oncogene in pancreatic cancer; it is activated by a point mutation in greater than 90% of cases. These mutations impair the intrinsic GTPase activity of the KRAS protein so that it is constitutively active. In turn, KRAS activates a number of intracellular signaling pathways that promote carcinogenesis (Chapter 6).
- The *p16 (CDKN2A)* gene is the most frequently inactivated tumor suppressor gene in pancreatic cancer, being turned off in 95% of cases. The p16 protein has a critical role in cell-cycle control; inactivation removes an important checkpoint.
- The *SMAD4* tumor suppressor gene is inactivated in 55% of pancreatic cancers and only rarely in other tumors; it codes for a protein that plays an important role in signal transduction downstream of the transforming growth factor-β receptor.
- Inactivation of the *TP53* tumor suppressor gene occurs in 50% to 70% of pancreatic cancers. Its gene

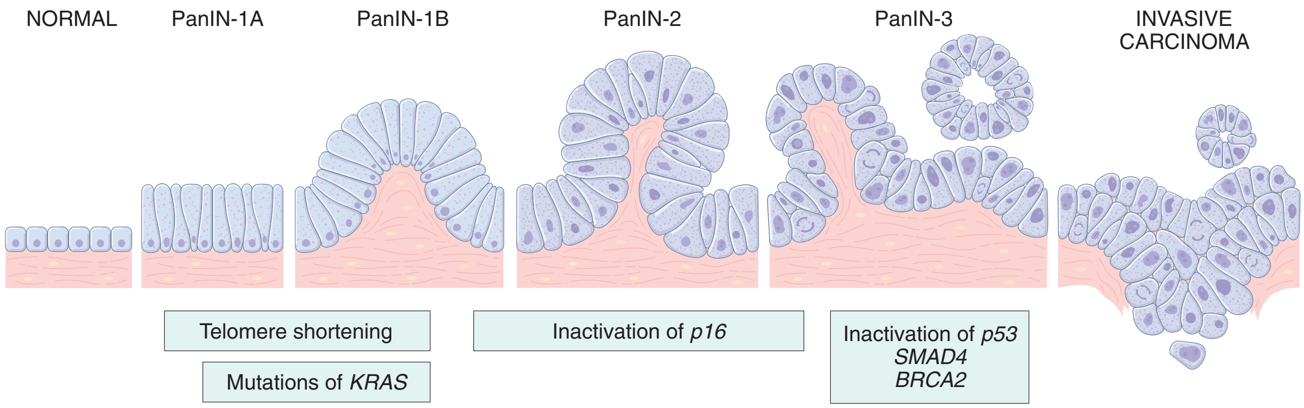

Fig. 17.8 Progression model for the development of pancreatic cancer. It is postulated that telomere shortening and mutations of the *KRAS* oncogene occur at early stages, inactivation of the p16 tumor suppressor gene occurs at intermediate stages, and inactivation of the *TP53*, *SMAD4*, and *BRCA2* tumor suppressor genes occurs at late stages. Note that while there is a general temporal sequence of changes, the accumulation of multiple mutations is more important than their occurrence in a specific order. PanIN, Pancreatic intraepithelial neoplasm. The numbers following the labels on the top refer to stages in the development of PanINs. *(Modified from Maitra A, Hruban RH: Pancreatic cancer,* Annu Rev Pathol Mech Dis *3:157, 2008.)*

product, p53, acts both to enforce cell-cycle checkpoints and as an inducer of apoptosis or senescence (Chapter 6). *BRCA2* is also mutated late in a subset of pancreatic cancers.

Pancreatic cancer is primarily a disease of older adults, with 80% of cases occurring between 60 and 80 years of age. The strongest environmental influence is smoking, which doubles the risk. Long-standing chronic pancreatitis and diabetes mellitus are also associated with a modestly increased risk for pancreatic cancer. These two entities have a bidirectional link with pancreatic cancer. Thus, for example, tumors arising in the head of the pancreas often cause chronic pancreatitis in the distal parenchyma, while diabetes caused by duct obstruction and subsequent pancreatitis may be the manifestation of an underlying neoplasm. In fact, approximately 1% of the older adult population with new-onset diabetes harbor an unsuspected pancreatic cancer. Familial clustering of pancreatic cancer has been reported, and a growing number of inherited genetic defects are now recognized that increase pancreatic cancer risk. For example, germ line mutations of the familial breast/ovarian cancer gene *BRCA2* are seen in approximately 10% of cases arising in individuals of Ashkenazi Jewish heritage.

MORPHOLOGY

Approximately 60% of pancreatic cancers arise in the head of the gland, 15% in the body, and 5% in the tail; in the remaining 20%, the neoplasm diffusely involves the entire organ. Carcinomas of the pancreas usually are hard, gray-white, stellate, poorly defined masses (Fig. 17.9A).

Two features are characteristic of pancreatic cancer: It is highly invasive (even "early" invasive pancreatic cancers invade peripancreatic tissues extensively), and it elicits an intense host reaction in the form of dense fibrosis **(desmoplastic response).**

Most carcinomas of the head of the pancreas obstruct the distal common bile duct as it courses through the head of the pancreas. In 50% of such cases, there is marked distention of the biliary tree, and patients typically exhibit jaundice. In contrast, carcinomas of the body and tail of the pancreas do not impinge on the biliary tract. Pancreatic cancers often extend through the retroperitoneal space, entrapping adjacent nerves (thus, accounting for the pain), and occasionally invade the spleen, adrenal glands, vertebral column, transverse colon, and stomach. Peripancreatic, gastric, mesenteric, omental, and portahepatic lymph nodes frequently are involved, and the liver often is enlarged with metastatic deposits. Distant metastases may occur, principally to the lungs and bones.

On microscopic examination, pancreatic carcinoma usually is a **moderately to poorly differentiated adenocarcinoma** forming abortive glands with mucin secretion or cell clusters and exhibiting an aggressive, deeply infiltrative growth pattern (see Fig. 17.9B). Dense stromal fibrosis accompanies tumor invasion, and there is a proclivity for perineural invasion within and beyond the organ. Lymphatic invasion also is commonly seen.

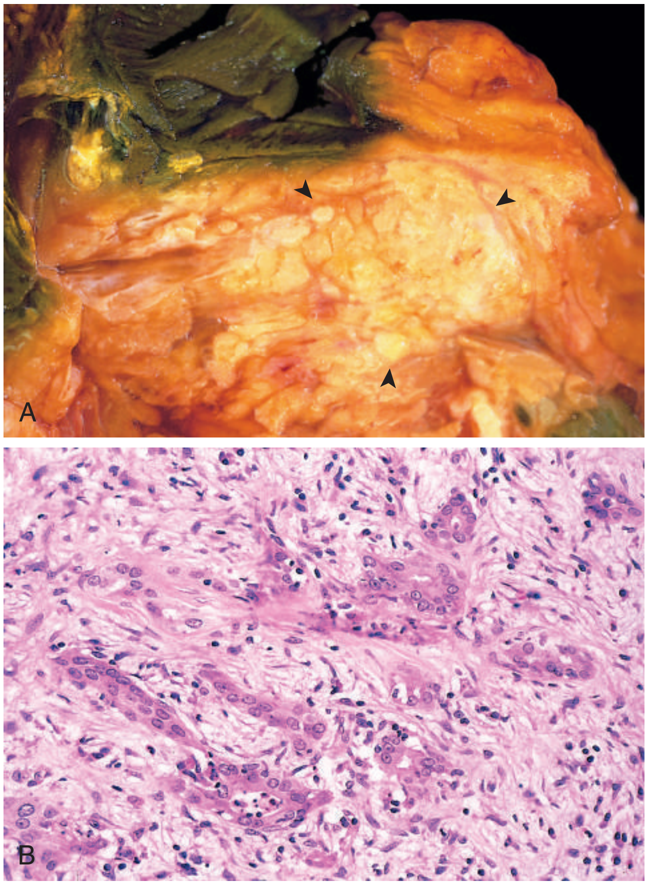

Fig. 17.9 Carcinoma of the pancreas. (A) Cross-section through the head of the pancreas and adjacent common bile duct showing both an ill-defined mass in the pancreatic substance *(arrowheads)* and the green discoloration of the duct resulting from total obstruction of bile flow. (B) Poorly formed glands are present in a densely fibrotic (desmoplastic) stroma within the pancreatic substance.

Less common variants of pancreatic cancer include **adenosquamous carcinomas** with focal squamous differentiation in addition to glandular differentiation; and undifferentiated carcinomas with osteoclast-like giant cells of monocytic lineage intermixed within the neoplasm.

Clinical Features

Carcinomas of the pancreas typically remain silent until their extension impinges on some other structure. Pain usually is the first symptom, but by that point these cancers are often beyond cure. *Obstructive jaundice* can be associated with carcinoma in the head of the pancreas, but it rarely draws attention to the cancer soon enough for timely intervention. Weight loss, anorexia, and generalized malaise and weakness are manifestations of advanced disease. *Migratory thrombophlebitis (Trousseau syndrome)* occurs in about 10% of patients and is attributable to the elaboration of platelet-aggregating factors and pro-coagulants from the tumor or its necrotic products (Chapter 6). As previously stated, new-onset diabetes is the first manifestation of pancreatic cancer in some patients.

The clinical course of pancreatic carcinoma is rapidly progressive and often distressingly brief. Less than 20% of pancreatic cancers are resectable at the time of diagnosis. It has long been recognized that there is a profound need for biomarkers capable of detecting early, potentially curable, pancreatic cancers. Although serum levels of many enzymes and antigens (e.g., carcinoembryonic and CA19-9 antigens) are elevated, these markers are neither specific nor sensitive enough to be useful for screening. Several imaging techniques, such as endoscopic ultrasonography and high-resolution CT scans, are helpful for investigation in cases of suspected cancer but are not practical screening tests.

SUMMARY

PANCREATIC NEOPLASMS

- Pancreatic cancer probably arises from noninvasive precursor lesions (most commonly, PanINs), developing by progressive accumulation of mutations of oncogenes (e.g., *KRAS*) and tumor suppressor genes (e.g., *CDKN2A/p16*, *TP53*, and *SMAD4*).
- Typically, these neoplasms are ductal adenocarcinomas that produce an intense desmoplastic response.
- Most pancreatic cancers are diagnosed at an advanced stage, accounting for the high mortality rate.
- Obstructive jaundice is a feature of carcinoma of the head of the pancreas; many patients also experience debilitating pain.
- Carcinomas of the tail of the pancreas are often not detected until late in their course.

CHAPTER 18

Male Genital System and Lower Urinary Tract

CHAPTER OUTLINE

PENIS

Malformations

Among the most common malformations of the penis are those in which the distal urethral orifice is abnormally located. In *hypospadias,* the abnormal urethral opening is found on the ventral aspect of the penis anywhere along the shaft. This anomalous orifice is sometimes constricted, resulting in urinary tract obstruction and an increased risk for urinary tract infections. Hypospadias occurs in 1 in 300 live male births and may be associated with other congenital anomalies, such as inguinal hernia and undescended testis. In *epispadias,* which is less common, the abnormal urethral orifice is on the dorsal aspect of the penis.

Inflammatory Lesions

Balanitis and *balanoposthitis* refer to local inflammation of the glans penis and of the overlying prepuce, respectively. Among the more common agents are *Candida albicans,* anaerobic bacteria, *Gardnerella,* and pyogenic bacteria. Most cases occur as a consequence of poor hygiene in uncircumcised males, leading to the accumulation of desquamated epithelial cells, sweat, and debris, termed *smegma,* which acts as a local irritant. *Phimosis* is a condition in which the prepuce cannot be retracted easily over the glans penis. Phimosis may be a congenital anomaly, but most cases stem from scarring of the prepuce caused by balanoposthitis.

Neoplasms

More than 95% of penile neoplasms arise on squamous epithelium. In the United States, squamous cell carcinomas of the penis are relatively uncommon, accounting for about 0.4% of all cancers in males. In developing countries, however, penile carcinoma occurs at much higher rates. Most cases occur in uncircumcised patients older than 40 years of age. Several factors have been implicated in the pathogenesis of penile squamous cell carcinoma, including poor hygiene (with resultant exposure to potential carcinogens in smegma), smoking, and infection with human papillomavirus (HPV), particularly types 16 and 18.

Squamous cell carcinoma in situ of the penis (Bowen disease) occurs in older uncircumcised males and appears grossly as a solitary plaque on the shaft of the penis. Histologic examination reveals dysplastic cells throughout the epidermis with no invasion of the underlying stroma (Fig. 18.1). It gives rise to invasive squamous cell carcinoma in approximately 10% of patients.

Invasive squamous cell carcinoma of the penis appears as a gray, crusted, papular lesion, most commonly on the glans penis or prepuce. In many cases, infiltration of the underlying connective tissue produces an indurated, ulcerated lesion with irregular margins (Fig. 18.2). Histologically, the tumor is most often a typical keratinizing squamous cell carcinoma. The prognosis is related to the stage of the tumor. With localized lesions, the 5-year survival rate is 66%, whereas metastasis to inguinal lymph nodes carries a grim 27% 5-year survival rate. *Verrucous carcinoma* is a non-HPV–related variant of squamous cell

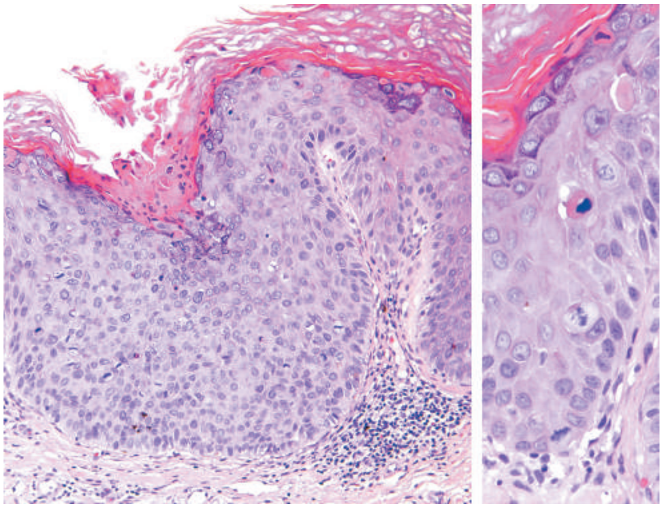

Fig. 18.1 Carcinoma in situ (Bowen disease) of the penis. The epithelium above the intact basement membrane shows delayed maturation and disorganization *(left)*. Higher magnification *(right)* shows several mitotic figures, some above the basal layer, and nuclear pleomorphism.

carcinoma characterized by papillary architecture, virtually no cytologic atypia, and rounded, pushing deep margins. Verrucous carcinomas are locally invasive but do not metastasize.

SUMMARY

LESIONS OF THE PENIS

- Squamous cell carcinoma and its precursor lesions are the most important penile lesions. Many are associated with HPV infection.
- Squamous cell carcinoma occurs on the glans or shaft of the penis as an ulcerated infiltrative lesion that may spread to inguinal nodes and infrequently to distant sites. Most cases occur in uncircumcised males.
- Other important penile disorders include congenital abnormalities involving the position of the urethra (epispadias, hypospadias) and inflammatory disorders (balanitis, phimosis).

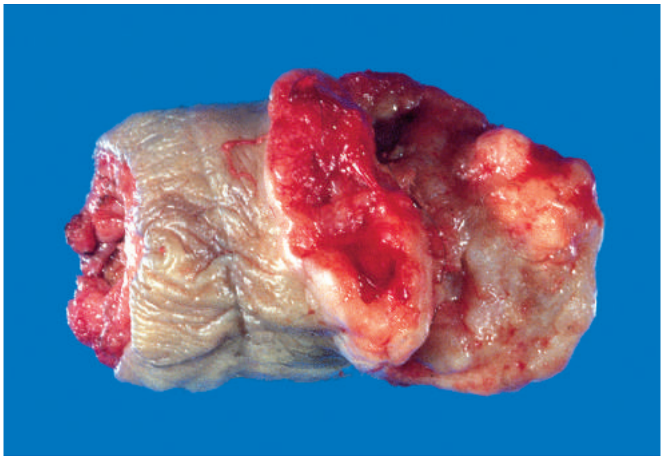

Fig. 18.2 Carcinoma of the penis. The glans penis is deformed by an ulcerated, infiltrative mass.

SCROTUM, TESTIS, AND EPIDIDYMIS

Several inflammatory processes may affect the skin of the scrotum, including local fungal infections and systemic dermatoses, such as psoriasis (Chapter 24). Neoplasms of the scrotal sac are unusual. *Squamous cell carcinoma,* the most common of these, is of historical interest in that it represents the first human malignancy associated with environmental exposures, dating from Sir Percival Pott's observation of a high incidence of the disease in chimney sweeps. The subsequent edict by the Chimney Sweeps Guild that its members must bathe daily remains one of the most successful public health measures for cancer prevention. Several disorders unrelated to the testes and epididymis may present as scrotal enlargement. *Hydrocele,* the most common cause of scrotal swelling, is caused by an accumulation of serous fluid within the tunica vaginalis. It may be idiopathic or arise in response to neighboring infections or tumors. The clear fluid of a hydrocele allows light to pass through (transluminescence), distinguishing it from collections of blood, pus, or lymph, all of which are cloudy or opaque. Accumulation of blood or lymphatic fluid within the tunica vaginalis, termed *hematocele* and *chylocele,* respectively, also may cause scrotal enlargement. In extreme cases of lymphatic obstruction, caused, for example, by filariasis, the scrotum and the lower extremities may enlarge to grotesque sizes—a condition termed *elephantiasis.*

Cryptorchidism and Testicular Atrophy

Cryptorchidism is a *failure of testicular descent* into the scrotum. Normally, the testes descend from the abdominal cavity into the pelvis by the third month of gestation and then through the inguinal canals into the scrotum during the last 2 months of intrauterine life. The diagnosis of cryptorchidism is only established with certainty after 1 year of age, particularly in premature infants, because testicular descent into the scrotum is not always complete at birth. Cryptorchidism affects 1% of the male population. In the vast majority of cases, the cause is unknown. The condition is bilateral in approximately 10% of affected patients, a small percentage of whom have chromosomal aberrations and other developmental abnormalities. Because undescended testes become atrophic, bilateral cryptorchidism results in sterility. For unclear reasons, even unilateral cryptorchidism may be associated with atrophy of the contralateral descended gonad.

In addition to infertility, failure of testicular descent is associated with a 3- to 5-fold increased risk for testicular cancer. Patients with unilateral cryptorchidism also are at increased risk for the development of cancer in the contralateral, normally descended testis, suggesting that some intrinsic abnormality, rather than simple failure of descent, underlies the increased cancer risk. Surgical placement of the undescended testis into the scrotum (orchiopexy) is recommended by 18 months of age to decrease the likelihood of testicular atrophy, infertility, and testicular cancer.

The cryptorchid testis may be of normal size early in life, but some degree of atrophy usually is evident by the

onset of puberty. Microscopically, tubular atrophy begins to appear by 5 to 6 years of age, and is usually advanced by the time of puberty. *Germ cell neoplasia in-situ* (discussed later) may be present in cryptorchid testes and is a likely precursor of subsequent germ cell tumors. Atrophic changes similar to those in cryptorchid testes may be caused by other insults, including chronic ischemia, trauma, irradiation, and anti-neoplastic chemotherapy, as well as conditions associated with chronically elevated estrogen levels (e.g., cirrhosis).

SUMMARY

CRYPTORCHIDISM

- *Cryptorchidism* refers to incomplete descent of the testis from the abdomen to the scrotum and is present in about 1% of 1-year-old male infants.
- Bilateral or, in some cases, even unilateral cryptorchidism is associated with tubular atrophy and sterility.
- The cryptorchid testis carries a 3- to 5-fold higher risk for testicular cancer, which arises from foci of germ cell neoplasia in-situ within the atrophic tubules. Early orchiopexy reduces the risk for sterility and cancer.

Inflammatory Lesions

Inflammatory lesions of the testis are more common in the epididymis than in the testis proper. Sexually transmitted infectious disorders are discussed later in the chapter. Other causes of testicular inflammation include nonspecific epididymitis and orchitis, mumps, and tuberculosis. *Nonspecific epididymitis* and *orchitis* usually begin as a primary urinary tract infection that spreads to the testis through the vas deferens or the lymphatics of the spermatic cord. The involved testis is swollen and tender, and histologic examination reveals numerous neutrophils. *Mumps infection* involving the testes is rare in male children but occurs in roughly 20% of infected adults. Affected testes are edematous and congested, and contain a lymphoplasmacytic inflammatory infiltrate. Severe mumps orchitis may lead to extensive necrosis, loss of seminiferous epithelium, tubular atrophy, fibrosis, and sterility. Several conditions, including infections and autoimmune injury, may elicit granulomatous inflammation in the testis. Of these, *tuberculosis* is the most common. Testicular tuberculosis generally begins as an epididymitis, with secondary involvement of the testis. Histologically, there is granulomatous inflammation and caseous necrosis identical to that seen in active tuberculosis in other sites.

Vascular Disturbances

Torsion, or twisting of the spermatic cord, typically results in obstruction of testicular venous drainage while leaving the thick-walled and more resilient arteries patent. This leads to intense vascular engorgement and infarction unless the torsion is relieved. There are two types of testicular torsion. *Neonatal torsion* occurs either in utero or shortly after birth. There is no associated anatomic defect to account for its occurrence. *Adult torsion* typically is seen in adolescence and manifests with the sudden onset of testicular pain. In contrast with neonatal torsion, adult torsion results from a bilateral congenital anomaly whereby the testis is abnormally anchored in the scrotal sac giving rise to increased mobility (*bell clapper abnormality).* It often occurs without any inciting injury; sudden pain heralding the torsion may even awaken the patient from sleep.

Torsion constitutes one of the few urologic emergencies. If the testis is explored surgically and the cord is manually untwisted within approximately 6 hours, the testis will likely remain viable. To prevent the catastrophic occurrence of torsion in the contralateral testis, the unaffected testis typically is surgically fixed within the scrotum (orchiopexy).

Testicular Neoplasms

Testicular neoplasms occur in roughly 6 per 100,000 males. In the 15- to 34-year-old age group, when these neoplasms peak in incidence, they are the most common tumors in men. Neoplasms of the testis are heterogeneous and include germ cell tumors and sex cord–stromal tumors. **In postpubertal males, 95% of testicular tumors arise from germ cells, and almost all are malignant.** By contrast, sex cord-stromal tumors derived from Sertoli or Leydig cells are uncommon and usually benign. The focus of the remainder of this discussion is on testicular germ cell tumors.

The cause of testicular neoplasms is poorly understood. Testicular tumors are more common in whites than in blacks, and the incidence has increased in white populations over recent decades. As discussed earlier, cryptorchidism is associated with a 3- to 5-fold increase in the risk for cancer in the undescended testis, as well as an increased risk for cancer in the contralateral descended testis. A history of cryptorchidism is present in approximately 10% of cases of testicular cancer. Intersex syndromes, including androgen insensitivity syndrome and gonadal dysgenesis, also are associated with an increased frequency of testicular cancer. Family history is important, as brothers of males with germ cell tumors have an 8- to 10-fold increased risk, presumably owing to inherited factors. The development of cancer in one testis also is associated with a markedly increased risk for neoplasia in the contralateral testis. Extra copies of the short arm of chromosome 12, usually due to the presence of an isochromosome 12 [i(12p)], are found in virtually all germ cell tumors. Of note, point mutations that create oncogenes are relatively rare in germ cell tumors, occurring at the lowest frequency of any solid tumor in adults. Among these are oncogenic mutations in *KIT* which are found in up to 25% of tumors.

Most testicular tumors in postpubertal males arise from *germ cell neoplasia in situ.* This precursor lesion is present in conditions associated with a high risk for developing germ cell tumors (e.g., cryptorchidism, dysgenetic gonads) and exhibits the same abnormality of chromosome 12 that is characteristic of fully developed germ cell tumors. As might be expected, germ cell neoplasia in situ often is found in "normal" testis adjacent to full-blown germ cell tumors.

Testicular germ cell tumors are subclassified into seminomas and nonseminomatous germ cell tumors (Table 18.1). Seminomas are most common, accounting for about

Table 18.1 Summary of Testicular Tumors

Tumor	Peak Patient Age (years)	Morphology	Tumor Marker(s)
Seminoma	40–50	Sheets of uniform polygonal cells with cleared cytoplasm; lymphocytes in the stroma	10% of patients have elevated hCG
Embryonal carcinoma	20–30	Poorly differentiated, pleomorphic cells in cords, sheets, or papillary formation; most contain some yolk sac and choriocarcinoma cells	Negative (pure embryonal carcinoma)
Spermatocytic tumor	50-60	Small, medium, and large polygonal cells; no inflammatory infiltrate	Negative
Yolk sac tumor	3	Poorly differentiated endothelium-like, cuboidal, or columnar cells	90% of patients have elevated AFP
Choriocarcinoma	20–30	Cytotrophoblast and syncytiotrophoblast without villus formation	100% of patients have elevated hCG
Teratoma	All ages	Tissues from all three germ cell layers with varying degrees of differentiation	Negative (pure teratoma)
Mixed tumor	15–30	Variable, depending on mixture; commonly teratoma and embryonal carcinoma	90% of patients have elevated hCG and AFP

AFP, Alpha fetoprotein; *hCG,* human chorionic gonadotropin.

50% of testicular germ cell neoplasms. They are histologically identical to tumors called *dysgerminomas,* which occur in the ovary, and *germinomas,* which occur in the central nervous system and other extragonadal sites.

MORPHOLOGY

Germ cell tumors may be "pure" (i.e., composed of a single histologic type) or mixed (seen in 40% of cases). **Seminoma** presents as a soft, well-demarcated, gray-white tumor that bulges from the cut surface of the affected testis (Fig. 18.3). Large tumors may contain foci of coagulative necrosis, usually without hemorrhage. Seminomas are composed of **large, uniform cells with distinct cell borders, clear, glycogen-rich cytoplasm, round nuclei, and conspicuous nucleoli** (Fig. 18.4). The cells often are arrayed in small lobules with intervening fibrous septa. A lymphocytic infiltrate usually is present and may, on occasion, overshadow the neoplastic cells. Seminomas also may elicit a granulomatous reaction. In approximately 15% of cases, syncytiotrophoblasts are present; these cells are the source of the minimally elevated serum human choriogonadotropin (hCG) that is encountered in approximately 10% of cases. Their presence has no bearing on prognosis.

Spermatocytic tumor (formerly called *spermatocytic seminoma*) is a distinct clinical and histologic entity. It is an uncommon tumor that occurs in older men than other testicular tumors; affected patients generally are beyond 50 years of age. In contrast with seminomas, spermatocytic tumors lack lymphocytic infiltrates, granulomas, and syncytiotrophoblasts; are not admixed with other germ cell tumor histologies; are not associated with germ cell neoplasia in-situ; and do not metastasize. The tumor usually comprises polygonal cells of variable size that are arranged in nodules or sheets.

Embryonal carcinoma presents as ill-defined, invasive masses containing foci of hemorrhage and necrosis (Fig. 18.5). The primary lesions may be small, even in patients with systemic metastases. **The tumor cells are large and have basophilic cytoplasm, indistinct cell borders, large nuclei, and prominent nucleoli.** The neoplastic cells may be arrayed in undifferentiated, solid sheets or may form primitive glandular

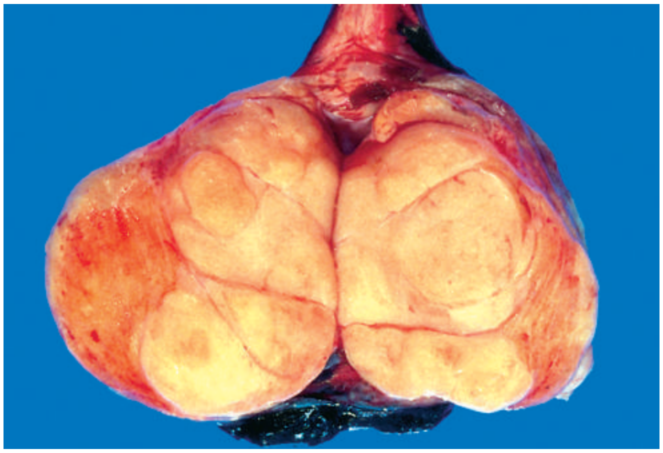

Fig. 18.3 Seminoma of the testis appearing as a well-circumscribed, pale, fleshy, homogeneous mass.

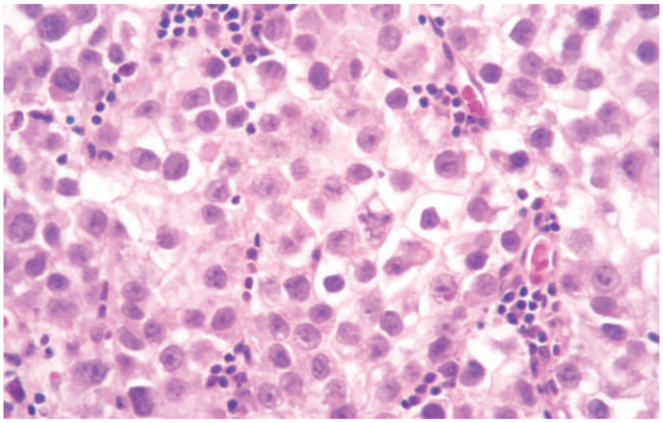

Fig. 18.4 Seminoma of the testis. Microscopic examination reveals large cells with distinct cell borders, pale nuclei, prominent nucleoli, and a sparse lymphocytic infiltrate.

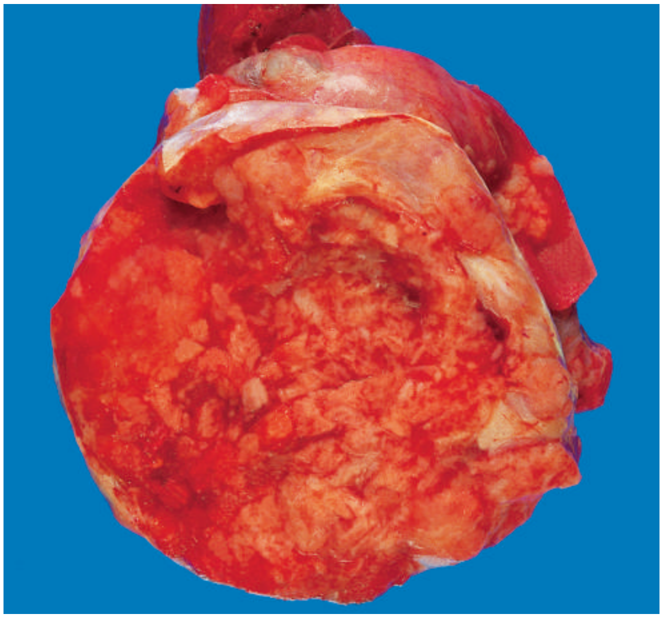

Fig. 18.5 Embryonal carcinoma. In contrast with the seminoma in Fig. 18.3, this tumor is hemorrhagic.

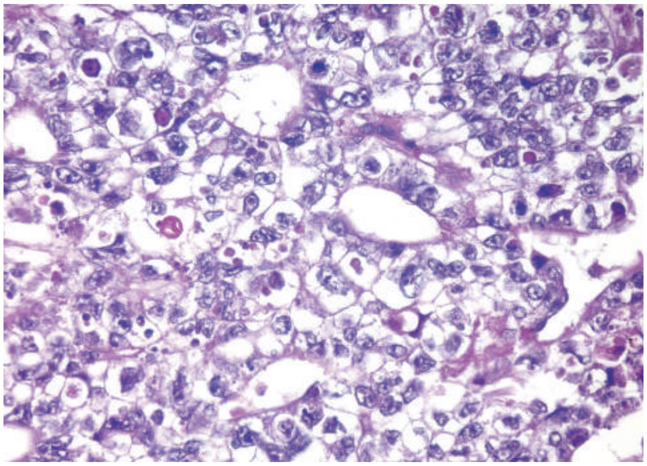

Fig. 18.6 Embryonal carcinoma. Note the sheets of undifferentiated cells and primitive glandlike structures. The nuclei are large and hyperchromatic.

structures and irregular papillae (Fig. 18.6). In most cases, cells characteristic of other germ cell tumors (e.g., yolk sac tumor, teratoma, choriocarcinoma) are admixed with the embryonal areas. Pure embryonal carcinomas account for only 2% to 3% of all testicular germ cell tumors.

Yolk sac tumor is the most common primary testicular neoplasm in children younger than 3 years of age; in this age group, it has a very good prognosis. In adults, yolk sac tumors most often are seen admixed with embryonal carcinoma. These tumors often are large and may be well demarcated. They are composed of low cuboidal to columnar epithelial cells that form microcysts, lacelike (reticular) patterns, sheets, glands, and papillae (Fig. 18.7). A distinctive feature is the presence of structures resembling primitive glomeruli, the so-called **Schiller-Duval bodies.** These tumors often have eosinophilic hyaline globules containing α_1-anti-trypsin and alpha fetoprotein (AFP), which can be demonstrated by immunohistochemical techniques.

Choriocarcinoma is a tumor in which the pluripotential neoplastic germ cells differentiate into cells resembling placental **trophoblasts.** The primary tumors often are small and nonpalpable, even in patients with extensive metastatic disease. The tumor is composed of sheets of small cuboidal **cytotrophoblast like cells** that are irregularly intermingled with or capped by large, eosinophilic **syncytiotrophoblast like cells** containing multiple dark, pleomorphic nuclei (Fig. 18.8). HCG can be identified in the syncytiotrophoblastic cells by immunohistochemical staining.

Teratoma is a tumor in which the neoplastic germ cells differentiate along multiple somatic cell lineages. These tumors form firm masses that often contain cysts and recognizable areas

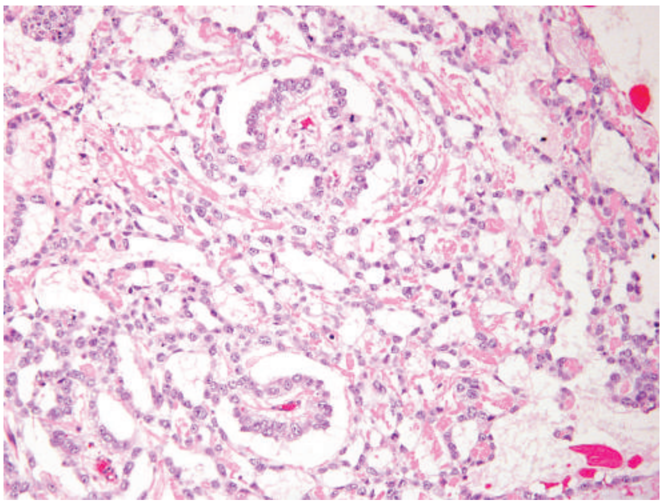

Fig. 18.7 Yolk sac tumor demonstrating areas of loosely textured, microcystic tissue and papillary structures resembling a developing glomerulus (Schiller-Duval bodies).

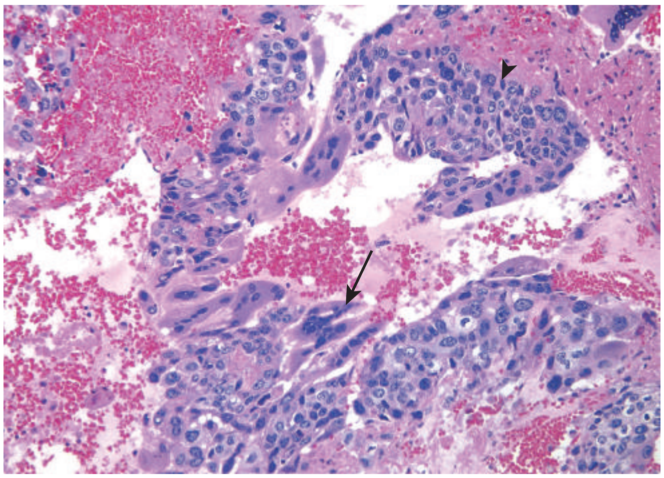

Fig. 18.8 Choriocarcinoma. Both cytotrophoblastic cells with single central nuclei *(arrowhead, upper-right)* and syncytiotrophoblastic cells with multiple dark nuclei embedded in eosinophilic cytoplasm *(arrow, middle)* are present. Hemorrhage and necrosis are prominent.

of cartilage. They may occur at any age from infancy to adult life. Pure forms of teratoma are fairly common in infants and children, being second in frequency only to yolk sac tumors. In adults, pure teratomas are rare, constituting 2% to 3% of germ cell tumors, and the remaining tumors are seen in combination with other histologic types. Teratomas are composed of a heterogeneous, helter-skelter collection of differentiated cells or organoid structures, such as neural tissue, muscle bundles, islands of cartilage, clusters of squamous epithelium, structures reminiscent of thyroid gland, bronchial epithelium, and bits of intestinal wall or brain substance, all embedded in a fibrous or myxoid stroma (Fig. 18.9). Elements may be mature (resembling various tissues within the adult) or immature (sharing histologic features with fetal or embryonal tissues). **In prepubertal males, teratomas are benign, whereas the majority of teratomas in postpubertal males are malignant, being capable of metastasis regardless of whether they are composed of mature or immature elements.**

Rarely, non–germ cell tumors may arise in teratoma—a phenomenon referred to as **teratoma with malignant transformation.** Examples of such neoplasms include squamous cell carcinoma, adenocarcinoma, and various sarcomas. These non–germ cell malignancies do not respond to therapies that are effective against metastatic germ cell tumors (discussed later); thus, the only hope for cure in such cases resides in surgical resection.

Clinical Features

Patients with testicular germ cell neoplasms present most frequently with a painless testicular mass that (unlike enlargements caused by hydroceles) is nontranslucent. Biopsy of a testicular neoplasm is associated with a risk for tumor spillage, which would necessitate excision of the scrotal skin in addition to orchiectomy. Consequently, the standard management of a solid testicular mass is radical orchiectomy, based on the presumption of malignancy. Some tumors, especially nonseminomatous germ cell neoplasms, may have metastasized widely by the time of diagnosis in the absence of a palpable testicular lesion.

Seminomas and nonseminomatous tumors differ in their behavior and clinical course.

- *Seminomas* often remain confined to the testis for long periods and may reach considerable size before diagnosis. Metastases most commonly are encountered in the iliac and paraaortic lymph nodes, particularly in the upper lumbar region. Hematogenous metastases occur late in the course of the disease.
- *Nonseminomatous germ cell neoplasms* tend to metastasize earlier, by lymphatic as well as hematogenous routes. Hematogenous metastases are most common in the liver and lungs. Metastatic lesions may be identical to the primary testicular tumor or may contain elements of other germ cell tumors.

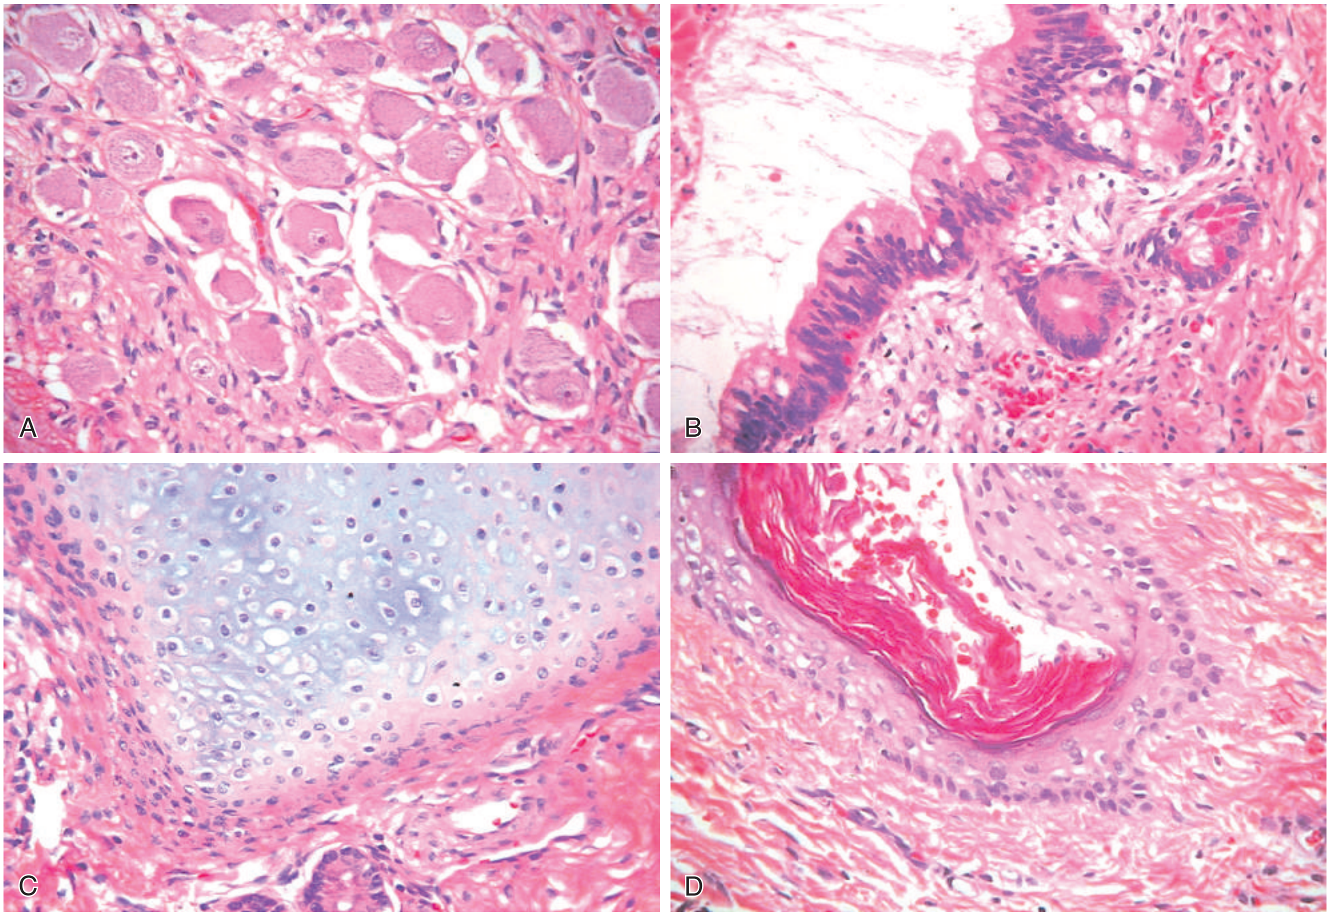

Fig. 18.9 Teratoma. Testicular teratomas contain mature cells from endodermal, mesodermal, and ectodermal lines. (A to D) Four different fields from the same tumor specimen contain neural (ectodermal) (A), glandular (endodermal) (B), cartilaginous (mesodermal) (C), and squamous epithelial (D) elements.

Assay of *tumor markers* secreted by germ cell tumors is important in two ways; these markers (summarized in Table 18.1, along with salient clinical and morphologic features) are helpful diagnostically and very valuable in following the response of tumors to therapy after the diagnosis is established. HCG is always elevated in patients with choriocarcinoma and, as noted, may be minimally elevated in individuals with other germ cell tumors containing syncytiotrophoblastic cells. Increased AFP in the setting of a testicular neoplasm indicates a yolk sac tumor component. The levels of lactate dehydrogenase (LDH) correlate with the tumor burden.

The treatment of testicular germ cell neoplasms is a remarkable clinical success story. Although roughly 8000 new cases of testicular cancer occur in the United States yearly, fewer than 400 men are expected to die of the disease. Seminoma, which is extremely radiosensitive and tends to remain localized for long periods, has the best prognosis. More than 95% of patients with early-stage disease can be cured. Among nonseminomatous germ cell tumors, the histologic subtype does not influence the therapy. Approximately 90% of patients achieve complete remission with aggressive chemotherapy, and most are cured. The exception is choriocarcinoma, which is associated with a poorer prognosis. With all testicular tumors, recurrences, typically in the form of distant metastases, usually occur within the first 2 years after treatment.

SUMMARY

TESTICULAR TUMORS

- Testicular neoplasms are the most common cause of painless testicular enlargement. They occur with increased frequency in association with undescended testes and with testicular dysgenesis.
- Germ cells are the source of 95% of testicular tumors, and the remainder arise from Sertoli or Leydig cells. Germ cell tumors may be composed of a single "pure" histologic pattern (60% of cases) or mixed patterns (40%).
- The most common histologic patterns of germ cell tumors are seminoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma. Mixed tumors contain more than one element, most commonly embryonal carcinoma, teratoma, and yolk sac tumor.
- Clinically, testicular germ cell tumors are divided into two groups: seminomas and nonseminomatous tumors. Seminomas remain confined to the testis for a long time and spread mainly to paraaortic nodes; distant spread is rare. Nonseminomatous tumors tend to spread earlier, by both lymphatics and blood vessels.
- HCG is produced by syncytiotrophoblasts and is always elevated in patients with choriocarcinomas and those with seminomas containing syncytiotrophoblasts. AFP is elevated when there is a yolk sac tumor component.

PROSTATE

The prostate can be divided into biologically distinct regions, the most important of which are the peripheral and transition zones (Fig. 18.10). The types of proliferative lesions are different in each region. For example, most hyperplastic lesions arise in the inner transition zone, while most carcinomas (70%–80%) arise in the peripheral zones. As a result, carcinomas are often detected by rectal examination, whereas hyperplasias are more likely to cause urinary obstruction. The normal prostate contains glands with two cell layers, a flat basal cell layer and an overlying columnar secretory cell layer. Surrounding prostatic stroma contains a mixture of smooth muscle and fibrous tissue. The prostate is involved by infectious, inflammatory, hyperplastic, and neoplastic disorders, of which prostate cancer is by far the most important clinically.

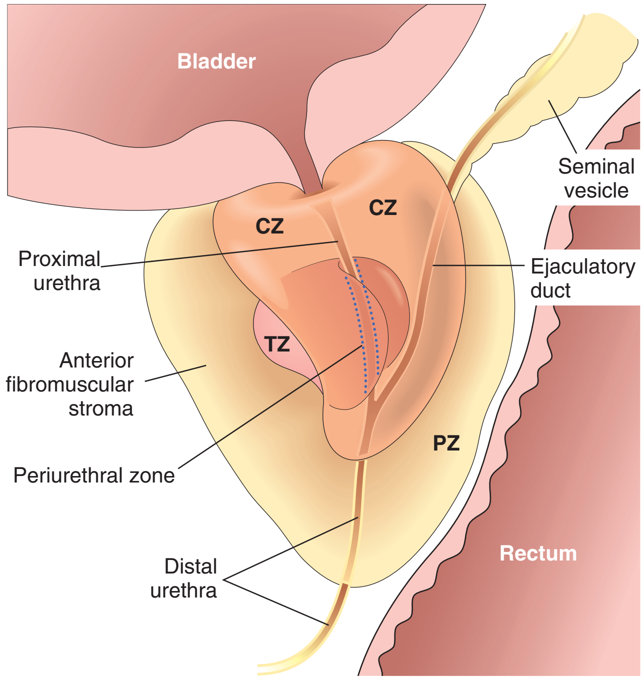

Fig. 18.10 Adult prostate. The normal prostate contains several distinct regions, including a central zone (CZ), a peripheral zone (PZ), a transitional zone (TZ), and a periurethral zone. Most carcinomas arise from the peripheral glands of the organ, whereas nodular hyperplasia arises from more centrally situated glands.

Prostatitis

Prostatitis is divided into three categories: (1) *acute bacterial prostatitis* (2%–5% of cases), caused by the same organisms associated with other acute urinary tract infections; (2) *chronic bacterial prostatitis* (2%–5% of cases), also caused by common uropathogens; and (3) *chronic pelvic pain syndrome* (90%–95% of cases). The latter can be subdivided into inflammatory cases, which are associated with leukocytes in prostatic secretions, and noninflammatory cases, in which leukocytes are absent.

The diagnosis of prostatitis is not typically based on biopsy, as the histologic findings are nonspecific and biopsy of an infected prostatitis can result in sepsis. The exception is *granulomatous prostatitis,* which may produce prostatic induration, leading to biopsy to rule out prostate cancer. In the United States, the most common cause of granulomatous prostatitis is instillation of Bacille Calmette-Guérin (BCG) within the bladder for treatment of

superficial bladder cancer. BCG is an attenuated tuberculosis strain that produces a granulomatous immune reaction that is histologically indistinguishable from tuberculosis. Prostatic tuberculosis also occurs but is rare in the Western world. Fungal granulomatous prostatitis is typically seen only in immunocompromised hosts. *Nonspecific granulomatous prostatitis* is relatively common and stems from a foreign-body reaction to fluids that leak into tissue from ruptured prostatic ducts and acini. Postsurgical prostatic granulomas also may be seen.

Clinical Features

Acute bacterial prostatitis presents with sudden onset of fever, chills, dysuria, perineal pain, and bladder outlet obstruction; it may be complicated by sepsis. If acute prostatitis is suspected, digital rectal examination is contraindicated, as pressure on the boggy, exquisitely tender prostate can cause bacteremia. *Chronic bacterial prostatitis* usually is associated with recurrent urinary tract infections bracketed by asymptomatic periods. Presenting manifestations include low back pain, dysuria, and perineal and suprapubic discomfort. Both acute and chronic bacterial prostatitis is treated with antibiotics. *Chronic pelvic pain syndrome* is characterized by chronic pain localized to the perineum, suprapubic area, and penis. Pain during or after ejaculation is a prominent finding. The etiology is uncertain, and it is a diagnosis of exclusion; indeed, it is not even clear if the pain is related to an abnormality of the prostate. Therapy for chronic pelvic pain syndrome is empirical and depends on the nature of the symptoms.

SUMMARY

PROSTATITIS

- Bacterial prostatitis may be acute or chronic; the responsible organism usually is *E. coli* or another gram-negative rod.
- Chronic pelvic pain syndrome, despite shared symptomatology with chronic bacterial prostatitis, is of unknown etiology and difficult to treat.
- Granulomatous prostatitis may be either infectious (e.g., following treatment with BCG) or noninfectious.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is an extremely common cause of prostatic enlargement resulting from proliferation of of stromal and glandular elements. It is present in a significant number of men by 40 years of age, and its frequency rises progressively thereafter, reaching 90% by the eighth decade of life. The enlargement of the prostate in men with BPH is an important cause of urinary obstruction.

Although the cause of BPH is incompletely understood, excessive androgen-dependent growth of stromal and glandular elements has a central role. BPH does not occur in males who are castrated before the onset of puberty or in males with genetic diseases that block androgen activity. Dihydrotestosterone (DHT), the ultimate mediator of prostatic growth, is synthesized in the prostate from circulating testosterone by the action of the enzyme *5α-reductase, type 2*. DHT binds to nuclear androgen receptors, which regulate the expression of genes that support the growth and survival of prostatic epithelium and stromal cells. Although testosterone can also bind to androgen receptors and stimulate growth, DHT is 10 times more potent.

MORPHOLOGY

BPH virtually always occurs in the inner transition zone of the prostate. The affected prostate is enlarged, typically weighing between 60 and 100 g, and contains many well-circumscribed nodules that bulge from the cut surface (Fig. 18.11). The nodules may appear solid or contain cystic spaces, the latter corresponding to dilated glands. The urethra is usually compressed, often to a narrow slit, by the hyperplastic nodules. In some cases, hyperplastic glandular and stromal elements lying just under the epithelium of the proximal prostatic urethra project into the bladder lumen as a pedunculated mass, producing a ball-valve type of urethral obstruction.

Microscopically, the hyperplastic nodules are composed of variable proportions of proliferating glandular elements and fibromuscular stroma. The hyperplastic glands are lined by tall, columnar epithelial cells and a peripheral layer of flattened basal cells (Fig. 18.12). The glandular lumina often contain laminated proteinaceous secretory material known as corpora amylacea.

Clinical Features

Because BPH preferentially involves the inner portions of the prostate, the most common manifestations are related to lower urinary tract obstruction, often in the form of difficulty in starting the stream of urine (hesitancy)

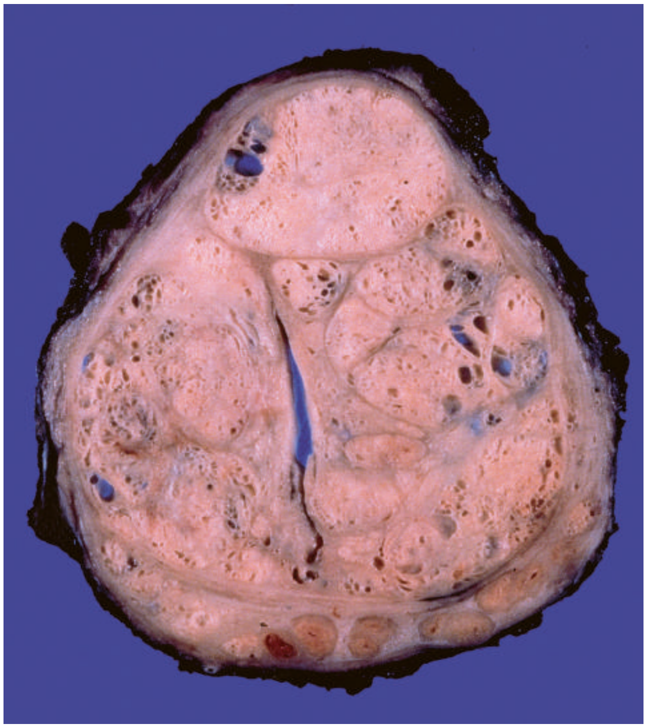

Fig. 18.11 Nodular prostatic hyperplasia. Well-defined nodules compress the urethra into a slitlike lumen.

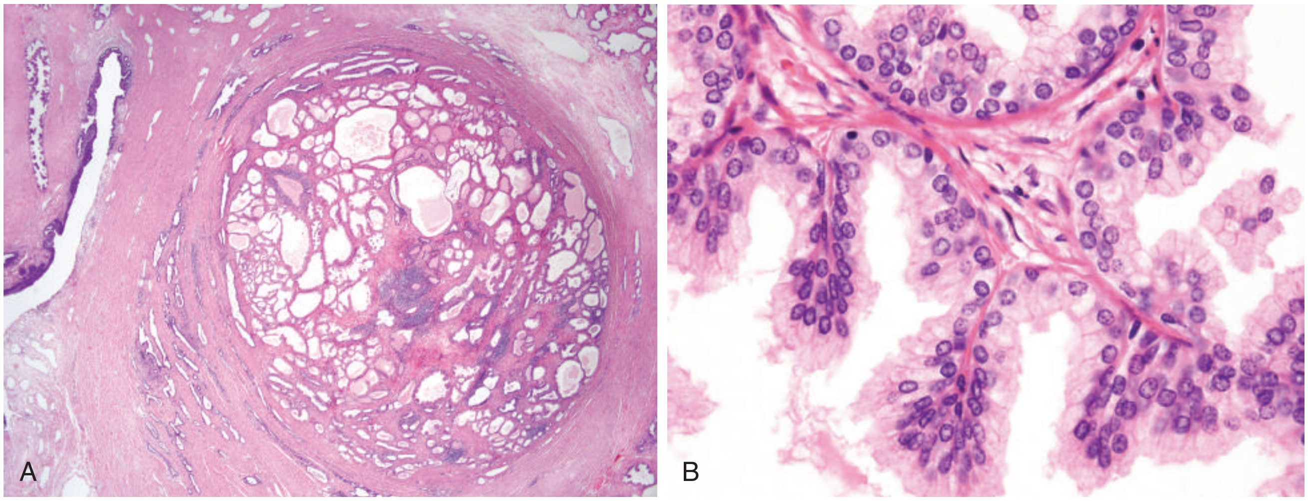

Fig. 18.12 Nodular hyperplasia of the prostate. (A) Low-power photomicrograph demonstrates a well-demarcated nodule at the right of the field, with a portion of urethra seen to the left. In other cases of nodular hyperplasia, the nodularity is caused predominantly by stromal, rather than glandular, proliferation. (B) Higher-power photomicrograph demonstrates the morphology of the hyperplastic glands, which are large and have papillary infoldings.

and intermittent interruption of the urinary stream while voiding. These symptoms frequently are accompanied by urinary urgency, frequency, and nocturia, all indicative of bladder irritation. Clinical manifestations of prostatic hyperplasia occur in only about 10% of men with pathologic evidence of BPH. The presence of residual urine in the bladder due to chronic obstruction increases the risk for urinary tract infections. In some affected men, BPH leads to complete urinary obstruction, with resultant painful distention of the bladder and, in the absence of appropriate treatment, hydronephrosis (Chapter 14). Initial treatment is pharmacologic, using targeted therapeutic agents that inhibit the formation of DHT from testosterone (such as 5-alpha reductase inhibitors) or that relax prostatic smooth muscle by blocking α_1-adrenergic receptors. Various surgical techniques are reserved for severely symptomatic cases that are recalcitrant to medical therapy.

SUMMARY

BENIGN PROSTATIC HYPERPLASIA

- BPH is characterized by proliferation of benign stromal and glandular elements. DHT, an androgen derived from testosterone, is the major hormonal stimulus for proliferation.
- BPH originates in the periurethral transition zone. The hyperplastic nodules exhibit variable proportions of stroma and glands. Hyperplastic glands are lined by two cell layers, an inner columnar layer and an outer layer composed of flattened basal cells.
- Clinical findings result from urinary tract obstruction and include hesitancy, urgency, nocturia, and poor urinary stream. Chronic obstruction predisposes to recurrent urinary tract infections.

Carcinoma of the Prostate

Adenocarcinoma of the prostate and is the most common form of cancer in men, accounting for 27% of cancer cases in the United States in 2014. Its is uncommon before the age of 50 years. Over the past several decades, mortality from prostate cancer has decreased significantly, and it currently causes only 10% of cancer deaths in the United States.

The relatively low rate of mortality in men with prostate cancer is related in part to increased detection of the disease through screening (discussed later), but how effective screening is at saving lives is controversial. This seeming paradox is related to the wide variation in the natural history of prostate cancer, from aggressive and rapidly fatal to indolent disease of no clinical significance. Indeed, prostate carcinoma commonly is found incidentally at autopsy in men dying of other causes, and many more men die with prostate cancer than of prostate cancer. It is not currently possible to identify the tumors that will be "bad actors" with certainty; thus, while some men are no doubt saved by early detection and treatment of their prostate cancers, it is equally certain that others are being "cured" of clinically inconsequential tumors.

Pathogenesis

Clinical and experimental observations suggest that androgens, heredity, environmental factors, and acquired somatic mutations have roles in the pathogenesis and progression of prostate cancer.

- *Androgens* are of central importance. Cancer of the prostate does not develop in males who are castrated before puberty, indicating that androgens somehow provide the "soil," the cellular context, within which prostate cancer develops. This dependence on androgens extends to established cancers, which often regress for a time in response to surgical or chemical castration. Notably, *tumors that are resistant to anti-androgen therapy often acquire androgen receptor gene amplifications or mutations that permit androgen receptors to activate the expression of their target genes despite therapy.* Thus, tumors that recur in the face of anti-androgen therapies still depend on gene products regulated by androgen receptors for their growth and survival. However, while prostate cancer, like normal prostate, is dependent on androgens for its

survival, there is no evidence that androgens initiate carcinogenesis, nor are androgen levels associated with prostate cancer risk.

- *Heredity* also contributes, as there is an increased risk among first-degree relatives of patients with prostate cancer. Prostate cancer is uncommon in Asians and its incidence is highest among African-Americans and in Scandinavian countries. Aggressive, clinically significant disease is more common in African-Americans than in Caucasians. Genome-wide association studies have identified a number of genetic variants that are associated with increased risk for developing prostate cancer. Although each variant carries only a small increased risk, the effect is multiplicative, such that men with multiple risk alleles may have up to a 5-fold increase in risk compared to the general population.
- *Environment* also plays a role, as evidenced by the fact that in Japanese immigrants to the United States the incidence of the disease rises (although not to the level seen in native-born Americans). Also, as the diet in Asia becomes more westernized, the incidence of clinically significant prostate cancer in this region of the world is increasing. However, the relationship between specific dietary components and prostate cancer risk is unclear.
- *Acquired genetic aberrations,* as in other cancers, are the actual drivers of cellular transformation. Copy number variations in specific chromosomal regions and gene rearrangements are frequently seen in primary tumors. The most common gene rearrangements in prostate cancer create fusion genes consisting of the androgen-regulated promoter of the *TMPRSS2* gene and the coding sequence of *ETS* family transcription factors. ***TMPRSS2-ETS*** **fusion genes are found in approximately 40% to 60% of prostate cancers in Caucasian populations, and they occur relatively early in tumorigenesis.** Notably, the prevalence of these rearrangements is lower among African-Americans and other ethnic groups. Other mutations commonly lead to activation of the PI3K/AKT signaling pathway (Chapter 6); of these, the most common are loss-of-function mutations involving the tumor suppressor PTEN, which acts as a brake on PI3K activity.

MORPHOLOGY

Carcinomas detected clinically are usually not visible grossly. More advanced lesions appear as firm, gray-white lesions with ill-defined margins that infiltrate the adjacent gland (Fig. 18.13).

Most prostate cancers are **moderately differentiated adenocarcinomas** that produce well-defined glands. The glands typically are smaller than benign glands and are lined by a single uniform layer of cuboidal or low columnar epithelium, lacking the basal cell layer seen in benign glands. In further contrast with benign glands, malignant glands are crowded together and characteristically lack branching and papillary infolding. The cytoplasm of the tumor cells ranges from pale-clear (as in benign glands) to a distinctive amphophilic (dark purple) appearance. Nuclei are enlarged and often contain one or more prominent nucleoli (Fig. 18.14). Some variation in nuclear size and shape is usual, but in general, pleomorphism is not marked. Mitotic figures are uncommon. With increasing grade, irregular or ragged glandular structures, cribriform glands, sheets of cells, or infiltrating individual cells are present. In approximately 80% of cases, prostatic tissue removed for carcinoma also harbors presumptive precursor lesions, referred to as *high-grade prostatic intraepithelial neoplasia (HGPIN)*. Many of the molecular changes seen in invasive cancers are also seen in HPIN.

Prostate cancer is graded by the **Gleason system,** created in 1967 and updated in 2014. According to this system, prostate cancers are stratified into five grades on the basis of glandular patterns of differentiation. Grade 1 represents the most well differentiated tumors, and grade 5 tumors show no glandular differentiation. Most tumors are patterns 3, 4, or 5. Since the majority of tumors contain more than one pattern, a primary grade is assigned to the dominant pattern and a secondary grade to the next most frequent pattern. The two numerical grades are then added to obtain a combined Gleason score. Tumors with only one pattern are treated as if their primary and secondary grades are the same, and, hence, the number is doubled. Thus, the most differentiated tumors have a Gleason score of 2 (1 + 1), and the least differentiated tumors merit a score of 10 (5 + 5). A new grading system also based on glandular pattern was recently accepted by the World Health Organization (WHO) to be used initially in conjunction with the Gleason system; it ranges from 1 (excellent prognosis) to 5 (poor prognosis).

Fig. 18.13 Adenocarcinoma of the prostate. Carcinomatous tissue is seen on the posterior aspect *(lower left)*. Note the solid whiter tissue of cancer, in contrast with the spongy appearance of the benign peripheral zone on the contralateral side.

Clinical Features

In the United States, most prostate cancers are small, nonpalpable, asymptomatic lesions discovered on needle biopsy performed to investigate an elevated serum prostate-specific antigen (PSA) level (discussed later). Some 70% to 80% of prostate cancers arise in the outer (peripheral) glands, and a subset of these may be palpable as irregular hard nodules on digital rectal examination. A minority of carcinomas is discovered unexpectedly during histologic examination of prostate tissue removed by transurethral resection for BPH. Because of the peripheral location, prostate cancer is less likely than BPH to cause urethral obstruction in its initial stages. Locally advanced cancers often infiltrate the seminal vesicles and periurethral zones

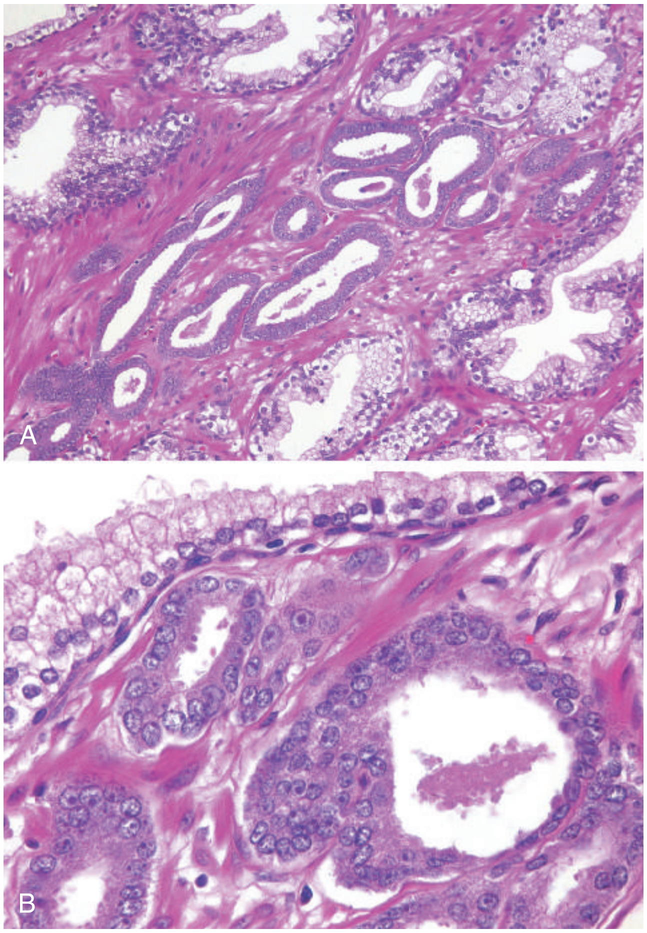

Fig. 18.14 (A) Adenocarcinoma of the prostate demonstrating small glands crowded in between larger benign glands. (B) Higher magnification shows several small malignant glands with enlarged nuclei, prominent nucleoli, and dark cytoplasm, as compared with the larger, benign gland *(top)*.

of the prostate and may invade the adjacent soft tissues, the wall of the urinary bladder, or (less commonly) the rectum. Bone metastases, particularly to the axial skeleton, are frequent late in the disease and typically cause osteoblastic (bone-producing) lesions that can be detected on *radionuclide bone scans.*

The PSA assay is the most widely used test in the diagnosis and management of prostate cancer, but it suffers from a number of limitations. PSA is a product of prostatic epithelium and is normally secreted in the semen. Although PSA screening can detect prostate cancers early in their course, studies of the natural history of the disease (so-called "watch-and-wait studies") have confirmed that many prostate cancers are clinically insignificant, requiring no treatment, sometimes for decades. Overtreatment of these indolent cancers can cause significant morbidity, particularly erectile dysfunction and incontinence. A second limitation of PSA as a biomarker is that it is not cancer-specific. BPH, prostatitis, prostatic infarcts, instrumentation of the prostate, and ejaculation all may increase serum PSA levels. Conversely, 20% to 40% of patients with organ-confined prostate cancer have PSA values below the cutoffs that are used to identify patients who are likely to have prostate cancer.

Because of these problems, PSA assays are being reappraised as screening tests. By contrast, once cancer is diagnosed, serial measurements of PSA are of great value in assessing the response to therapy. For example, a rising PSA level after radical prostatectomy or radiotherapy for localized disease is indicative of recurrent or disseminated disease.

The most common treatments for clinically localized prostate cancer are radical prostatectomy and radiotherapy. The prognosis after radical prostatectomy is based on the pathologic stage, whether the margins of the resected specimens are free of tumor, and Gleason grade. The Gleason grade, clinical stage, and serum PSA values are important predictors of outcome after radiotherapy. Because many prostate cancers follow an indolent course, active surveillance ("watchful waiting") is an appropriate approach for older men, patients with significant comorbidity, or even some younger men with low serum PSA values and small, low-grade cancers. Advanced metastatic carcinoma is treated by androgen deprivation, either by orchiectomy or by administration of synthetic agonists of luteinizing hormone–releasing hormone (LHRH). In addition, there are many new therapies that reduce androgen synthesis or signaling in metastatic prostate cancer. Although anti-androgen therapy induces remissions, androgen-independent clones almost invariably emerge, leading to rapid disease progression and death. As discussed earlier, these mutant clones commonly continue to express many genes that in normal prostate are androgen-dependent, suggesting that mechanisms arise to reactivate androgen signaling, even in the context of androgen deprivation therapy.

SUMMARY

CARCINOMA OF THE PROSTATE

- Carcinoma of the prostate is a common cancer of older men between 65 and 75 years of age.
- Prostate carcinomas range from indolent lesions that will never cause harm to aggressive fatal tumors, which are more common in African-Americans.
- The most common acquired mutations in prostatic carcinomas create *TPRSS2-ETS* fusion genes or act to enhance PI3K/AKT signaling, which promotes tumor cell growth and survival.
- Carcinomas of the prostate arise most commonly in the outer, peripheral zone of the gland and may be palpable by rectal examination.
- Grading of prostate cancer by the Gleason system correlates with pathologic stage and prognosis.
- Serum PSA measurement is a controversial cancer screening test, but has clear value in monitoring progressive or recurrent prostate cancer.

URETER, BLADDER, AND URETHRA

The renal pelves, ureters, bladder, and urethra are lined by specialized multi-layer transitional epithelium called urothelium. Beneath the mucosa are the lamina propria

and, deeper yet, the muscularis propria (detrusor muscle), which makes up the bladder wall. Clinically significant disorders involving these organs include congenital aberrations, infectious and other inflammatory diseases, and neoplasms.

Ureter

Disorders of the ureter are uncommon and include congenital disorders, neoplasms, and reactive conditions. A few merit brief mention.

- *Ureteropelvic* junction (UPJ) obstruction, a congenital disorder, results in hydronephrosis. It usually manifests in infancy or childhood and is much more common in boys than in girls. It is the most frequent cause of hydronephrosis in infants and children.
- *Malignant* tumors of the ureter are pathologically similar to those arising in the renal pelvis, calyces, and bladder (discussed later). Most are urothelial carcinomas.
- *Retroperitoneal fibrosis* is an uncommon cause of ureteral narrowing or obstruction characterized by a fibrous proliferative inflammatory process encasing the retroperitoneal structures and causing hydronephrosis. The disorder occurs in middle to old age. At least a proportion of these cases occur in association with IgG4-related disease, characterized by fibroinflammatory lesions rich in IgG4-secreting plasma cells (Chapter 5). Other cases are associated with drug exposures (ergot derivatives, adrenergic blockers), radiation, infection, prior surgery, or malignant disease (lymphomas, urinary tract carcinomas). Most cases, however, have no obvious cause and are considered primary, or idiopathic (Ormond disease).

Urinary Bladder

Nonneoplastic Conditions

A bladder or vesical *diverticulum* consists of a pouchlike evagination of the bladder wall. Diverticula may be congenital but more commonly are acquired lesions that arise as a consequence of persistent urethral obstruction caused, for example, by benign prostatic hyperplasia. Although most diverticula are small and asymptomatic, they sometimes lead to urinary stasis predisposing to recurrent urinary tract infections and bladder stone formation.

Cystitis takes many forms.

- *Bacterial cystitis* is common, particularly in women. The most common etiologic agents are coliform bacteria.
- *Hemorrhagic cystitis* may occur in patients receiving cytotoxic anti-tumor drugs, such as cyclophosphamide, and sometimes complicates adenovirus infection.
- *Interstitial cystitis* causes a chronic pelvic pain syndrome, typically in women. It is characterized by suprapubic pain that increases with bladder filling and is relieved by bladder emptying, leading to very frequent urination during both day and night. Other symptoms include urgency, hematuria, and dysuria. Cystoscopic findings are nonspecific and include petechial hemorrhages. Up to 50% of patients have spontaneous remissions. Late in the course, transmural fibrosis may ensue, leading to a contracted bladder.
- *Malakoplakia* is an uncommon inflammatory disease that most commonly occurs in the bladder. It results from defects in the phagocytic or degradative function of macrophages. As a result of this defect, undigested bacterial products accumulate within distended phagosomes, which are seen in histologic sections as abundant granular material within the cytoplasm of macrophages. The abnormal macrophages also contain laminated mineralized concretions known as *Michaelis-Gutmann bodies,* which result from deposition of calcium salts in the enlarged lysosomes.
- *Polypoid cystitis* is an inflammatory condition resulting from irritation to the bladder mucosa in which the urothelium is thrown into broad bulbous polypoid projections as a result of marked submucosal edema. Polypoid cystitis may be confused with papillary urothelial carcinoma both clinically and histologically.

Transitional epithelium lining the bladder may undergo various forms of metaplasia. Nests of urothelium *(Brunn nests)* sometimes grow downward into the lamina propria. Here, their central epithelial cells may variously differentiate into a cuboidal or columnar epithelium lining *(cystitis glandularis);* cystic spaces filled with clear fluid lined by flattened urothelium *(cystitis cystica);* or goblet cells resembling intestinal mucosa *(intestinal metaplasia).* As a response to injury, the urothelium often undergoes *squamous metaplasia,* which must be differentiated from normal glycogenated squamous epithelium, commonly found at the trigone in women.

Neoplasms

Bladder cancer accounts for approximately 5% of cancers and 3% of cancer deaths in the United States. The vast majority of bladder cancers (95%–97% in the United States; 60%–90% in Africa) are urothelial carcinomas. Squamous cell carcinomas represent about 3% to 7% of bladder cancers in the United States but are much more common in countries such as Egypt, where urinary schistosomiasis is endemic. Adenocarcinomas of the bladder are rare. Carcinoma of the bladder is more common in men than in women, in industrialized than in developing nations, in urban than in rural dwellers, and in whites than in African-Americans. About 80% of patients are between 50 and 80 years of age.

Pathogenesis

Environmental factors are important in the pathogenesis of urothelial carcinoma and include *cigarette smoking, various occupational carcinogens, and prior cyclophosphamide or radiation therapy.* A family history of bladder cancer is a known risk factor. Squamous cell carcinoma is related to *Schistosoma haematobium* infections in areas where it is endemic. Cancers occurring in the setting of schistosoma infections arise in a background of chronic inflammation, which you will recall provides the "soil" for the development of a number of different cancers (Chapter 6).

Acquired genetic aberrations have been identified in urothelial carcinoma. Based on these observations, a model for bladder carcinogenesis has been proposed in which the tumor is initiated by deletions of tumor-suppressor genes on 9p and 9q, leading to the formation of superficial

papillary tumors, which may then acquire *TP53* mutations and progress to invasive disease. A second pathway, possibly initiated by *TP53* mutations, leads first to carcinoma in situ and then, with loss of genes from chromosome 9, progresses to invasion. Additional genetic alterations in superficial tumors include mutations in telomerase, as well as mutations in fibroblast growth factor receptor 3 (FGFR3) and components of the RAS and PI3K/AKT pathways. Muscle invasive tumors often have mutations involving both *TP53* and *RB* (Chapter 6).

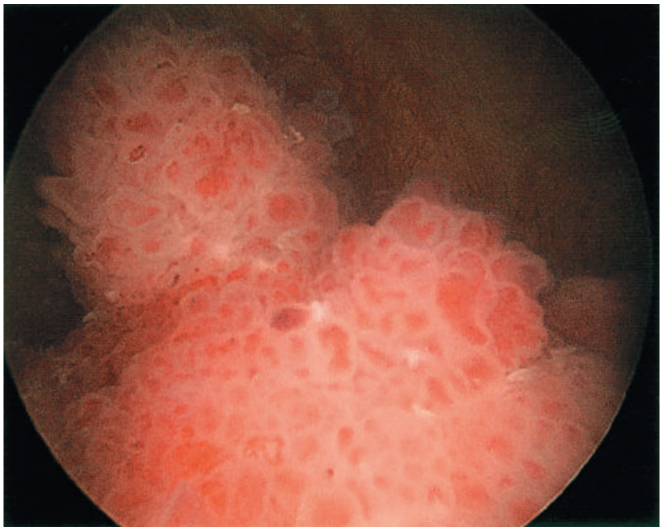

Fig. 18.16 Cystoscopic appearance of a papillary urothelial tumor, resembling coral, within the bladder.

MORPHOLOGY

Two distinct precursor lesions of invasive urothelial carcinoma are recognized (Fig. 18.15). The most common is a noninvasive papillary tumor (Fig. 18.16). The other precursor is carcinoma in situ (CIS), which is discussed later. In about one-half of patients with invasive bladder cancer, no precursor lesion is found; in such cases, it is presumed that the precursor lesion was overgrown by the high-grade invasive component.

The most important prognostic factor in noninvasive papillary urothelial neoplasms is their grade, which is based on both architectural and cytologic features. As shown in Table 18.2, the grading system subclassifies tumors as follows: (1) **papilloma;** (2) **papillary urothelial neoplasm of low malignant potential (PUNLMP);** (3) **low-grade papillary urothelial carcinoma;** and (4) **high-grade papillary urothelial carcinoma** (Fig. 18.17). These exophytic papillary neoplasms are to be distinguished from **inverted urothelial papilloma,** which is entirely benign and not associated with an increased risk for subsequent carcinoma.

CIS is defined by the presence of overtly malignant-appearing cells within a flat urothelium (Fig. 18.18). Like high-grade papillary urothelial carcinoma, the tumor cells in CIS lack cohesiveness and are shed into the urine, where they can be detected by cytology. CIS commonly is multifocal and sometimes involves most of the bladder surface or extends into the ureters and urethra. Without treatment, 50% to 75% of CIS cases progress to invasive cancer.

Invasive urothelial cancer associated with papillary urothelial cancer (usually of high grade) or CIS may superficially invade the lamina propria or extend more deeply into underlying muscle. **The extent of invasion and spread (staging) at the time of initial diagnosis is the most important prognostic factor.** Almost all infiltrating urothelial carcinomas are high grade.

Squamous cell carcinomas of the bladder typically show extensive keratinization and are nearly always associated with chronic bladder irritation and infection. Adenocarcinomas of the bladder are histologically identical to adenocarcinomas seen in the gastrointestinal tract. Some arise from urachal remnants in the dome of the bladder or in association with extensive intestinal metaplasia.

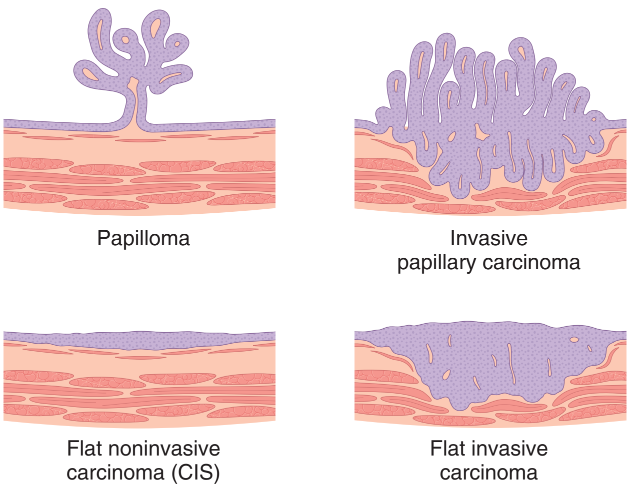

Fig. 18.15 Morphologic patterns of urothelial neoplasia.

Table 18.2 Noninvasive Papillary Urothelial Neoplasms

Neoplasm	Recurrences	Coexistent Invasion	Progression	Death
Papilloma	Rare	None	Rare*	None
PUNLMP	30%	None	2%	None
LGUC	45%	<10%	8%–10%	2%–3%
HGUC	45%	Up to 80%	30%	20%

HGUC, High-grade papillary urothelial carcinoma; *LGUC*, low-grade papillary urothelial carcinoma; *PUNLMP*, papillary urothelial neoplasia of uncertain malignant potential.
*Rare cases of progression have occurred in immunocompromised patients.

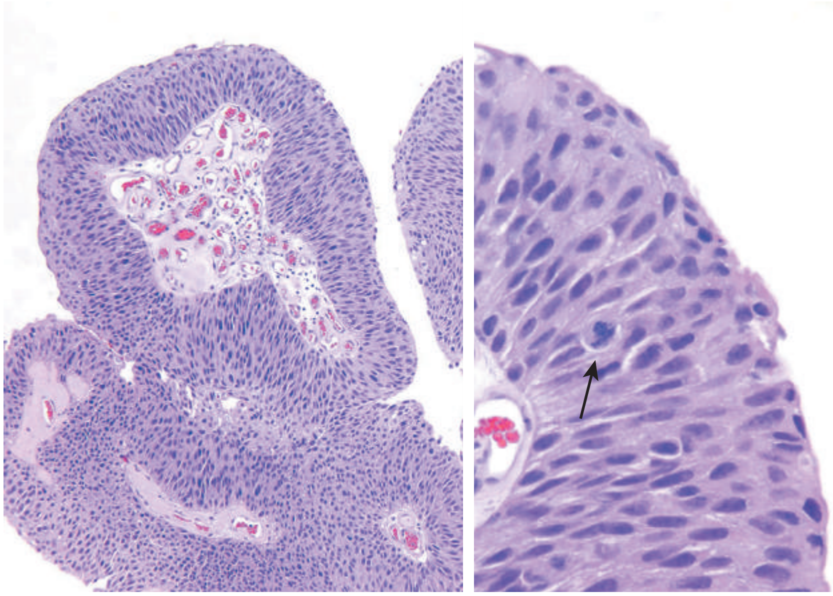

Fig. 18.17 Noninvasive low-grade papillary urothelial carcinoma. Higher magnification *(right)* shows slightly irregular nuclei with scattered mitotic figures *(arrow)*.

Clinical Features

Bladder tumors most commonly present with *painless hematuria.* Patients with urothelial tumors, whatever their grade, have a tendency to develop new tumors after excision, and recurrences may exhibit a higher grade. The risk for recurrence is related to several factors, including tumor size, stage, grade, multifocality, mitotic index, and associated dysplasia and/or CIS in the surrounding mucosa. Many recurrent tumors arise at sites different than that of the original lesion, yet share the same clonal abnormalities as those of the initial tumor; thus, these are true recurrences that stem from shedding and implantation of the original tumor cells at new sites. **Whereas high-grade papillary urothelial carcinomas frequently are associated with either concurrent or subsequent invasive urothelial carcinoma, lower-grade papillary urothelial neoplasms often recur but infrequently invade** (see Table 18.2).

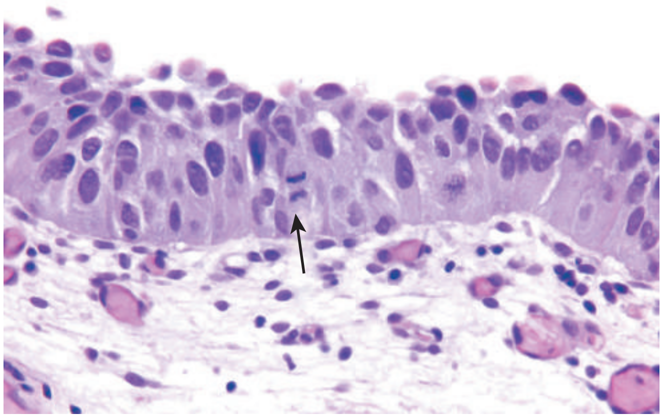

Fig. 18.18 Carcinoma in situ (CIS) with enlarged hyperchromatic nuclei and a mitotic figure *(arrow)*.

Treatment of bladder cancer depends on tumor grade and stage and on whether the lesion is flat or papillary. For small, localized papillary tumors that are not high-grade, transurethral resection is both diagnostic and therapeutically sufficient. Patients with tumors that are at high risk for recurrence or progression typically receive topical immunotherapy consisting of intravesical instillation of an attenuated strain of the tuberculosis bacillus called *Bacillus Calmette-Guérin (BCG),* sometimes followed by intravesical chemotherapy. BCG elicits a granulomatous reaction that also triggers an effective local anti-tumor immune response. Patients are closely monitored for tumor recurrence with periodic cystoscopy and urine cytologic studies. Radical cystectomy is reserved for (1) tumor invading the muscularis propria; (2) CIS or high-grade papillary cancer refractory to BCG; and (3) CIS extending into the prostatic urethra and down the prostatic ducts, where BCG cannot come in contact the neoplastic cells. Advanced bladder cancer is treated using chemotherapy, which can palliate but is seldom curative.

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases (STDs) have complicated human existence for centuries. Globally, approximately 15 million new cases of STD occur every year; of these, 4 million affect 15- to 19-year-olds, and 6 million affect 20- to 24-year-olds. Women are far more likely to become infected by an STD and to be asymptomatic. Of the 10 leading infectious diseases that require notification of the Centers for Disease Control and Prevention (CDC) in the United States, five—chlamydial infection, gonorrhea, acquired immunodeficiency syndrome (AIDS), syphilis, and hepatitis B—are STDs (Table 18.3). In the United States, the two most common STDs are genital herpes and genital HPV infection, but these do not require CDC notification.

Table 18.3 Classification of Important Sexually Transmitted Diseases

	Associated Disease(s)—Distribution by Gender		
Pathogen	**Males**	**Both**	**Females**
Viruses			
Herpes simplex virus		Primary and recurrent herpes, neonatal herpes	
Hepatitis B virus		Hepatitis	
Human papillomavirus	Cancer of penis (some cases)	Condyloma acuminatum, anal cancer, oropharyngeal carcinoma	Cervical dysplasia and cancer, vulvar cancer
Human immunodeficiency virus		Acquired immunodeficiency syndrome	
Chlamydiae			
Chlamydia trachomatis	Urethritis, epididymitis, proctitis	Lymphogranuloma venereum	Urethral syndrome, cervicitis, bartholinitis, salpingitis, and sequelae
Mycoplasmas			
Ureaplasma urealyticum	Urethritis		Cervicitis
Bacteria			
Neisseria gonorrhoeae	Epididymitis, prostatitis, urethral stricture	Urethritis, proctitis, pharyngitis, disseminated gonococcal infection	Cervicitis, endometritis, bartholinitis, salpingitis, and sequelae (infertility, ectopic pregnancy, recurrent salpingitis)
Treponema pallidum		Syphilis	
Haemophilus ducreyi		Chancroid	
Calymmatobacterium granulomatis		Granuloma inguinale (donovanosis)	
Protozoa			
Trichomonas vaginalis	Urethritis, balanitis		Vaginitis

Several of these entities, such as human immunodeficiency virus (HIV) infection, HPV infection, hepatitis B, and infection with *E. histolytica,* are discussed in other chapters.

Syphilis

Syphilis, or *lues,* is a chronic venereal infection caused by the spirochete *Treponema pallidum*. First recognized in epidemic form in 16th-century Europe as the Great Pox, syphilis is endemic in all parts of the world. In the United States, 20,000 cases of primary and secondary syphilis were reported to the CDC in 2014, representing almost a threefold increase since the year 2000. The increase for the most part can be attributed to the increased incidence in men who have sex with men. During 2013-2014, the incidence began to increase in women as well, raising the concern that there may be an impending increase in cases of congenital syphilis acquired from the mother. A strong racial disparity is evident; African Americans are affected six times more often than whites. Syphilis also is more common in HIV-infected patients, in whom syphilis is more likely to progress to organ involvement and neurosyphilis.

T. pallidum is a fastidious organism whose only natural host is man. The usual source of infection is contact with a cutaneous or mucosal lesion in a sexual partner in the early (primary or secondary) stages of syphilis. The organism is transmitted from such lesions during sexual activity through minute breaks in the skin or mucous membranes of the uninfected partner. In congenital cases, *T. pallidum* is transmitted across the placenta from mother to fetus, particularly during the early stages of maternal infection.

Once introduced into the body, the organisms rapidly disseminate to distant sites through lymphatics and the blood, even before the appearance of lesions at the primary inoculation site. This widespread dissemination accounts for the protean manifestations of the disease (Fig. 18.19), which in adults can be divided into primary, secondary, and tertiary stages.

- *Primary syphilis*. Several weeks after infection (mean, 21 days), a primary lesion, termed a *chancre,* appears at the point of spirochete entry. Systemic dissemination of organisms occurs during this period, while the host mounts an immune response. Two types of antibodies are formed: antibodies that cross-react with host constituents (nontreponemal antibodies) and antibodies to specific treponemal antigens. This humoral response, however, fails to eradicate the organisms.
- *Secondary syphilis.* The chancre of *primary syphilis* resolves spontaneously over a period of 4 to 6 weeks and is followed in approximately 25% of untreated patients by the development of secondary syphilis. The manifestations of secondary syphilis, discussed in greater detail later, include generalized lymphadenopathy and mucocutaneous lesions. *The mucocutaneous lesions of both primary and secondary syphilis are teeming with spirochetes and are highly infectious.* Like the chancre, the lesions of secondary syphilis resolve even without antimicrobial therapy, at which point patients are said to be in *early latent-phase syphilis.*
- *Tertiary syphilis*. Patients with untreated syphilis next enter an asymptomatic, *late latent* phase of the illness, defined as being more than 1 year after the initial infection. In about one third of cases, new symptoms develop over the next 5 to 20 years. This late symptomatic phase, or *tertiary syphilis,* is marked by the development of lesions in the cardiovascular system, central nervous system, or, less frequently, other organs. Spirochetes are much more difficult to demonstrate during the later

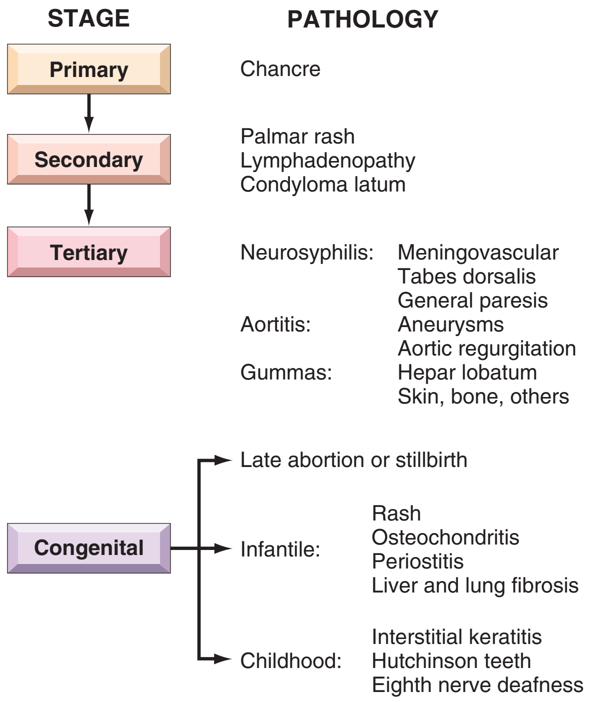

Fig. 18.19 Protean manifestations of syphilis.

stages of disease, and patients are accordingly much less likely to be infectious than are those in the primary or secondary stages of disease.

T. pallidum also may be transmitted across the placenta from an infected mother to the fetus at any time during pregnancy, leading to the development of *congenital syphilis*. The likelihood of transmission is greatest during the early (primary and secondary) stages of disease, when spirochetes are most numerous. Because the manifestations of maternal disease may be subtle, routine serologic testing for syphilis is mandatory in all pregnancies. The stigmata of congenital syphilis typically do not develop until after the fourth month of pregnancy. In the absence of treatment, as many as 40% of infected infants die in utero, typically after the fourth month. The incidence of congenital syphilis is expected to rise because infection rates in women have increased in recent years.

MORPHOLOGY

The pathognomonic microscopic lesion of syphilis is a proliferative endarteritis with an accompanying inflammatory infiltrate rich in plasma cells. Endarteritis has a central role in tissue injury at all sites involved by syphilis, but its pathogenesis is not understood; there is no evidence that the spirochetes cause any damage to host tissues directly. Instead, it is thought that the host immune response is responsible for the endothelial cell activation and proliferation that is the hallmark of the endarteritis, which eventually leads to perivascular fibrosis and luminal narrowing.

Both **primary and secondary syphilis** are associated with characteristic lesions. The **chancre** of primary syphilis is typically indurated and has been referred to as a hard chancre, to distinguish it from the soft chancre of chancroid caused by *Haemophilus ducreyi* (discussed later). The primary chancre in males usually is on the glans, corona, or perianal region. In females, multiple chancres may be present, usually on the labia or vagina as well as the perianal region. The chancre begins as a small, painless, firm papule 2 to 4 weeks after sexual exposure, which gradually enlarges to produce a painless ulcer with well-defined, indurated margins and a "clean," moist base (Fig. 18.20). Regional lymph nodes often are slightly enlarged and firm. Microscopic examination of the ulcer reveals the typical lymphocytic and plasmacytic inflammatory infiltrate and endarteritis. Spirochetes are readily demonstrable in histologic sections of early lesions with the use of standard silver stains (e.g., Warthin-Starry stains) or immunohistochemical stains specific for spirochetes. Within approximately 2 months of resolution of the chancre, the lesions

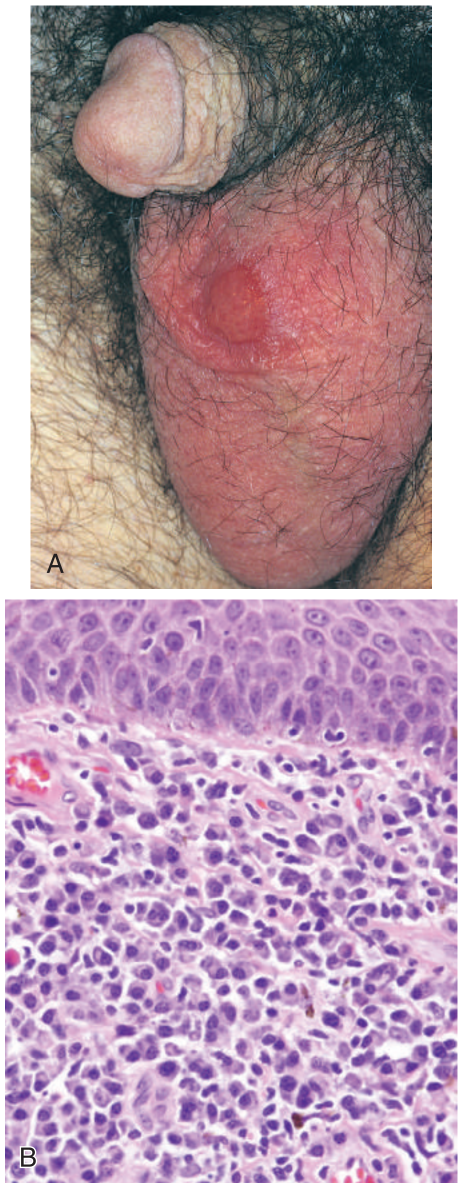

Fig. 18.20 (A) Syphilitic chancre of the scrotum. Such lesions typically are painless despite the presence of ulceration, and they heal spontaneously. (B) Histologic features of the chancre include a diffuse plasma cell infiltrate beneath squamous epithelium of skin.

of secondary syphilis appear. The manifestations of secondary syphilis are varied but typically include a combination of generalized lymph node enlargement and a variety of **mucocutaneous lesions.** Skin lesions usually are symmetrically distributed; may be maculopapular, scaly, or pustular; and characteristically involve the **palms of the hands and soles of the feet.** In moist skin areas, such as the anogenital region, inner thighs, and axillae, broad-based, elevated lesions termed **condylomata lata** may appear (not to be confused with condyloma acuminata caused by HPV) (Chapters 18 and 23). Superficial mucosal lesions resembling condylomata lata can occur anywhere but are particularly common in the oral cavity and pharynx and on the external genitalia. Histologic examination of mucocutaneous lesions during the secondary phase of the disease reveals the characteristic proliferative endarteritis and, with special stains or immunohistochemistry, spirochetes, which are often abundant. Lymphadenopathy is most common in the neck and inguinal areas. Histologic examination of enlarged nodes demonstrates hyperplasia of germinal centers accompanied by increased numbers of plasma cells or, less commonly, granulomas or neutrophils. Less common manifestations of secondary syphilis include hepatitis, renal disease, eye disease (iritis), and gastrointestinal abnormalities.

Lesions associated with **tertiary syphilis** develop in approximately one third of untreated patients, usually after a latent period of 5 years or more. These are divided into three major categories: cardiovascular syphilis, neurosyphilis, and so-called "benign" tertiary syphilis, which may occur singly or in combination. Cardiovascular syphilis takes the form of **syphilitic aortitis** and accounts for more than 80% of cases of tertiary disease; it is much more common in men than in women. Syphilitic aortitis is discussed further in Chapter 10. **Neurosyphilis** accounts for 10% of cases of tertiary syphilis overall but occurs at increased frequency in those with concomitant HIV infection; it is discussed in detail in Chapter 22. Large areas of parenchymal damage in tertiary syphilis result in the formation of a **gumma.** On microscopic examination, the gumma contains a central zone of coagulative necrosis surrounded by dense fibrous tissue containing a mixed inflammatory infiltrate composed of lymphocytes, plasma cells, activated macrophages (epithelioid cells), and occasional giant cells, features that suggest a delayed hypersensitivity reaction. Gummas occur most commonly in bone, skin, and the mucous membranes of the upper airway and mouth, but any organ may be affected. Spirochetes are only rarely demonstrable. Once common, gummas have become exceedingly rare thanks to effective antibiotics such as penicillin. They are reported now mostly in patients with AIDS.

Manifestations of **congenital syphilis** include stillbirth, infantile syphilis, and late (tardive) congenital syphilis.

- Among infants who are stillborn, the most common manifestations are hepatomegaly, bone abnormalities, pancreatic fibrosis, and pneumonitis. The liver often shows extramedullary hematopoiesis and portal tract inflammation. Changes in the bones include inflammation and disruption of the osteochondral junction in long bones and, on occasion, bone resorption and fibrosis of the flat bones of the skull. The lungs may be firm and pale as a result of the presence of inflammatory cells and fibrosis in the alveolar septa (pneumonia alba). With special stains, spirochetes are readily seen in tissue sections.
- **Infantile syphilis** refers to congenital syphilis in infants that manifests at birth or within the first few months of life. Affected infants present with chronic rhinitis (snuffles) and mucocutaneous lesions similar to those seen in secondary syphilis in adults. Visceral and skeletal changes resembling those seen in stillborn infants also may be present.
- **Late, or tardive, congenital syphilis** refers to cases of untreated congenital syphilis of more than 2 years' duration. Classic manifestations include the Hutchinson triad: notched central incisors, interstitial keratitis with blindness, and deafness from eighth cranial nerve injury. Other changes include a so-called "saber shin" deformity caused by chronic inflammation of the periosteum of the tibia, deformed molar teeth ("mulberry molars"), chronic meningitis, chorioretinitis, and gummas of the nasal bone and cartilage with a resultant "saddlenose" deformity.

Clinical Features

Syphilis remains highly sensitive to antibiotics such as penicillin, a short course of which is sufficient to treat all stages of the disease. Serology is the mainstay of diagnosis. Serologic tests for syphilis include nontreponemal antibody tests and antitreponemal antibody tests. Nontreponemal tests measure antibody to cardiolipin, an antigen that is present in both host tissues and the treponemal cell wall. These antibodies are detected by the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. Nontreponemal antibody tests are usually positive by 4 to 6 weeks of infection and are strongly positive in the secondary phase of infection. However, nontreponemal antibody test results may revert to negative during the tertiary phase or, conversely, may on occasion be persistently positive in some patients after successful treatment. Two additional points regarding nontreponemal antibody tests deserve emphasis:

- Nontreponemal antibody test results often are negative during the early stages of disease, even in the presence of a primary chancre. If there is a high degree of suspicion, these tests should be repeated in a few weeks.
- As many as 15% of positive VDRL test results are unrelated to syphilis. These false-positive results, which may be acute (transient) or chronic (persistent), increase in frequency with age and are associated with a variety of conditions, including the antiphospholipid antibody syndrome (Chapter 4).

Treponemal antibody tests also become positive within 4 to 6 weeks after an infection but (unlike those for nontreponemal antibody tests) they usually remain positive indefinitely, even after successful treatment. Historically, treponemal antibody tests have been used to confirm the diagnosis of syphilis in those with a positive nontreponemal antibody test. However, thanks to recent test improvements, some centers have reversed this algorithm and now use treponemal antibody tests for screening and nontreponemal antibody tests to confirm the diagnosis. As with all serologic tests for infection, certain pitfalls must be considered when interpreting these tests, including the timing of the test relative to the infection (e.g., too early for an antibody response to have been mounted) and the confounding influence of altered immunity, particularly in those who are HIV-infected.

SUMMARY

SYPHILIS

- Syphilis is caused by *T. pallidum* and has three stages.
  - Primary syphilis: A painless lesion called a *chancre* develops on the external genitalia along with regional lymph node enlargement.
  - Secondary syphilis: Generalized lymphadenopathy and mucocutaneous lesions that may be maculopapular or take the form of flat raised lesions called *condylomata lata*.
  - Tertiary syphilis: May cause proximal aortitis and aortic insufficiency; may involve the brain, meninges, and the spinal cord; or may cause focal granulomatous lesions called *gummas* in multiple organs.
- Congenital syphilis is caused by maternal transmission of the spirochetes during vaginal birth, mostly during the primary and secondary stages of disease in the mother. It may lead to stillbirth or cause widespread tissue injury in liver, spleen, lung, bones, and pancreas.
- Most syphilitic lesions demonstrate proliferative endarteritis and a plasma cell–rich inflammatory infiltrate. Gummas have a central area of necrosis surrounded by lymphoplasmacytic infiltrates, activated macrophages, and fibrosis.
- The diagnostic mainstay is serologic testing. Nontreponemal antibody tests (VDRL and RPR) are usually positive in early disease, but may be negative in advanced disease. Treponeme-specific antibody test results become positive later and remain positive indefinitely.

Gonorrhea

Gonorrhea is a sexually transmitted infection caused by *Neisseria gonorrhoeae.* It is second only to chlamydial infection (discussed later) among reportable communicable diseases in the United States. With an estimated 350,000 cases reported in 2014, it remains a major public health problem. Coinfection with other STDs is common, particularly *Chlamydia trachomatis,* which is found in 30% of males with gonorrhea. The gravity of gonococcal infections has increased with the emergence of strains of *N. gonorrhoeae* that are resistant to multiple antibiotics.

Humans are the only natural reservoir for *N. gonorrhoeae.* The organism is highly fastidious, and spread of infection requires direct contact with the mucosa of an infected individual, usually during sexual activity. The bacteria initially attach to mucosal epithelium, particularly of the columnar or transitional type, using a variety of membrane-associated adhesion molecules and structures termed *pili* (Chapter 9). Such attachment prevents the organism from being unceremoniously flushed away by body fluids such as urine or endocervical mucus. The organism then penetrates through the epithelial cells to invade the deeper tissues of the host.

MORPHOLOGY

N. gonorrhoeae provokes an intense, suppurative inflammatory reaction. In males, this manifests most often as a purulent urethral discharge, associated with an edematous, congested urethral meatus. Gram-negative diplococci, many within the cytoplasm of neutrophils, are readily identified in Gram stains of the purulent exudate (Fig. 18.21). Ascending infection may result in the development of acute prostatitis, epididymitis (Fig. 18.22), or orchitis. Abscesses may complicate severe cases. Urethral and endocervical exudates tend to be less conspicuous in females, although acute inflammation of adjacent structures, such as the Bartholin glands, is fairly common. Ascending infection involving the uterus, fallopian tubes, and ovaries results in acute salpingitis, sometimes complicated by tuboovarian abscesses. The acute inflammatory process is followed by the development of granulation tissue and scarring, with resultant strictures and other permanent deformities of the involved structures, giving rise to *pelvic inflammatory disease* (Chapter 19).

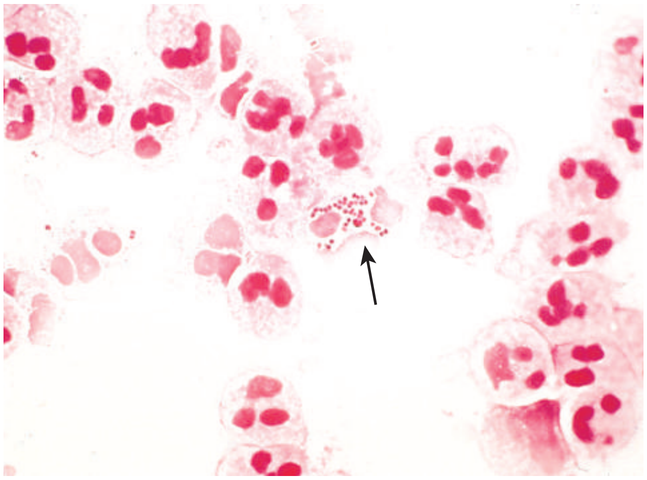

Fig. 18.21 *Neisseria gonorrhoeae.* Gram stain of urethral discharge demonstrates characteristic gram-negative, intracellular diplococci *(arrow). (Courtesy of Dr. Rita Gander, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

Fig. 18.22 Acute epididymitis caused by gonococcal infection. The epididymis is involved by an abscess. Normal testis is seen on the right.

Clinical Features

In most infected males, gonorrhea is manifested by the presence of *dysuria, urinary frequency, and a mucopurulent urethral exudate* within 2 to 14 days of the time of initial infection. However, urethral gonococcal infection can be detected in 40% of asymptomatic male contacts of women with symptomatic gonorrhea. Treatment with appropriate anti-microbial therapy results in eradication of the organism and prompt resolution of symptoms. Untreated infections may ascend to involve the prostate, seminal vesicles, epididymis, and testis. Neglected cases may be complicated by chronic urethral stricture and, in more advanced cases, by permanent sterility. Untreated men also may become chronic carriers of *N. gonorrhoeae.*

Among female patients, acute infections acquired by vaginal intercourse may be asymptomatic or may be associated with *dysuria, lower pelvic pain, and vaginal discharge.* Untreated cases may be complicated by ascending infection, leading to acute inflammation of the fallopian tubes (salpingitis) and ovaries. Scarring of the fallopian tubes may occur, with resultant infertility and an increased risk for ectopic pregnancy. Gonococcal infection of the upper genital tract may spread to the peritoneal cavity, where the exudate may extend up the right paracolic gutter to the dome of the liver, resulting in gonococcal perihepatitis. Depending on sexual practices, other sites of primary infection in both males and females include the oropharynx and the anorectal area, with resultant acute pharyngitis and proctitis, respectively.

Disseminated infection is much less common than local infection, occurring in 0.5% to 3% of cases of gonorrhea. It is more frequent in females than in males. Manifestations include, most commonly, tenosynovitis, arthritis, and pustular or hemorrhagic skin lesions. Endocarditis and meningitis are rare presentations. Strains that cause disseminated infection usually are resistant to the lytic action of complement, but rare patients with inherited complement deficiencies are susceptible to systemic spread regardless of the infecting strain.

Gonococcal infection may be transmitted to infants during passage through the birth canal. The affected neonate may develop purulent infection of the eyes (*ophthalmia neonatorum*), an important cause of blindness in the past. The routine application of antibiotic ointment to the eyes of newborns has markedly reduced this disorder.

Both culture and a variety of tests that detect organism-specific nucleic acids can be used to diagnose gonococcal infections. The advantage of culture is that it permits determination of antibiotic sensitivity. Nucleic acid–based tests are more rapid and somewhat more sensitive than culture, and are being used increasingly.

SUMMARY

GONORRHEA

- Gonorrhea is a common STD affecting the genitourinary tract. Control of dissemination requires an effective complement-mediated immune response.
- Gonorrhea presents with dysuria and a milky, purulent urethral discharge, although a high frequency of cases are asymptomatic.
- About 30% of men with gonococcal urethritis also are infected with *C. trachomatis*.
- Pregnant women can transmit gonorrhea to newborns during passage through the birth canal.
- Diagnosis can be made by culture of the exudates as well as by nucleic acid amplification techniques.

Nongonococcal Urethritis and Cervicitis

Nongonococcal urethritis (NGU) and cervicitis are the most common forms of STD. A variety of organisms are implicated in the pathogenesis of NGU and cervicitis, including *C. trachomatis, Mycoplasma genitalium, Trichomonas vaginalis,* and *Ureaplasma urealyticum.* **In the United States, most cases are apparently caused by *C. trachomatis*, and this organism is believed to be the most common bacterial cause of STD in the United States.** *Mycoplasma genitalium* is a close second as a cause of NGU. The frequency of causative agents varies geographically and in certain patient populations such a men having sex with men. In almost 50% of the cases world wide no pathogen can be identified. As discussed earlier, gonorrhea infection frequently is accompanied by chlamydial infection.

C. trachomatis is a small gram-negative bacterium that is an obligate intracellular pathogen. It exists in two forms. The infectious form, the *elementary body,* is capable of at least limited survival in the extracellular environment. The elementary body is taken up by host cells, primarily through a process of receptor-mediated endocytosis. Once inside the cell, the elementary body differentiates into a metabolically active form, termed the *reticulate body.* Using the energy sources of the host cell, the reticulate body replicates and ultimately forms new infectious elementary bodies, which have a tropism for columnar epithelial cells.

C. trachomatis infections are associated with a wide range of clinical features that are virtually indistinguishable from those caused by *N. gonorrhoeae.* Clinically, patients typically present 1 to 5 weeks after exposure with dysuria with or without urethral discharge. Patients may develop epididymitis, prostatitis, pelvic inflammatory disease, pharyngitis, conjunctivitis, perihepatic inflammation, and, among individuals who engage in anal sex, proctitis. It is the most common cause of epididymitis in young men. Similar to gonococcus, a large percentage of both men and women are asymptomatic. *C. trachomatis* also causes lymphogranuloma venereum (LGV), discussed in the next section. The infection may be transmitted to newborns during vaginal birth, where up to 15% of exposed newborns develop chlamydial pneumonia and 50% develop chlamydial conjunctivitis.

The morphologic and clinical features of chlamydial infection, with the exception of lymphogranuloma venereum, are virtually identical to those of gonorrhea. The primary infection is characterized by a watery to mucopurulent discharge that contains a predominance of neutrophils. Organisms are not visible in Gram-stained sections. In contrast with the gonococcus, *C. trachomatis* cannot be isolated with the use of conventional culture media. The diagnosis is best made by a nucleic acid amplification test on voided urine, which is now the gold standard. Another important manifestation of chlamydial infection is *reactive*

arthritis (formerly known as *Reiter syndrome*), predominantly in patients who are HLA-B27 positive. This condition typically manifests as a combination of urethritis, conjunctivitis, arthritis, and generalized mucocutaneous lesions.

SUMMARY

NONGONOCOCCAL URETHRITIS AND CERVICITIS

- NGU and cervicitis are the most common forms of STD. Most cases are caused by *C. trachomatis*, and the rest by *T. vaginalis*, *M. genitalium and U. urealyticum.*
- *C. trachomatis* is a gram-negative intracellular bacterium that causes a disease that is clinically indistinguishable from gonorrhea in both men and women. Diagnosis can be made by sensitive nucleic acid amplification tests in urine samples or vaginal swabs.
- In patients who are HLA-B27 positive, *C. trachomatis* infection can cause reactive arthritis along with conjunctivitis and generalized mucocutaneous lesions.

Lymphogranuloma Venereum

LGV is a chronic, ulcerative disease caused by certain strains of *C. trachomatis* that are distinct from those causing the more common nongonococcal urethritis or cervicitis discussed earlier. It is endemic in parts of Asia, Africa, the Caribbean region, and South America. An increased incidence has been noted in the US in the past 15 years, due in large part of infections in men having sex with men, who are often co infected with HIV. As in the case of granuloma inguinale (discussed later), sporadic cases of LGV are seen most often among individuals with multiple sexual partners.

MORPHOLOGY

LGV may present as nonspecific urethritis or papular or ulcerative lesions involving the lower genitalia. Subsequently, tender enlarged matted inguinal and/or femoral lymphadenopathy ensues that typically is unilateral and is often associated with fistulous tracts. Proctocolitis also can be seen. The lesions contain a **mixed granulomatous and neutrophilic inflammatory response.** Variable numbers of chlamydial inclusions may be seen in the cytoplasm of epithelial cells or inflammatory cells with special staining methods. Regional lymphadenopathy is common, usually appearing within 30 days of the time of infection. Lymph node involvement is characterized by a granulomatous inflammatory reaction associated with irregularly shaped foci of necrosis and neutrophilic infiltration **(stellate abscesses).** With time, the inflammatory reaction gives rise to extensive fibrosis that can cause local lymphatic obstruction and strictures, producing **lymphedema.**

Clinical Features

Within 1 to 2 weeks of exposure, primary infection appears at the site of inoculation in the form of a genital ulcer or a mucosal inflammatory reaction. These primary lesions heal spontaneously, but the organisms at these sites seed draining lymph nodes, triggering a necrotizing lymphadenitis 2 to 6 weeks after the initial exposure. The lymphadenitis is usually unilateral and painful, and may lead to abscess formation. Abscesses sometimes rupture, spreading the inflammatory process into surrounding soft tissues. Rectal infections may progress to proctocolitis, associated with pain, constipation, fever, and bleeding, features that mimic inflammatory bowel disease. If untreated, rectal fissures and strictures may develop secondary to inflammation and fibrosis.

The diagnosis of LGV is difficult because laboratory tests are not standardized and serologic tests have low specificity. As with other chlamydial infections, nucleic acid amplification tests have the highest sensitivity and specific and are becoming more widely available. Culture and serologic tests are less sensitive but are still used, particularly in areas where nucleic acid amplification tests are not available.

Chancroid (Soft Chancre)

Chancroid, sometimes called the "third" venereal disease (after syphilis and gonorrhea), is an acute, ulcerative infection caused by *Haemophilus ducreyi,* a small, gram-negative coccobacillus. The disease is most common in tropical and subtropical areas and is more prevalent in lower socioeconomic groups, particularly among men who have regular contact with prostitutes**. Chancroid is one of the most common causes of genital ulcers in Africa and Southeast Asia, where it serves as an important cofactor in the transmission of HIV infection.** Chancroid probably is underdiagnosed in the United States because most STD clinics do not have facilities for isolating *H. ducreyi,* and PCR-based tests are not widely available.

MORPHOLOGY

The primary lesion of chanchroid appears first as a papule that rapidly breaks down to produce a ulcer. On microscopic examination, the ulcer of chancroid contains a superficial zone of neutrophilic debris and fibrin, with an underlying zone of granulation tissue containing areas of necrosis and thrombosed vessels. A dense, lymphoplasmacytic inflammatory infiltrate is present beneath the layer of granulation tissue. Secondarily involved draining lymph nodes also exhibit necrotizing inflammation that frequently progresses to abscess formation.

Clinical Features

The primary lesion of chanchroid appears within 4 to 7 days of inoculation. In male patients, the primary lesion is usually on the penis; in female patients, most lesions occur in the vagina or periurethral area. Over the course of several days, the surface of the primary lesion erodes to produce an irregular ulcer, which is more likely to be painful in males than in females. The regional lymph nodes, particularly in the inguinal region, become enlarged and tender in about 50% of cases within 1 to 2 weeks of the primary inoculation. In untreated cases, the inflamed and enlarged nodes (buboes) may erode the overlying skin to produce chronic, draining ulcers. A definitive diagnosis requires the identification of *H. ducreyi* on special culture media that are not widely available from commercial sources; even when such media are used, sensitivity is less than 80%. Therefore, the diagnosis often is based on clinical grounds alone.

Granuloma Inguinale

Granuloma inguinale is a chronic inflammatory disease caused by *Calymmatobacterium granulomatis,* a minute, encapsulated coccobacillus related to the *Klebsiella* genus. This disease is uncommon in the United States and Western Europe, but it is endemic in the rural parts of certain tropical and subtropical regions. When it occurs in urban settings, transmission of *C. granulomatis* typically is associated with a history of multiple sexual partners. Untreated cases are characterized by extensive scarring, often associated with lymphatic obstruction and lymphedema (elephantiasis) of the external genitalia. Culture of the organism is difficult, and PCR-based assays are not widely available.

MORPHOLOGY

Granuloma inguinale causes genital ulceration, accompanied by the development of abundant granulation tissue. Disfiguring scars may develop in untreated cases, sometimes associated with formation of urethral, vulvar, or anal strictures. In contrast with chancroid, regional lymph nodes typically are spared or show only nonspecific reactive changes.

Microscopic examination of active lesions reveals marked epithelial hyperplasia at the borders of the ulcer, sometimes mimicking carcinoma **(pseudoepitheliomatous hyperplasia).** A mixture of neutrophils and mononuclear inflammatory cells is present at the base of the ulcer and beneath the surrounding epithelium. The organisms are demonstrable in Giemsa-stained smears of the exudate as minute coccobacilli within vacuoles in macrophages **(Donovan bodies).** Silver stains (e.g., the Warthin-Starry stain) also may be used to demonstrate the organism.

SUMMARY

LYMPHOGRANULOMA VENEREUM, CHANCROID, AND GRANULOMA INGUINALE

- LGV is caused by *C. trachomatis* serotypes that are distinct from those that cause nongonococcal urethritis. LGV is associated with urethritis, ulcerative genital lesions, lymphadenopathy, and involvement of the rectum. The lesions show both acute and chronic inflammation; they progress to fibrosis, with consequent lymphedema and formation of rectal strictures. Diagnosis is made by nucleic acid amplification tests and serology.
- *H. ducreyi* infection causes an acute painful ulcerative genital infection called *chancroid.* Inguinal node involvement occurs in many cases and leads to their enlargement and ulceration. Ulcers show a superficial area of acute inflammation and necrosis, with an underlying zone of granulation tissue and mononuclear infiltrate. Diagnosis is possible by culture of the organism.
- *Granuloma inguinale* is a chronic fibrosing STD caused by *C. granulomatis*. The initial papular lesion on the genitalia expands and ulcerates, with formation of urethral, vulvar, or anal strictures in some cases. Microscopic examination reveals granulation tissue and intense epithelial hyperplasia that can mimic squamous cell carcinoma. Organisms are visible as small intracellular coccobacilli within vacuolated macrophages (Donovan bodies).

Trichomoniasis

T. vaginalis is a sexually transmitted protozoan that is a frequent cause of vaginitis. The trophozoite form adheres to the mucosa, where it causes superficial lesions. In females, *T. vaginalis* infection often is associated with loss of acid-producing lactobacilli. The incubation period is 4 to 28 days. It may be asymptomatic or be associated with pruritus and a profuse, frothy, yellow vaginal discharge. Urethral colonization may cause urinary frequency and dysuria. *T. vaginalis* infection typically is asymptomatic in males but in some cases may manifest as nongonococcal urethritis. The organism usually is demonstrable in smears of vaginal scrapings.

Genital Herpes Simplex

Genital herpes infection, or herpes genitalis, is a very common STD. According to CDC, approximately 800,000 people get new infections every year in the United States. One in six persons between the ages of 14 and 49 has HSV-2 infection in the US. With increasing rate of HSV-1 infections the overall prevalence of genital herpes is likely much higher. Although both herpes simplex virus 1 (HSV-1) and HSV-2 can cause anogenital or oral infections, most cases of anogenital herpes are caused by HSV-2. However, recent years have seen a rise in the number of genital infections caused by HSV-1, in part due to the increasing practice of oral sex. Genital HSV infection may occur in any sexually active population. As with other STDs, the risk for infection is directly related to the number of sexual contacts. Up to 95% of HIV-positive men who have sex with men are seropositive for HSV-1 and/or HSV-2. HSV is transmitted when the virus comes into contact with a mucosal surface or broken skin of a susceptible host. Such transmission requires direct contact with an infected individual, because the virus is readily inactivated at room temperature, particularly if dried.

MORPHOLOGY

The initial lesions of genital HSV infection are **painful, erythematous vesicles** on the mucosa or skin of the lower genitalia and adjacent extragenital sites. The anorectal area is a particularly common site of primary infection among men who have sex with men. Histologic changes include the presence of **intraepithelial vesicles** accompanied by necrotic cellular debris, neutrophils, and cells harboring characteristic intranuclear viral inclusions. The classic **Cowdry type A inclusion** appears as a light purple, homogeneous intranuclear structure surrounded by a clear halo. Infected cells commonly fuse to form multinucleate syncytia. The inclusions stain with antibodies to HSV, permitting a rapid, specific diagnosis of HSV infection in histologic sections or smears.

Clinical Features

As discussed earlier, both HSV-1 and HSV-2 can cause genital or oral infection, and both produce indistinguishable primary or recurrent mucocutaneous lesions. Primary infection with HSV-2 often may be asymptomatic or may produce a variety of signs and symptoms. Locally painful vesicular lesions may be accompanied by dysuria, urethral discharge, local lymph node enlargement and tenderness,

and systemic manifestations, such as fever, muscle aches, and headache. HSV is actively shed during this period, and shedding continues until the mucosal lesions have completely healed. However, asymptomatic viral shedding can occur as long as 3 months after diagnosis. Signs and symptoms may last for several weeks during the primary phase of disease. Recurrences are milder and of shorter duration than in the primary episode. Diagnosis is most often made by viral culture or nucleic acid amplification testing of fluid collected after "unroofing" of a vesicular lesion.

In immunocompetent adults, herpes genitalis generally is not life-threatening. However, HSV poses a major threat to immunosuppressed patients, in whom fatal, disseminated disease may develop. Also life-threatening is *neonatal herpes infection,* which occurs in about one-half of infants delivered vaginally of mothers suffering from either primary or recurrent genital HSV infection. The viral infection is acquired during passage through the birth canal. Its incidence has risen in parallel with the rise in genital HSV infection. The manifestations of neonatal herpes vary from involvement of superficial sites (skin, eyes and mouth) to involvement of the CNS, with or without disseminated infection of other organs such as the liver and lungs. Approximately 60% of affected infants die of the disease, with significant morbidity occurring in about one-half of the survivors. PCR-based testing is far more sensitive and the preferred method for diagnosis of encephalitis.

Human Papillomavirus Infection

HPV causes a number of squamous proliferations in the genital tract, including condyloma acuminatum, as well as several precancerous lesions that commonly undergo transformation to carcinomas. The latter most commonly involve the cervix (Chapter 19), but also occur in the penis, vulva, oropharyngeal tonsil, and conjunctiva. *Condylomata acuminata,* also known as *venereal warts,* are caused by HPV types 6 and 11. These lesions occur on the penis as well as on the female genitalia. They should not be confused with the condylomata lata of secondary syphilis. Genital HPV infection may be transmitted to neonates during vaginal delivery. Recurrent and potentially life-threatening papillomas of the upper respiratory tract may develop subsequently in affected infants.

MORPHOLOGY

In males, condylomata acuminata usually occur on the coronal sulcus or inner surface of the prepuce, where they range in size from small, sessile lesions to large, papillary proliferations measuring several centimeters in diameter. In females, they commonly occur on the vulva. Examples of the microscopic appearance of these lesions are presented in Chapter 19.

SUMMARY

HERPES SIMPLEX VIRUS AND HUMAN PAPILLOMAVIRUS INFECTIONS

- HSV-2 and, less commonly, HSV-1 can cause genital infections. Initial (primary) infection may be asymptomatic or cause painful, erythematous, intraepithelial vesicles on the mucosa and skin of external genitalia, along with painful regional lymph node enlargement. Recurrent lesions in general are less painful and less extensive than primary lesions.
- On histologic examination, the vesicles of HSV infection contain necrotic cells and fused multinucleate giant cells with intranuclear inclusions (Cowdry type A) that stain with antibodies to the virus.
- Neonatal herpes can be life-threatening and occurs in children born to mothers with genital herpes. Affected infants may have generalized herpes, often associated with encephalitis and consequent high mortality.
- HPV causes many proliferative lesions of the genital mucosa, including condyloma acuminatum, precancerous lesions, and invasive cancers.

CHAPTER

Female Genital System and Breast

19

CHAPTER OUTLINE

Vulva

The vulva is the external female genitalia and includes the hair-bearing skin (labia majora) and mucosa (labia minora). Disorders of the vulva most frequently are inflammatory, rendering them more uncomfortable than serious. Malignant tumors of the vulva, although life-threatening, are rare.

VULVITIS

One of the most common causes of vulvitis is reactive inflammation in response to an exogenous stimulus, which may be an irritant (contact irritant dermatitis) or an allergen (contact allergic dermatitis). Scratching-induced trauma secondary to associated intense "itching" (pruritus) often exacerbates the primary condition.

Contact irritant eczematous dermatitis manifests as well-defined erythematous weeping and crusting papules and plaques and may be a reaction to urine, soaps, detergents, antiseptics, deodorants, or alcohol. Allergic dermatitis has a similar clinical appearance and may result from allergy to perfumes; additives in creams, lotions, and soaps; chemical treatments on clothing; and other antigens.

Vulvitis also may be caused by infections, which often are sexually transmitted. The most important infectious agents in North America are human papillomavirus (HPV), the causative agent of condyloma acuminatum, vulvar intraepithelial neoplasia (VIN), and one type of vulvar squamous carcinoma (discussed later); herpes simplex virus (HSV-1 or HSV-2), the agent of genital herpes; *N. gonorrhoeae,* a cause of suppurative infection of the vulvovaginal glands; and *Treponema pallidum,* which causes primary chancre at vulvar sites of inoculation. Candida also is a cause of vulvitis, but is not sexually transmitted.

An important complication of vulvitis is obstruction of the excretory ducts of Bartholin glands. This blockage may

result in painful dilation of the glands *(Bartholin cyst)* and abscess formation.

Nonneoplastic Epithelial Disorders

Lichen Sclerosus

Lichen sclerosus is characterized by thinning of the epidermis, disappearance of rete pegs, a zone of acellular, homogenized, dermal fibrosis, and a bandlike mononuclear inflammatory cell infiltrate (Fig. 19.1). It appears as smooth, white plaques (termed *leukoplakia*) or papules that in time may extend and coalesce. When the entire vulva is affected, the labia become atrophic and stiffened, and the vaginal orifice is constricted. Lichen sclerosus occurs in all age groups but most commonly affects postmenopausal women and prepubertal girls. The pathogenesis is uncertain, but the presence of activated T cells in the subepithelial inflammatory infiltrate and the increased frequency of autoimmune disorders in affected women suggest an autoimmune etiology. Lichen sclerosus is benign; however, 1% to 5% of women with symptomatic lichen sclerosus develop HPV negative squamous cell carcinoma of the vulva.

Lichen Simplex Chronicus

Lichen simplex chronicus is marked by epithelial thickening (particularly of the stratum granulosum) and hyperkeratosis. Increased mitotic activity is seen in the basal and suprabasal layers; however, there is no epithelial atypia (Fig. 19.1). Leukocytic infiltration of the dermis is sometimes pronounced. These nonspecific changes are a consequence of chronic irritation, often caused by pruritus related to an underlying inflammatory dermatosis. Lichen simplex chronicus appears as an area of leukoplakia. While no increased predisposition to cancer has been demonstrated when lesions are isolated, lichen simplex chronicus often is present at the margins of established vulvar cancer, suggesting some association with neoplastic disease.

Lichen sclerosus and lichen simplex chronicus may coexist in different areas of the body in the same person, and both lesions may take the form of leukoplakia. Similar white patches or plaques also are seen in a variety of other benign dermatoses, such as psoriasis and lichen planus (Chapter 24), as well as in malignant lesions of the vulva, such as squamous cell carcinoma in situ and invasive squamous cell carcinoma. Thus, biopsy and microscopic examination are often needed to differentiate these clinically similar-appearing lesions.

SUMMARY

NONNEOPLASTIC EPITHELIAL DISORDERS

- Lichen sclerosus is characterized by atrophic epithelium, subepithelial dermal fibrosis, and bandlike chronic inflammation.
- Lichen sclerosus carries a slightly increased risk for development of squamous cell carcinoma.
- Lichen simplex chronicus is characterized by thickened epithelium (hyperplasia), usually with a dermal inflammatory infiltrate.
- The lesions of lichen sclerosus and lichen simplex chronicus must be biopsied to distinguish them definitively from other causes of leukoplakia, such as squamous cell carcinoma of the vulva.

TUMORS

Condylomas

***Condyloma* is the name given to any warty lesion of the vulva.** Most such lesions can be assigned to one of two distinctive forms. *Condylomata lata,* not commonly seen today, are flat, minimally elevated lesions that occur in secondary syphilis (Chapter 18). The more common *condylomata acuminata* may be papillary and distinctly elevated or somewhat flat and rugose. They may occur anywhere on the anogenital surface, sometimes as single but more often as multiple lesions. When located on the vulva, they range from a few millimeters to many centimeters in

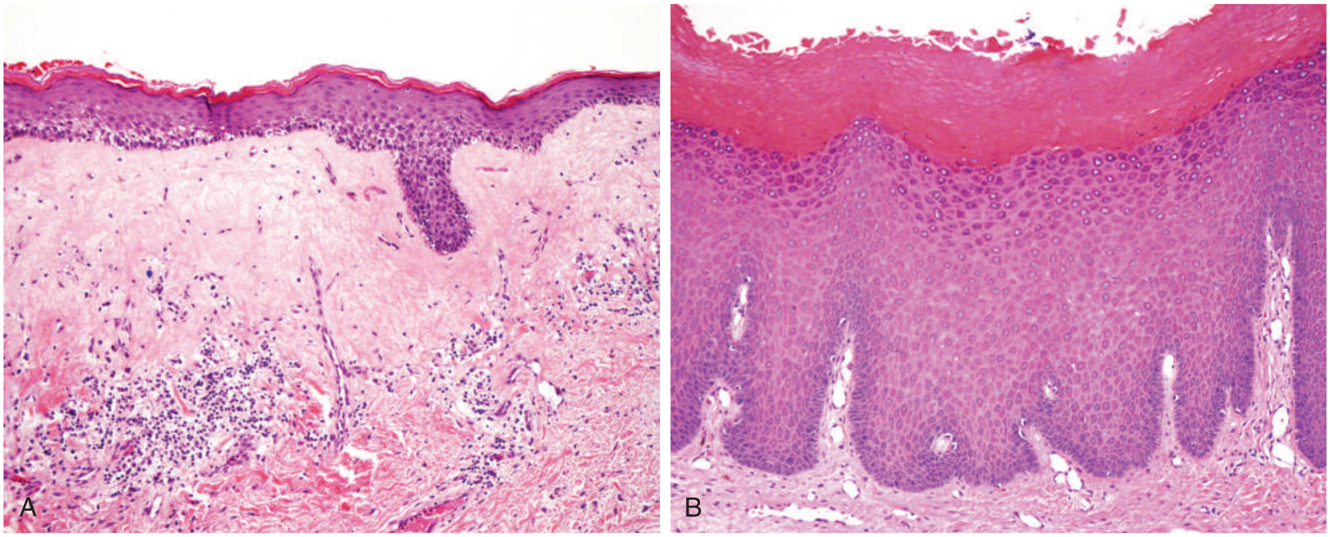

Fig. 19.1 Nonneoplastic vulvar epithelial disorders. (A) Lichen sclerosus. There is marked thinning of the epidermis, fibrosis of the superficial dermis, and chronic inflammatory cells in the deeper dermis. (B) Lichen simplex chronicus displaying thickened epidermis and hyperkeratosis.

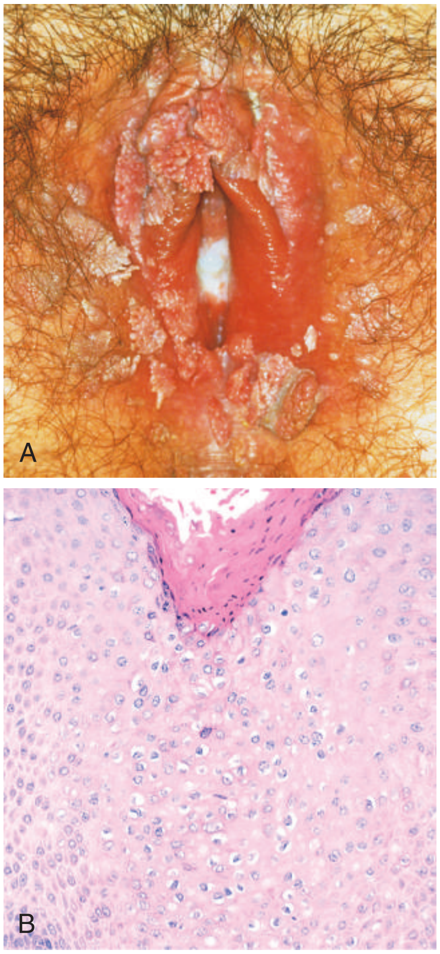

Fig. 19.2 (A) Numerous condylomas of the vulva. (B) Histopathologic features of condyloma acuminatum include acanthosis, hyperkeratosis, and cytoplasmic vacuolization (koilocytosis, *center*). *(A, Courtesy of Dr. Alex Ferenczy, McGill University, Montreal, Quebec, Canada.)*

diameter and are red-pink to pink-brown (Fig. 19.2). On histologic examination, the characteristic cellular feature is koilocytosis (a cytopathic change characterized by perinuclear cytoplasmic vacuolization and a wrinkled nuclear contour), a hallmark of HPV infection (Fig. 19.2). Indeed, more than 90% of condylomata acuminata are positive for HPV subtypes 6 and 11. HPV is sexually transmitted, and identical lesions occur in men on the penis and around the anus in men and women. HPV 6 and 11 are low-risk viral types, and hence, vulvar condylomas do not commonly progress to cancer. However, women with condyloma acuminata are at risk of having other HPV-related lesions in the vagina and cervix.

Carcinoma of the Vulva

Carcinoma of the vulva represents about 3% of all female genital tract cancers, occurring mostly in women older than age 60. Approximately 90% of carcinomas are squamous cell carcinomas; most of the other tumors are adenocarcinomas or basal cell carcinomas.

There appear to be two distinct forms of vulvar squamous cell carcinomas that differ in pathogenesis and course. The less common form is related to high-risk HPV strains (especially HPV type 16) and occurs in middle-aged women, particularly cigarette smokers. This form is often preceded by precancerous changes in the epithelium termed vulvar intraepithelial neoplasia (VIN). VIN progresses in many patients to greater degrees of atypia and eventually to carcinoma in situ; however, progression to invasive carcinoma is not inevitable and may occur only after many years. Environmental factors such as cigarette smoking and immunodeficiency appear to increase the risk of such progression.

A second form of squamous carcinoma occurs in older women, sometimes following a long history of reactive epithelial changes, principally lichen sclerosus. It is preceded by a subtle lesion, differentiated vulvar intraepithelial neoplasia (dVIN), characterized by cytologic atypia confined to the basal layer and abnormal keratinization. If left untreated it may give rise to HPV negative, well-differentiated, keratinizing squamous cell carcinoma.

MORPHOLOGY

VIN and early vulvar carcinomas commonly manifest as areas of **leukoplakia**. In about one-fourth of the cases, the lesions are pigmented owing to the presence of melanin. With time, these areas are transformed into overt exophytic or ulcerative endophytic tumors. HPV-positive tumors are often multifocal and warty and tend to be poorly differentiated **squamous cell carcinomas,** whereas HPV-negative tumors usually are unifocal and typically are well-differentiated keratinizing squamous cell carcinomas.

Both forms of vulvar carcinoma tend to remain confined to their site of origin for a few years but ultimately invade and spread, usually first to regional lymph nodes. The risk of metastasis correlates with the depth of invasion. As with most carcinomas, outcome is dependent on tumor stage. The overall 5-year survival is 70% to 93% for patients with negative lymph nodes but decreases to 25% to 41% for patients with lymph node metastases.

Extramammary Paget Disease

Paget disease is an intraepidermal proliferation of epithelial cells that can occur in the skin of the vulva or nipple of the breast (described later). However, unlike in the breast, where Paget disease is virtually always associated with an underlying carcinoma, only a minority of cases of vulvar (extramammary) Paget disease have an underlying tumor. Instead, vulvar Paget cells most commonly appear to arise from epidermal progenitor cells.

Paget disease manifests as a red, scaly, crusted plaque that may mimic the appearance of an inflammatory dermatitis. On histologic examination, large cells with abundant pale, finely granular cytoplasm and occasional cytoplasmic vacuoles infiltrate the epidermis, singly and in groups (Fig. 19.3). The presence of mucin, as detected by periodic acid–Schiff (PAS) staining, is useful in distinguishing Paget disease from vulvar melanoma, which lacks mucin.

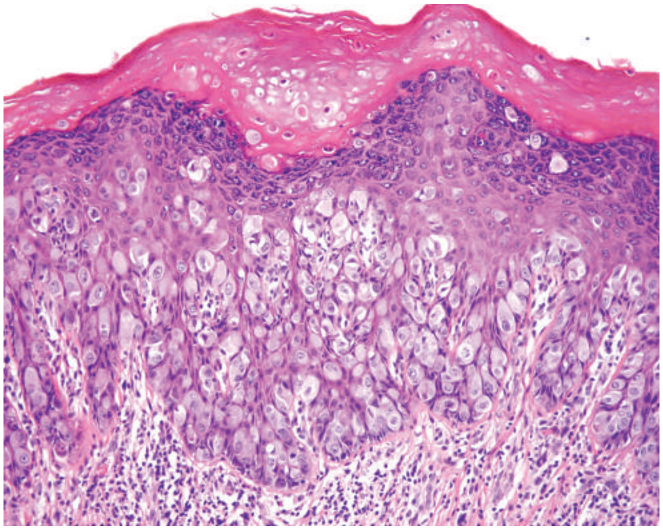

Fig. 19.3 Paget disease of the vulva. Large tumor cells with pale-pink cytoplasm are seen infiltrating the epidermis. Chronic inflammatory cells are present in the underlying dermis.

Intraepidermal Paget disease may persist for years or even decades without evidence of invasion. However, when there is an associated tumor involving skin appendages, the Paget cells may invade locally and ultimately metastasize. After metastasis occurs, the prognosis is poor.

SUMMARY

TUMORS OF THE VULVA

- HPV-related vulvar squamous cell carcinomas usually are poorly differentiated lesions and sometimes are multifocal. They often evolve from vulvar intraepithelial neoplasia.
- Non–HPV-related vulvar squamous cell carcinomas occur in older women and usually are well differentiated and unifocal. They are often preceded by "differentiated" vulvar intraepithelial neoplasia associated with lichen sclerosus.
- Vulvar Paget disease is characterized by a red, scaly plaque caused by proliferation of epithelial cells within the epidermis; usually, there is no underlying carcinoma, unlike Paget disease of the nipple.

Vagina

In adult females, the vagina is seldom a site of primary disease. More often, it is involved secondarily by cancer or infections arising in adjacent organs (e.g., cervix, vulva, bladder, rectum).

Congenital anomalies of the vagina fortunately are uncommon and include entities such as total absence of the vagina, a septate or double vagina (usually associated with a septate cervix and, sometimes, septate uterus), and congenital, lateral Gartner duct cysts arising from persistent wolffian duct rests.

VAGINITIS

Vaginitis is a common condition that is usually transient and of no clinical consequence. It is associated with the production of a vaginal discharge (leukorrhea). A large variety of organisms have been implicated, including bacteria, fungi, and parasites. Many are normal commensals that become pathogenic only in the setting of diabetes, systemic antibiotic therapy (which causes disruption of normal microbial flora), immunodeficiency, pregnancy, or recent abortion. In adults, primary gonorrheal infection of the vagina is uncommon. The other organisms worthy of mention, because they are frequent offenders, are *Candida albicans* and *Trichomonas vaginalis.* Candidal (monilial) vaginitis is characterized by a curdy white discharge. This organism is part of the normal vaginal flora in about 5% of women, so the appearance of symptomatic infection almost always involves one of the predisposing influences listed above or superinfection by a new, more aggressive strain. *T. vaginalis* is sexually transmitted; it produces a watery, copious gray-green discharge in which parasites can be identified by microscopy. Trichomonas also can be identified in about 10% of asymptomatic women; thus, active infection usually stems from sexual transmission of a new strain.

MALIGNANT NEOPLASMS

Squamous Cell Carcinoma

Squamous cell carcinoma of the vagina is an extremely uncommon cancer that usually occurs in women older than 60 years in the setting of risk factors similar to those associated with carcinoma of the cervix (discussed later). Vaginal intraepithelial neoplasia (VAIN) is a precursor lesion that is nearly always associated with HPV infection. Invasive squamous cell carcinoma of the vagina is associated with the presence of HPV DNA in more than half of the cases, presumably derived from HPV-positive VAIN.

Clear Cell Adenocarcinoma

In 1970, clear cell adenocarcinoma, a very rare tumor, was identified in a cluster of young women whose mothers took diethylstilbestrol during pregnancy to prevent threatened abortion. Follow-up studies determined that the incidence of this tumor in persons exposed to diethylstilbestrol in utero is low (<1 per 1000, albeit about 40 times greater than in the unexposed population). In about one-third of exposed women, small glandular or microcystic inclusions develop in the vaginal mucosa. These lesions appear as red, granular foci lined by mucus-secreting or ciliated columnar cells. This condition is called vaginal adenosis and is benign but is important to recognize because it is from such precursor lesions that clear cell adenocarcinoma arises.

Sarcoma Botryoides

Sarcoma botryoides (embryonal rhabdomyosarcoma) is a rare form of primary vaginal cancer that manifests as soft polypoid masses. It usually is encountered in infants and children younger than 5 years of age, but may occur uncommonly in young women. It also may be found in other sites, such as the urinary bladder and bile ducts. It is discussed further with other soft tissue tumors in Chapter 21.

Cervix

Most cervical lesions are relatively banal inflammations (cervicitis), but the cervix also is the site of one of the most common cancers in women worldwide.

CERVICITIS

Inflammatory conditions of the cervix are extremely common and may be associated with a purulent vaginal discharge. Cervicitis can be subclassified as infectious or noninfectious, although differentiation is difficult owing to the presence of normal vaginal flora including incidental vaginal aerobes and anaerobes, streptococci, staphylococci, enterococci, and *Escherichia coli* and *Candida* spp.

Much more important are *Chlamydia trachomatis, Ureaplasma urealyticum, T. vaginalis, Neisseria gonorrhoeae,* HSV-2 (the agent of herpes genitalis), and certain types of HPV, all of which are often sexually transmitted. *C. trachomatis* is by far the most common of these pathogens, accounting for as many as 40% of cases of cervicitis encountered in sexually transmitted infection clinics. Although less common, herpetic infections are noteworthy because maternal–infant transmission during childbirth may result in serious, sometimes fatal systemic herpetic infection in the newborn.

Cervicitis commonly comes to attention on routine examination or because of leukorrhea. It often is treated empirically with antibiotics that are active against chlamydia and gonococcus. In some instances, nucleic acid amplification tests are used on vaginal fluid to identify the presence of these organisms as well as *Trichomonas vaginalis*.

NEOPLASIA OF THE CERVIX

Most tumors of the cervix are of epithelial origin and are caused by oncogenic strains of HPV. During development, the columnar mucus-secreting epithelium of the endocervix is joined to the squamous epithelial covering of the exocervix at the cervical os. With the onset of puberty, the squamocolumnar junction undergoes eversion, causing the columnar epithelium to become visible on the exocervix. The exposed columnar cells, however, eventually undergo squamous metaplasia, forming a region called the transformation zone, where tumors most commonly arise (Fig. 19.4).

Pathogenesis

HPV, the causative agent of cervical neoplasia, has a tropism for the immature squamous cells of the transformation zone. Most HPV infections are transient and are eliminated within months by the host immune response. A subset of infections persists, however, and some cause squamous intraepithelial lesions (SILs), which are precursors from which most invasive cervical carcinomas develop.

HPV is detectable by molecular methods in nearly all cases of cervical intraepithelial neoplasia (CIN) and cervical carcinoma. Important risk factors for the development of CIN and invasive carcinoma thus are directly related to HPV exposure and include:

- Early age at first intercourse
- Multiple sexual partners
- Male partner with multiple previous sexual partners
- Persistent infection by high-risk strains of papillomavirus

Like most other DNA viruses, HPV uses host cell DNA polymerases to replicate its genome and produce virions. Virions must be shed from the surface of the squamous mucosa, yet under normal circumstances squamous cell maturation is accompanied by a cessation of DNA replication, which would prevent virus production. HPV "solves" this problem through the action of two viral oncoproteins, E6 and E7. **The E6 and E7 proteins of "high risk" HPV variants inhibit p53 and RB, respectively** (Chapter 6), two potent tumor suppressors that act to suppress the division of squamous cells as they mature. E6 and E7 thus have a central role in the life cycle of HPV and largely explain the carcinogenic activity of HPV in the cervix and other sites that are prone to HPV infection (e.g., vulva, penis, oropharynx).

HPV variants are classified as high-risk or low-risk types based on their propensity to induce carcinogenesis.

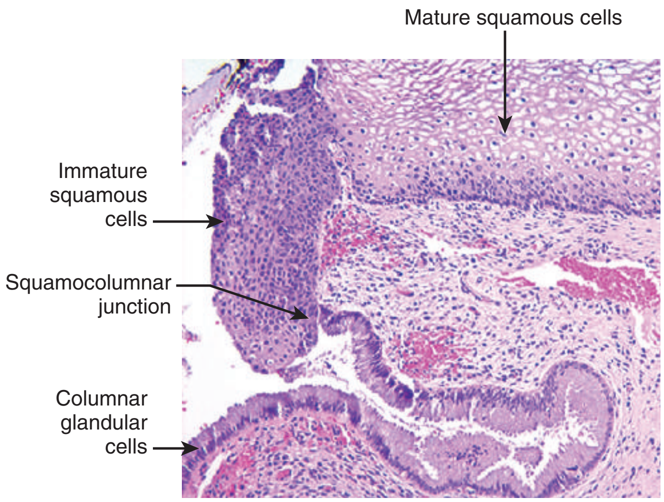

Fig. 19.4 Cervical transformation zone showing the transition from mature glycogenated squamous epithelium, to immature metaplastic squamous cells, to columnar endocervical glandular epithelium.

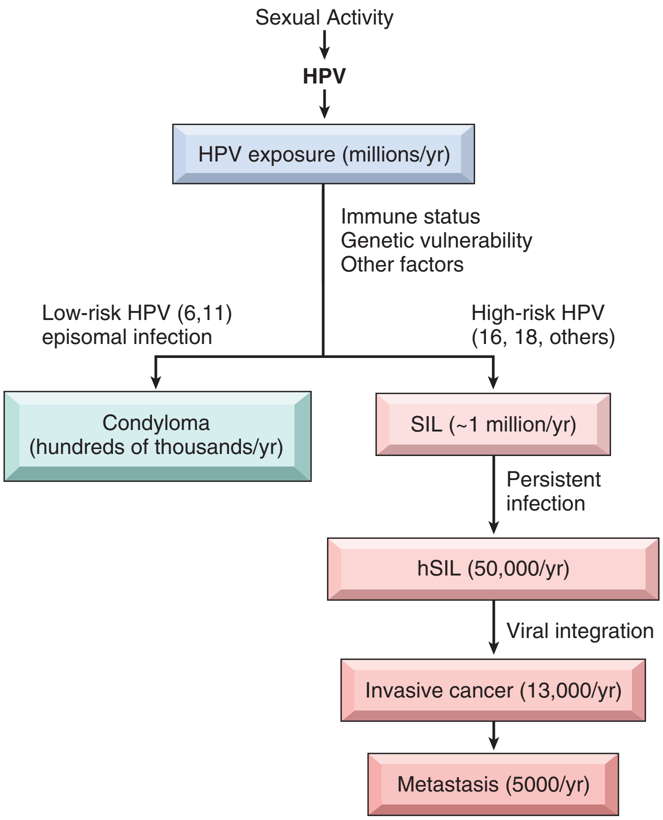

Fig. 19.5 Possible consequences of human papillomavirus (HPV) infection. Progression is associated with integration of virus and acquisition of additional mutations as discussed in the text. *SIL*, Squamous intraepithelial lesion; *hSIL*, High-grade cervical intraepithelial lesion.

High-risk HPV infection is the most important risk factor for the development of SIL that can progress to carcinoma. Two high-risk HPV viruses, types 16 and 18, account for approximately 70% of cases of SIL and cervical carcinoma. In general, infections with high-risk HPV types are more likely to persist, which is a risk factor for progression to carcinoma. These HPV types also show a propensity to integrate into the host cell genome, an event that is linked to progression. Low-risk HPV variants (e.g., types 6 and 11) associated with the development of condylomas of the lower genital tract (Fig. 19.5), by contrast, express E6 and E7 variants with different or weaker activities and do not integrate into the host genome, remaining instead as free episomal viral DNA. Despite the strong association of HPV infection with cancer of the cervix, HPV is not sufficient to drive the neoplastic process. As mentioned later, HPV-infected high-grade precursor lesions do not invariably progress to invasive cancer. Diverse other factors such as immune and hormonal status and coinfection with other sexually transmitted agents are suspected to play a role. Collectively these factors favor the acquisition of somatically acquired mutations that involve both oncogenes and tumor suppressor genes. Viral integration appear to contribute to transformation in two ways: 1) integration always disrupts an HPV gene that negatively regulates E6 and E7, which leads to their increased expression; and 2) sometimes HPV integrates near a host cell oncogene such as *MYC*, leading to its overexpression as well.

Squamous Intraepithelial Lesion (SIL, Cervical Intraepithelial Lesion)

HPV-related carcinogenesis begins with the precancerous epithelial change termed SIL, which usually precedes the development of an overt cancer by many years, sometimes decades. In support of this idea, SIL peaks in incidence at about 30 years of age, whereas invasive carcinoma peaks at about 45 years of age.

The classification of cervical precursor lesions has evolved with time. The current terminology is a two-tiered system that not only reflects the biology of the disease but also patient management, replacing a three-tiered system.

- SIL is divided into low-grade squamous intraepithelial lesion (LSIL), still often referred to as cervical intraepithelial neoplasia I (CIN I), and high-grade squamous intraepithelial lesion (HSIL), encompassing cervical intraepithelial neoplasia II and III (CIN II and III) of the previous three-tiered system.
- LSIL is associated with productive HPV infection and does not progress directly to invasive carcinoma. Actually, most LSILs regress and only a small percentage progress to HSIL.
- HSIL demonstrates increased proliferation, arrested epithelial maturation, and lower levels of viral replication. LSIL is not treated as a premalignant lesion, whereas HSIL is considered at high risk for progression to carcinoma.

Importantly, LSIL is 10 times more common than HSIL and while HSILs are precancerous, the majority of them fail to progress to cancer and may even regress. Patient management rests on the histopathologic diagnosis as discussed later. As shown in Table 19.1, the decision to treat HSIL and to observe LSIL is based on differences in the natural histories of these two groups of lesions.

Cervical precancerous lesions are associated with abnormalities in cytologic preparations that can be detected long before any abnormality is visible on gross inspection. Early detection of SIL is the rationale for the Papanicolaou (Pap) test, in which cells are scraped from the transformation zone and examined microscopically. **The Pap smear remains the most successful cancer-screening test ever developed.** In the United States, Pap screening has dramatically lowered the incidence of invasive cervical tumors to about 13,000 cases annually with a mortality of about 4000 per year; in fact, cervical cancer no longer ranks among the top 10 causes of cancer deaths in U.S. women. Paradoxically, the incidence of SIL has increased to its present level of more than 50,000 cases annually. Increased detection has certainly contributed to this. The U.S. Food and Drug Administration has approved testing for HPV DNA in cervical scrapings. This test is highly sensitive but has lower

Table 19.1 Natural History of Squamous Intraepithelial Lesions (SILs)

Lesion	Regress	Persist	Progress
LSIL (CIN I)	60%	30%	10% (to HSIL)
HSIL (CIN II, III)	30%	60%	10% (to carcinoma)[a]

[a]Progression within 10 years.
LSIL, Low-grade SIL; HSIL, high-grade SIL.

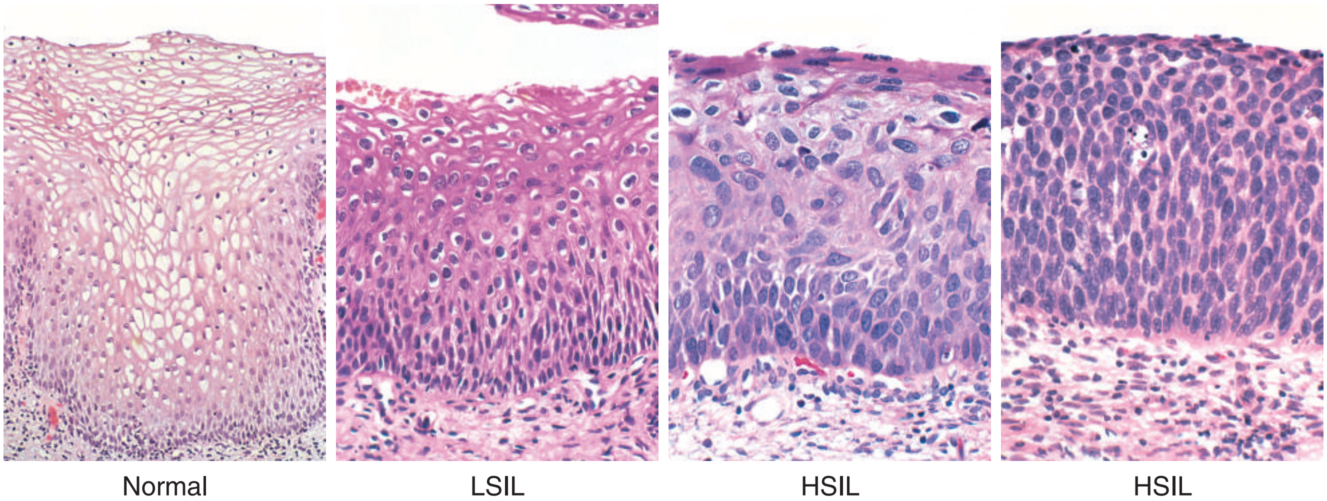

Fig. 19.6 Spectrum of squamous intraepithelial lesions (SIL) with normal squamous epithelium for comparison: LSIL with koilocytotic atypia; HSIL with progressive atypia in all layers of the epithelium; and HSIL with diffuse atypia and loss of maturation (carcinoma in situ, *far right image*).

specificity than the Pap smear, and specific guidelines for its use have not been well established. One consideration is that while most women acquire HPV infections in their early 20s, these are usually cleared by the immune system and never progress to SIL, a process that occurs over many years. For this reason, HPV DNA screening is only recommended for women aged 30 or older, as a positive test at this age is more likely to identify an individual with a persistent infection that may lead to cervical neoplasia.

The quadrivalent HPV vaccine for types 6, 11, 16, and 18, and the more recently introduced 9-valent vaccine, are very effective in preventing HPV infections and are expected to greatly lower the frequency of genital warts and cervical cancers associated with these HPV genotypes. Despite its efficacy, vaccination does not supplant the need for routine cervical cancer screening—many at-risk women are already infected, and current vaccines protect against only some of the many oncogenic HPV genotypes.

MORPHOLOGY

Fig. 19.6 illustrates the three stages of SIL. LSIL is characterized by dysplastic changes in the lower third of the squamous epithelium and **koilocytotic change** in the superficial layers of the epithelium. In HSIL (CIN II), dysplasia extends to the middle third of the epithelium in the form of variation in cell and nuclear size, heterogeneity of nuclear chromatin, and the presence of mitoses, some atypical, above the basal layer extending into the middle third of the epithelium. The superficial layer of cells in CIN II still shows differentiation and occasional koilocytotic changes HSIL (CIN III) is marked by almost complete loss of differentiation, even greater variation in cell and nuclear size, chromatin heterogeneity, disorderly orientation of the cells, and abnormal mitoses, changes that affect virtually all layers of the epithelium. Koilocytotic change usually is absent. These histologic features correlate with the cytologic appearances shown in Fig. 19.7.

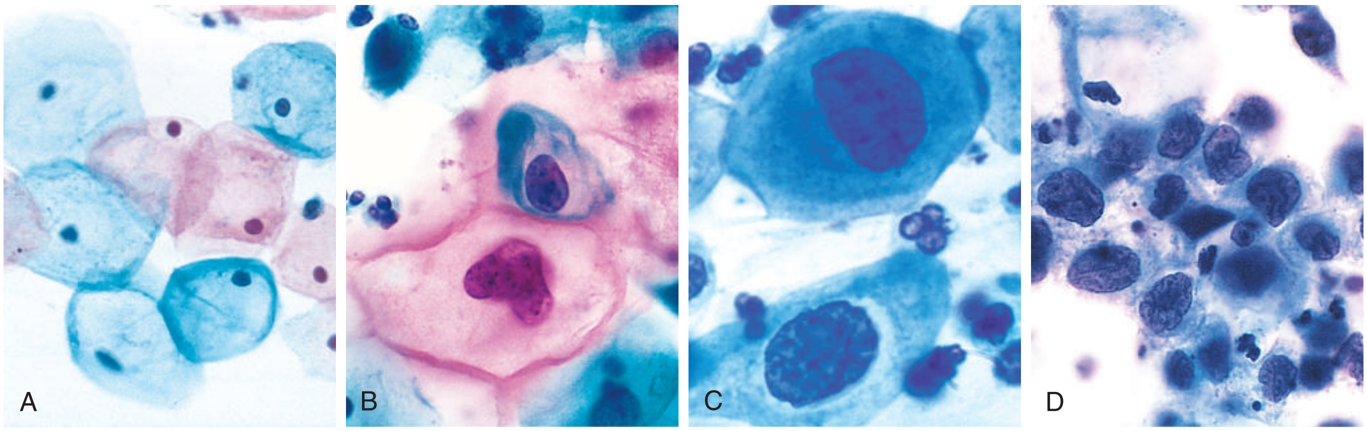

Fig. 19.7 Cytologic features of squamous intraepithelial lesion (SIL) in a Papanicolaou smear. Superficial squamous cells may stain either red or blue. (A) Normal exfoliated superficial squamous epithelial cells. (B) Low-grade squamous intraepithelial lesion (LSIL). (C and D) Both high-grade squamous intraepithelial lesions (HSILs). Note the reduction in cytoplasm and the increase in the nucleus-to-cytoplasm ratio as the grade of the lesion increases. This observation reflects the progressive loss of cellular differentiation on the surface of the cervical lesions from which these cells are exfoliated (see Fig. 19.6). *(Courtesy of Dr. Edmund S. Cibas, Brigham and Women's Hospital, Boston, Massachusetts.)*

SIL is asymptomatic and comes to clinical attention through an abnormal Pap smear result. These cases are followed up by colposcopy, in which acetic acid is used to highlight the lesions so they can be biopsied. Women with biopsy-documented LSIL are managed conservatively with careful observation, whereas HSILs and persistent LSIL are treated with surgical excision (cone biopsy). Follow-up smears and clinical examination are required in patients with HSIL, as these women remain at risk for HPV-associated cervical, vulvar, and vaginal cancers.

Invasive Carcinoma of the Cervix

The most common cervical carcinomas are squamous cell carcinomas (75%), followed by adenocarcinomas and mixed adenosquamous carcinomas (20%) and small cell neuroendocrine carcinomas (<5%). All of these types of carcinomas are associated with HPV. Of interest, the relative proportion of adenocarcinomas has been increasing in recent decades owing to the decreasing incidence of invasive squamous carcinoma and suboptimal detection of glandular lesions by Pap smear.

Squamous cell carcinoma has a peak incidence at the age of about 45 years, some 10 to 15 years after detection of precursor SIL. As already discussed, **progression of SIL to invasive carcinoma is variable and unpredictable and requires HPV infection as well as mutations in tumor suppressor genes and oncogenes.** Risk factors for progression include cigarette smoking and human immunodeficiency virus (HIV) infection, the latter finding suggesting that immune surveillance plays a role in preventing progression. Although risk factors may help identify patients who are likely to progress from SIL to carcinoma, the only reliable way to monitor the disease course is with frequent physical examinations coupled with Pap smears and biopsy of suspicious lesions.

MORPHOLOGY

Invasive carcinomas of the cervix develop in the **transformation zone** and range from microscopic foci of stromal invasion to grossly conspicuous exophytic tumors (Fig. 19.8). Microscopically, the invasive tumors often consist of tongues and nests of squamous cells that produce a desmoplastic stromal response. Grading is based on the degree of squamous differentiation, which ranges from minimal to well-differentiated tumors that elaborate keratin pearls. Rare tumors with neuroendocrine differentiation resemble small cell carcinomas of the lung morphologically. Tumors encircling the cervix and penetrating into the underlying stroma produce a **barrel cervix,** which can be identified by direct palpation. Extension into the parametrial soft tissues can affix the uterus to the surrounding pelvic structures. The likelihood of spread to pelvic lymph nodes correlates with the depth of tumor invasion and the presence of tumor cells in vascular spaces. The risk of metastasis increases from less than 1% for tumors less than 3 mm in depth to more than 10% after invasion exceeds 3 mm.

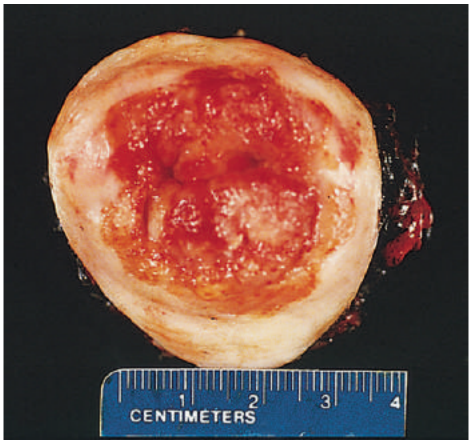

Fig. 19.8 Cervical os with surrounding, invasive, exophytic cervical carcinoma.

Clinical Features

Invasive cervical cancer most often is seen in women who have never had a Pap smear or who have not been screened for many years. In such cases, cervical cancer often is symptomatic, with patients coming to medical attention for unexpected vaginal bleeding, leukorrhea, painful coitus (dyspareunia), or dysuria. The primary treatment is hysterectomy and lymph node dissection; small microinvasive carcinomas may be treated with cone biopsy. Radiation and chemotherapy are also of benefit in instances where surgery alone is not curative. Mortality is most strongly predicted by tumor stage and, in the case of neuroendocrine carcinomas (which pursue an aggressive course) to cell type.

Endocervical Polyp

Endocervical polyps are benign polypoid masses seen protruding from the endocervical mucosa (sometimes through the exocervix). They can be as large as a few centimeters and have a smooth, glistening surface with underlying cystically dilated spaces filled with mucinous secretions. The surface epithelium and lining of the underlying cysts are composed of the same mucus-secreting columnar cells that line the endocervical canal. The stroma is edematous and may contain scattered mononuclear cells. Superimposed chronic inflammation may lead to squamous metaplasia of the overlying epithelium and ulcerations. These lesions may bleed, thereby arousing concern, but they have no malignant potential.

SUMMARY

CERVICAL NEOPLASIA

- Risk factors for cervical carcinoma are related to HPV exposure, such as early age at first intercourse, multiple sexual partners, and other factors including cigarette smoking and immunodeficiency.
- Nearly all cervical carcinomas are caused by HPV infections, particularly high-risk HPV types 16, 18, 31, and 33;

the HPV vaccine is effective in preventing infection resulting from the HPV types most commonly associated with carcinoma.

- HPV expresses E6 and E7 proteins that inactivate the p53 and RB tumor suppressors, respectively, resulting in increased cell proliferation and suppression of DNA damage–induced apoptosis.
- In cervical cancer, high-risk HPV is integrated in the host genome, an event that increases the expression of E6 and E7 and contributes to progression to cancer.
- The Pap smear is a highly effective screening tool for the detection of SIL and carcinoma and has significantly reduced the incidence of cervical carcinoma. HPV testing is currently being used in conjunction with the Pap smear.

Uterus

The body (corpus) of the uterus is composed of the endometrium, consisting of glands and stroma, and the myometrium, made up of smooth muscle. The more frequent and significant disorders of the uterus are considered here.

ENDOMETRITIS

Inflammation of the endometrium is classified as acute or chronic depending on whether a neutrophilic or a lymphoplasmacytic infiltrate predominates, respectively. The diagnosis of chronic endometritis generally requires the presence of plasma cells, as lymphocytes are present even in the normal endometrium.

Endometritis is a component of pelvic inflammatory disease and is frequently a result of *N. gonorrhoeae* or *C. trachomatis* infection. Histologic examination shows a neutrophilic infiltrate in the superficial endometrium coexisting with a stromal lymphoplasmacytic infiltrate. Prominent lymphoid follicles may be seen, particularly in chlamydial infection. Tuberculosis causes granulomatous endometritis, frequently with associated tuberculous salpingitis and peritonitis. Although seen in the United States mainly in immunocompromised persons, tuberculous endometritis is common in countries in which tuberculosis is endemic, and it should be included in the differential diagnosis for pelvic inflammatory disease in women who have recently emigrated from endemic areas.

Endometritis also may be a result of retained products of conception subsequent to miscarriage or delivery or the presence of a foreign body such as an intrauterine device. Retained tissue or foreign bodies act as a nidus for ascending infection by vaginal or intestinal tract flora. Removal of the offending tissue or foreign body typically results in resolution.

Clinically, all forms of endometritis manifest with fever, abdominal pain, and menstrual abnormalities. In addition, there is an increased risk of infertility and ectopic pregnancy due to damage and scarring of the fallopian tubes.

ADENOMYOSIS

Adenomyosis refers to the presence of endometrial tissue in the myometrium. Nests of endometrial stroma, glands, or both are found deep in the myometrium interposed between the muscle bundles. This endometrial tissue induces reactive hypertrophy of the myometrium, resulting in an enlarged, globular uterus, often with a thickened uterine wall. Extensive adenomyosis may produce menorrhagia, dysmenorrhea, and pelvic pain, particularly just prior to menstruation, and can coexist with endometriosis.

ENDOMETRIOSIS

Endometriosis is defined by the presence of endometrial glands and stroma in a location outside the uterus. It occurs in as many as 10% of women in their reproductive years and in nearly half of women with infertility. It frequently is multifocal and often involves pelvic structures (ovaries, pouch of Douglas, uterine ligaments, tubes, and rectovaginal septum). Less frequently, distant areas of the peritoneal cavity or periumbilical tissues are involved. Uncommonly, distant sites such as lymph nodes, lungs, and even heart, skeletal muscle, or bone are affected.

Four hypotheses have been put forth to explain the origin of dispersed endometriotic lesions, all of which are viable:

- The *regurgitation theory*, which is currently favored, proposes that menstrual backflow through the fallopian tubes leads to implantation.
- The *benign metastases theory* holds that endometrial tissue from the uterus can “spread” to distant sites via blood vessels and lymphatics.
- The *metaplastic theory,* on the other hand, posits endometrial differentiation of coelomic epithelium (mesothelium of pelvis and abdomen from which endometrium originates) as the source.
- The *extrauterine stem/progenitor cell theory,* proposes that circulating stem/progenitor cells from the bone marrow differentiate into endometrial tissue.

Studies suggest that endometriotic tissue is not just misplaced but is also abnormal (Fig. 19.9). As compared to normal endometrium, endometriotic tissue exhibits increased levels of inflammatory mediators, particularly prostaglandin E2. It is proposed that the inflammation results from the recruitment and activation of macrophages by factors made by endometrial stromal cells. Stromal cells also make aromatase, leading to local production of estrogen. These factors enhance the survival and persistence of the endometriotic tissue within a foreign location (a key feature in the pathogenesis of endometriosis) and help to explain the beneficial effects of COX-2 inhibitors and aromatase inhibitors in the treatment of endometriosis.

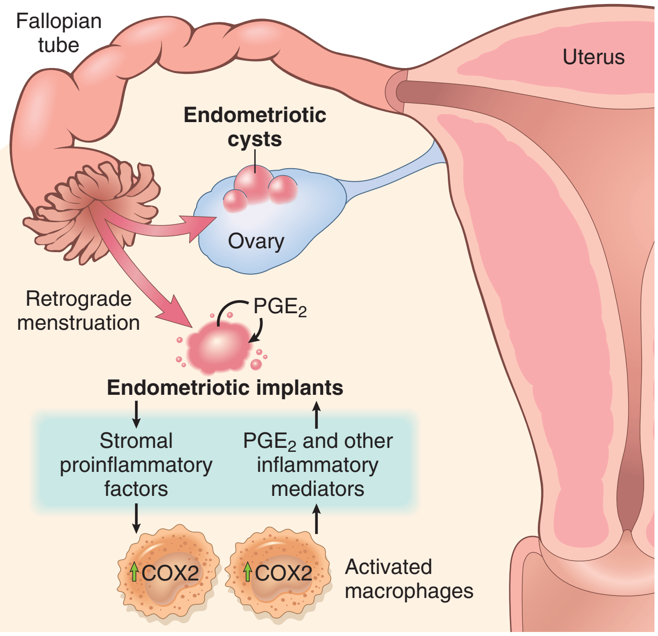

Fig. 19.9 Proposed origins of endometriosis.

MORPHOLOGY

Endometriosis typically consists of **functioning endometrium,** which undergoes cyclic bleeding. Because blood collects in these aberrant foci, they appear grossly as red-brown nodules or implants. They range in size from microscopic to 1 to 2 cm in diameter and lie on or just under the affected serosal surface. Often, individual lesions coalesce to form larger masses. When the ovaries are involved, the lesions may form large, blood-filled cysts that turn brown **(chocolate cysts)** as the blood ages (Fig. 19.10). With seepage and organization of the blood, widespread fibrosis occurs, leading to adhesions among pelvic structures, sealing of the tubal fimbriated ends, and distortion of the fallopian tubes and ovaries. The diagnosis depends on finding both endometrial glands and stroma at sites external to the endometrium.

Fig. 19.10 Ovarian endometriosis. Sectioning of ovary shows a large endometriotic cyst with degenerated blood ("chocolate cyst").

Clinical Features

The clinical manifestations of endometriosis depend on the distribution of the lesions. Extensive scarring of the fallopian tubes and ovaries often produces discomfort in the lower abdomen and eventual sterility. Rectal wall involvement may produce pain on defecation, whereas involvement of the uterine or bladder serosa can cause dyspareunia (painful intercourse) and dysuria, respectively. Almost all cases feature severe dysmenorrhea and pelvic pain resulting from intrapelvic bleeding and intraabdominal adhesions.

ABNORMAL UTERINE BLEEDING

Women commonly seek medical attention for abnormal uterine bleeding, such as *menorrhagia* (profuse or prolonged bleeding at the time of the period), *metrorrhagia* (irregular bleeding between the periods), or postmenopausal bleeding. Common causes include dysfunctional uterine bleeding, endometrial polyps, leiomyomas, endometrial hyperplasia, and endometrial carcinoma.

The probable cause of uterine bleeding in any given case varies depending on the age of the patient (Table 19.2). Abnormal bleeding from the uterus in the absence of an organic uterine lesion is called *dysfunctional uterine bleeding.* The most common cause of dysfunctional uterine bleeding is anovulation (failure to ovulate). Anovulatory cycles result from hormonal imbalances and are most common at menarche and in the perimenopausal period because of fluctuations in the hypothalamus/pituitary/ovarian axis. Less common causes of anovulation are

- *Endocrine disorders,* such as thyroid disease, adrenal disease, or pituitary tumors.
- *Ovarian lesions,* such as a functioning ovarian tumor (granulosa cell tumors) or polycystic ovarian syndrome (see section on ovaries that follows).
- *Generalized metabolic disturbances,* such as obesity, malnutrition, or other chronic systemic disorders.

Dysfunctional uterine bleeding also may result from an inadequate luteal phase, which is thought to stem from

Table 19.2 Causes of Abnormal Uterine Bleeding by Age Group

Age Group	Cause(s)
Prepuberty	Precocious puberty (hypothalamic, pituitary, or ovarian origin)
Adolescence	Anovulatory cycle
Reproductive age	Complications of pregnancy (abortion, trophoblastic disease, ectopic pregnancy) Proliferations (leiomyoma, adenomyosis, polyps, endometrial hyperplasia, carcinoma) Anovulatory cycle Ovulatory dysfunctional bleeding (e.g., inadequate luteal phase)
Perimenopause	Anovulatory cycle Irregular shedding Proliferations (carcinoma, hyperplasia, polyps)
Postmenopause	Proliferations (carcinoma, hyperplasia, polyps) Endometrial atrophy

insufficient production of progesterone by the corpus luteum.

SUMMARY

NONNEOPLASTIC DISORDERS OF ENDOMETRIUM

- Adenomyosis refers to growth of endometrium into the myometrium often with uterine enlargement.
- Endometriosis refers to endometrial glands and stroma located outside the uterus and most often involves the pelvic or abdominal peritoneum. Rarely, distant sites such as the lymph nodes and the lungs also are involved.
- The ectopic endometrium in endometriosis undergoes cyclic bleeding, and the condition is a common cause of dysmenorrhea and pelvic pain.

PROLIFERATIVE LESIONS OF THE ENDOMETRIUM AND MYOMETRIUM

The most common proliferative lesions of the uterine corpus are endometrial hyperplasia, endometrial carcinomas, endometrial polyps, and smooth muscle tumors. All tend to produce abnormal uterine bleeding as their earliest manifestation.

Endometrial Hyperplasia

An excess of estrogen relative to progestin, if sufficiently prolonged or marked, can induce exaggerated endometrial proliferation (hyperplasia), which is an important precursor of endometrial carcinoma. A common cause of estrogen excess is obesity, as adipose tissue converts steroid precursors into estrogens. Other potential causes of estrogen excess include failure of ovulation (such as in perimenopause), prolonged administration of estrogenic steroids without counterbalancing progestin, and estrogen-producing ovarian lesions (such as polycystic ovary syndrome and granulosa-theca cell tumors of the ovary).

Endometrial hyperplasia is placed in two categories based on the presence of cytologic atypia: hyperplasia without atypia and hyperplasia with atypia (Fig. 19.11). The importance of this classification is that the presence of cytologic atypia correlates with the development or concurrent finding of endometrial carcinoma. Hyperplasia without cellular atypia carries a low risk (between 1% and 3%) for progression to endometrial carcinoma, whereas hyperplasia with atypia, also called *endometrial intraepithelial neoplasia (EIN),* is associated with a much higher risk (20%–50%). When hyperplasia with atypia is discovered, it must be carefully evaluated for the presence of cancer and usually warrants a hysterectomy in patients no longer desiring fertility. In younger patients, treatment with high-dose progestins may be used in an attempt to preserve the uterus.

Unopposed estrogen is also a risk factor for the most common type of endometrial carcinoma (see later), and inactivation of the *PTEN* tumor suppressor gene has been identified at a substantial frequency in hyperplasia with atypia (approximately 50%) and endometrioid carcinoma (>70%). Along with clinicopathologic and epidemiologic studies, these findings indicate that hyperplasia with atypia is a precursor lesion for endometrioid endometrial carcinoma.

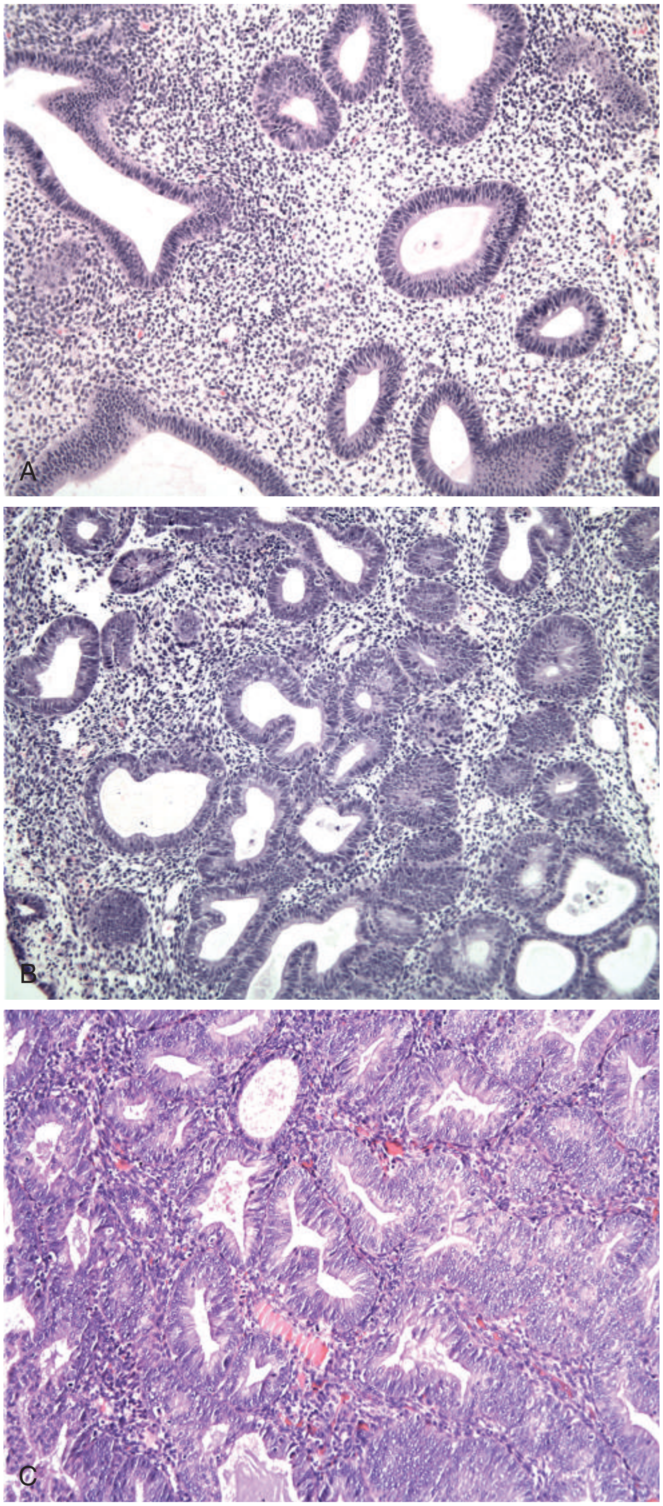

Fig. 19.11 Endometrial hyperplasia. (A) Anovulatory or "disordered" endometrium containing dilated glands. (B) Hyperplasia without atypia, characterized by nests of closely packed glands. (C) Hyperplasia with atypia, seen as glandular crowding and cellular atypia.

Endometrial Carcinoma

In the United States and many other Western countries, endometrial carcinoma is the most frequent cancer occurring in the female genital tract. It generally appears between the ages of 55 and 65 years and is uncommon before age 40. Endometrial carcinoma can be broadly divided into two histologically and pathogenically distinct categories: endometrioid and serous carcinoma. There are other less common types of endometrial carcinoma, such as clear cell carcinoma and mixed Mullerian tumor (carcinosarcoma), but these will not be discussed further.

Pathogenesis

Endometrioid cancers arise in association with estrogen excess in the setting of endometrial hyperplasia in perimenopausal women, whereas serous cancers arise in the setting of endometrial atrophy in older postmenopausal women. The *endometrioid type* accounts for 80% of cases of endometrial carcinomas. These tumors are designated as endometrioid because of their histologic similarity to normal endometrial glands. Risk factors for this type of carcinoma include (1) obesity, (2) diabetes, (3) hypertension, (4) infertility, and (5) exposure to unopposed estrogen. Many of these risk factors result in increased estrogenic stimulation of the endometrium and are associated with endometrial hyperplasia. In fact, it is well recognized that prolonged estrogen replacement therapy and estrogen-secreting ovarian tumors increase the risk of the endometrioid type of endometrial carcinoma. **Mutations in mismatch repair genes and the tumor suppressor gene *PTEN* are early events in the stepwise development of endometrioid carcinoma.** Women with germline mutations in *PTEN* (Cowden Syndrome) and germline alterations in DNA mismatch repair genes (Lynch Syndrome) are at high risk for this cancer. *TP53* mutations occur but are relatively uncommon and are late events in the genesis of this tumor type.

The *serous type* of endometrial carcinoma is less common but also far more aggressive. It accounts, for roughly 15% of tumors and is not associated with unopposed estrogen or endometrial hyperplasia. Nearly all cases of serous carcinoma have mutations in the *TP53* tumor suppressor gene, whereas mutations in DNA mismatch repair genes and in *PTEN* are rare. Serous tumors are preceded by a lesion called serous endometrial intraepithelial carcinoma (SEIC) in which *TP53* mutations are often detected, suggesting an early role for such mutations in the development of this form of endometrial carcinoma.

MORPHOLOGY

Endometrioid carcinomas closely resemble normal endometrium and may be exophytic or infiltrative (Fig. 19.12A–B). They include a range of histologic types, including those showing mucinous, tubal (ciliated), and squamous differentiation. Endometrioid carcinomas often infiltrate the myometrium and can enter vascular spaces (lymphovascular invasion). They may also metastasize to regional lymph nodes. Endometrioid carcinomas are graded 1 to 3, based on the degree of differentiation.

Serous carcinomas typically grow in small tufts and papillae with marked cytologic atypia. They can also form glands that at times create confusion with endometrioid carcinoma, however serous carcinomas exhibit much greater cytologic atypia. Serous carcinomas behave aggressively and thus are by definition high grade. Immunohistochemistry often shows diffuse, strong staining for p53 in serous carcinoma (Fig. 19.12C–D), a finding that correlates with the presence of *TP53* mutations (mutant p53 accumulates and hence is more easily detected by staining).

Clinical Features

Endometrial carcinomas usually manifest with irregular or postmenopausal bleeding. With progression, the uterus enlarges and may become affixed to surrounding structures as the cancer infiltrates surrounding tissues. Endometrioid carcinoma usually is slow to metastasize, but if left untreated, eventually disseminates to regional nodes and more distant sites. With therapy, the 5-year survival rate for early-stage endometrioid carcinoma is 90%, but survival drops precipitously in higher-stage tumors. The prognosis with serous carcinomas is strongly dependent on operative staging but because of its aggressive behavior it often presents as high-stage disease with a poor prognosis.

SUMMARY

ENDOMETRIAL HYPERPLASIA AND ENDOMETRIAL CARCINOMA

- Endometrial hyperplasia results from unopposed endogenous or exogenous estrogen.
- Risk factors for developing endometrial hyperplasia include anovulatory cycles, polycystic ovary syndrome, estrogen-producing ovarian tumor, obesity, and estrogen therapy without counterbalancing progestin.
- Hyperplasia is classified based on cytologic atypia, which determines the risk of developing endometrioid carcinoma.
- On the basis of clinical and molecular data, two major types of endometrial carcinoma are recognized:
  - *Endometrioid carcinoma* is associated with estrogen excess and endometrial hyperplasia. Early molecular changes include inactivation of DNA mismatch repair genes and the *PTEN* gene.
  - *Serous carcinoma* of the endometrium arises in older women and usually is associated with endometrial atrophy and a distinct precursor lesion, serous intraepithelial carcinoma. Mutations in the *TP53* gene are an early event, usually being present in serous endometrial intraepithelial carcinoma as well as invasive serous carcinoma.
- Stage is the major determinant of survival in both types. Serous tumors tend to manifest more frequently with extrauterine extension and therefore have a worse prognosis than endometrioid carcinomas.

Endometrial Polyps

These polyps are usually sessile and range from 0.5 to 3 cm in diameter. Larger polyps may project from the

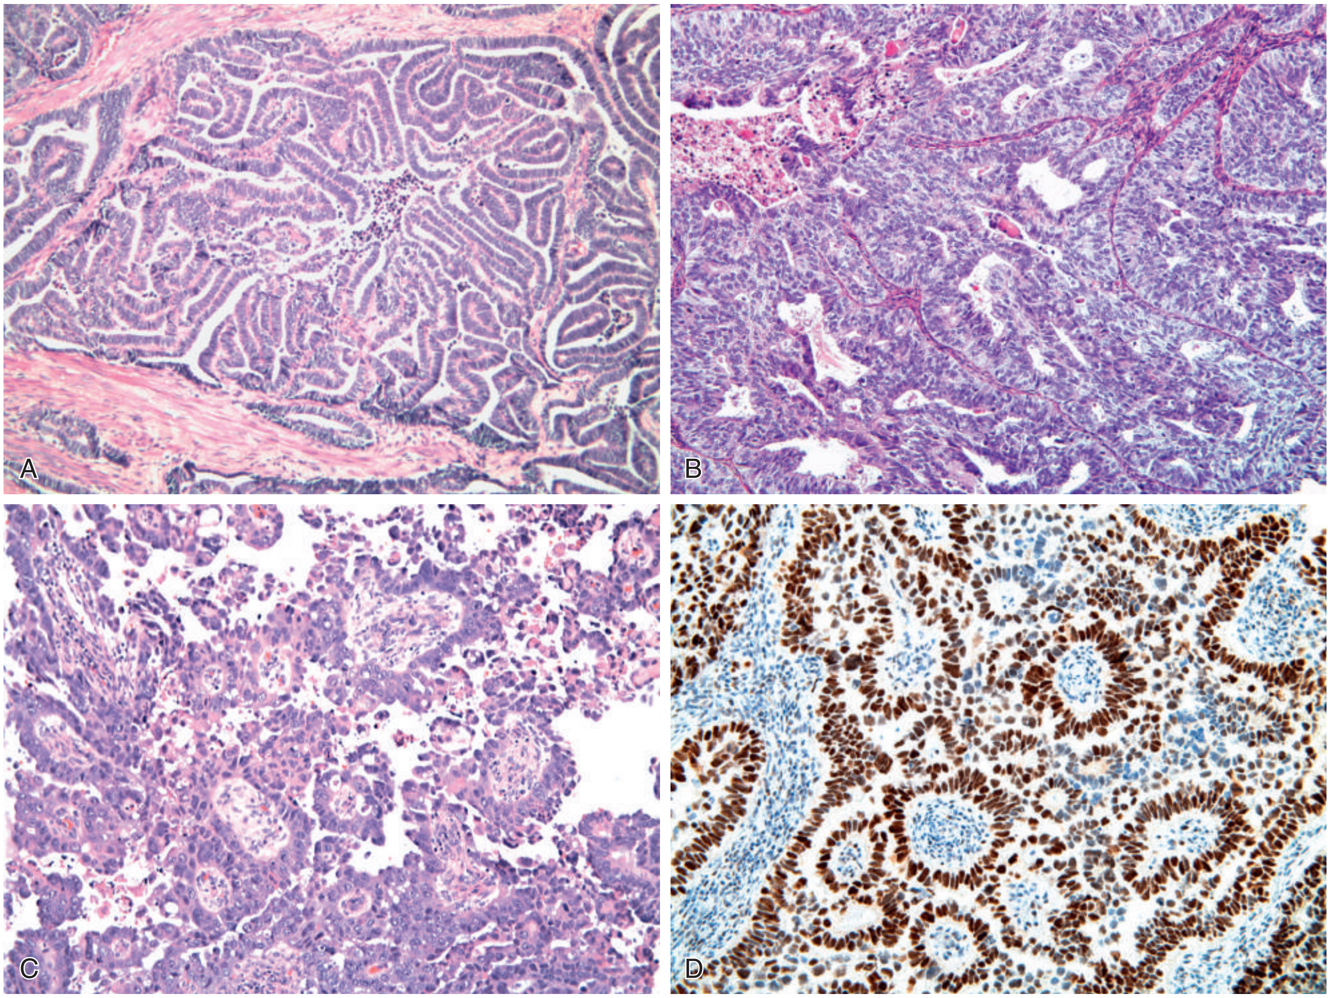

Fig. 19.12 Endometrial carcinoma. (A) Endometrioid type, grade 1, infiltrating myometrium and growing in a glandular pattern. (B) Endometrioid type, grade 3, has a predominantly solid growth pattern. (C) Serous carcinoma of the endometrium, with papilla formation and marked cytologic atypia. (D) Immunohistochemical staining shows accumulation of p53, a finding associated with *TP53* mutation.

endometrial mucosa into the uterine cavity. They are composed of endometrium resembling the basalis, frequently with small muscular arteries. Some glands are normal architecturally, but more often they are cystically dilated. The stromal cells are monoclonal, often with a rearrangement of chromosomal region 6p21, and thus constitute the neoplastic component of the polyp.

Although endometrial polyps may occur at any age, they are most common around the time of menopause. Their main clinical significance is that they may produce abnormal uterine bleeding.

Leiomyoma

Benign tumors that arise from the smooth muscle cells in the myometrium are properly termed *leiomyomas,* but because of their firmness often are referred to clinically as *fibroids.* Leiomyomas are the most common benign tumor in females, affecting 30% to 50% of women of reproductive age, and are considerably more frequent in black women. These tumors are associated with several different recurrent chromosomal abnormalities, including rearrangements of chromosomes 6 and 12 that also are found in a variety of other benign neoplasms, such as endometrial polyps and lipomas. Mutations in the *MED12* gene, which encodes a component of the RNA polymerase transcription complex, have been identified in up to 70% of leiomyomas. The mechanism by which *MED12* mutations contribute to the development of leiomyomas is not presently understood. Estrogens and possibly oral contraceptives stimulate the growth of leiomyomas; conversely, these tumors shrink postmenopausally.

MORPHOLOGY

Leiomyomas are typically **sharply circumscribed,** firm gray-white masses with a characteristic **whorled cut surface.** They may occur singly, but more often occur as **multiple tumors** that are scattered within the uterus, ranging from small nodules to large tumors (Fig. 19.13) that may dwarf the uterus. Some are embedded within the myometrium (intramural), whereas others may lie immediately beneath the endometrium (submucosal)

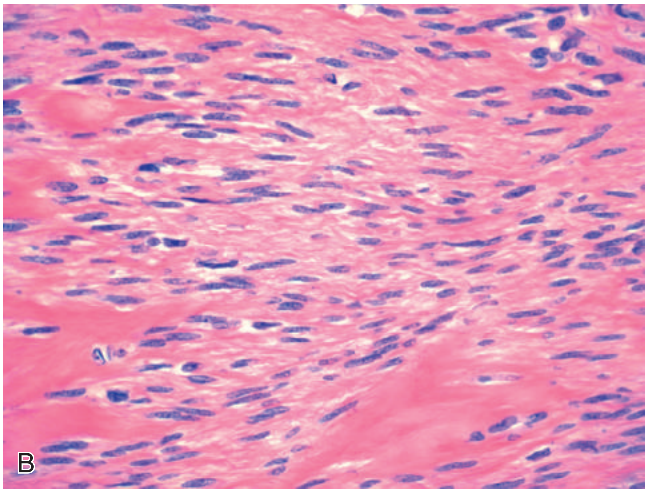

Fig. 19.13 Uterine leiomyomas. (A) The uterus is opened to show multiple submucosal, myometrial, and subserosal gray-white tumors, each with a characteristic whorled appearance on cut section. (B) Microscopic appearance of leiomyoma shows bundles of normal-looking smooth muscle cells.

or the serosa (subserosal). In the latter location, tumors may extend out on attenuated stalks and even become attached to surrounding organs, from which they may develop a blood supply (**parasitic** leiomyomas). On histologic examination, the tumors are characterized by **bundles of smooth muscle cells** mimicking the appearance of normal myometrium. Foci of fibrosis, calcification, and degenerative softening may be present.

Leiomyomas of the uterus often are asymptomatic, being discovered incidentally on routine pelvic examination. The most frequent presenting sign is menorrhagia, with or without metrorrhagia. Leiomyomas rarely, if ever, transform into sarcomas, and the presence of multiple lesions does not increase the risk of malignancy.

Leiomyosarcoma

Leiomyosarcomas of the uterus virtually always arise de novo from the mesenchymal cells of the myometrium. They are almost always solitary and most often occur in postmenopausal women, in contradistinction to leiomyomas, which frequently are multiple and usually arise premenopausally.

Recurrence after surgery is common with these cancers, and many metastasize, typically to the lungs, yielding a 5-year survival rate of about 40%. The outlook with anaplastic tumors is less favorable than with well-differentiated tumors.

MORPHOLOGY

Leiomyosarcomas typically take the form of **soft, hemorrhagic, necrotic masses.** The histologic appearance varies widely, from tumors that closely resemble leiomyoma to wildly anaplastic neoplasms. Well-differentiated tumors may lie at the morphologic interface between leiomyoma and leiomyosarcoma and are sometimes designated smooth muscle tumors of uncertain malignant potential. The diagnostic features of leiomyosarcoma include **tumor necrosis, cytologic atypia,** and **mitotic activity.** Because increased mitotic activity is sometimes seen in benign smooth muscle tumors, particularly in young women, an assessment of all three features is necessary to make a diagnosis of malignancy.

Fallopian Tubes

The most common disorder of the fallopian tubes is inflammation (salpingitis), almost invariably occurring as a component of pelvic inflammatory disease. Less common abnormalities are ectopic (tubal) pregnancy and endometriosis.

Inflammation of the fallopian tubes is almost always caused by infection. In addition to gonorrhea, nongonococcal organisms, such as *Chlamydia, Mycoplasma hominis,* coliforms, and (in the postpartum setting) streptococci and staphylococci are the major offenders. The morphologic changes produced by gonococci are similar to those in the male genital tract (Chapter 18). Infections with coliforms, streptococci, and staphylococci can penetrate the wall of the tubes, giving rise to blood-borne infections that seed to distant sites. Tuberculous salpingitis is far less common and is almost always encountered in combination with tuberculous endometritis. All forms of salpingitis may produce fever, lower abdominal or pelvic pain, and pelvic masses, which are the result of distention of the tubes with either exudate or inflammatory debris (Fig. 19.14). Adherence of the inflamed tube to the ovary and adjacent ligamentous tissues may produce a tuboovarian abscess. This may in turn result in adhesions between the ovary and the tubes when the inflammation subsides. Even more serious are adhesions of the tubal plicae, which are associated with increased risk of tubal ectopic pregnancy (discussed later).

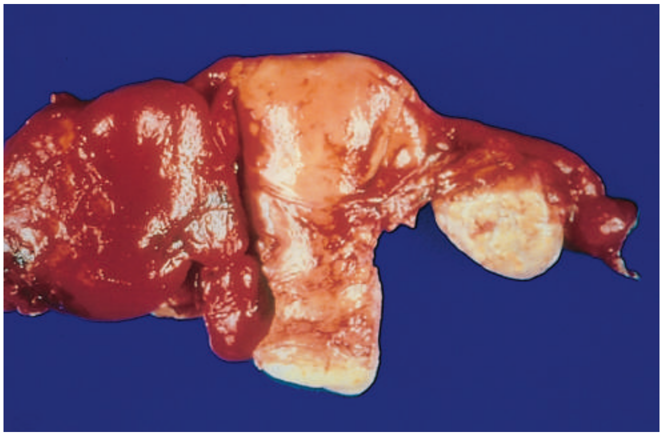

Fig. 19.14 Pelvic inflammatory disease, bilateral and asymmetric. The tube and ovary to the left of the uterus are totally obscured by a hemorrhagic inflammatory mass. The tube is adherent to the adjacent ovary on the other side.

Damage to or obstruction of the tubal lumina may produce permanent sterility.

Once thought to be uncommon, primary adenocarcinomas of the fallopian tube may be the site of origin for many of the high-grade serous carcinomas long thought to arise in the ovary. Studies have identified the presence of serous tubal intraepithelial carcinoma (STIC) in the fimbriated ends of fallopian tubes. Like the precursor of uterine serous carcinoma, STICs have mutations in *TP53* in more than 90% of cases. These lesions are found frequently in fallopian tubes removed prophylactically from women who carry mutations in *BRCA1* and *BRCA2* and less commonly in instances where tubes are removed from women without known genetic risk factors. This has led to the idea that sporadic "ovarian" serous carcinomas (discussed later) also originate in the fallopian tube. Because the fimbriated end of the fallopian tube is intimately associated with the ovary and has access to the peritoneal cavity, fallopian tube carcinomas frequently involve the ovary, omentum, and peritoneal cavity at presentation.

Ovaries

FOLLICLE AND LUTEAL CYSTS

Follicle and luteal cysts in the ovaries are so commonplace that they may be considered variants of normal physiology. These innocuous lesions originate from unruptured graafian follicles or from follicles that rupture and then immediately seal. Such cysts often are multiple and develop subjacent to the serosa of the ovary. They typically are small (1–1.5 cm in diameter) and are filled with clear serous fluid. Occasionally, they become sufficiently large (4–5 cm) to produce palpable masses and pelvic pain. When small, they are lined by granulosa lining cells or luteal cells, but as fluid accumulates, pressure may cause atrophy of these cells. Sometimes these cysts rupture, producing intraperitoneal bleeding and peritoneal symptoms (acute abdomen).

POLYCYSTIC OVARIAN SYNDROME

Polycystic ovarian syndrome (formerly called *Stein-Leventhal syndrome*) is a complex endocrine disorder characterized by hyperandrogenism, menstrual abnormalities, polycystic ovaries, chronic anovulation, and decreased fertility. It usually comes to attention after menarche in teenage girls or young adults who present with oligomenorrhea, hirsutism, infertility, and sometimes with obesity.

The ovaries are usually twice the normal size, gray-white with a smooth outer cortex, and studded with subcortical cysts 0.5 to 1.5 cm in diameter. Histologic examination shows a thickened, fibrotic ovarian capsule overlying innumerable cystic follicles lined by granulosa cells with a hyperplastic luteinized theca interna. There is a conspicuous absence of corpora lutea in the ovary.

TUMORS OF THE OVARY

In the United States it is estimated that there will be over 20,000 ovarian cancer cases diagnosed in 2016 leading to over 14,000 deaths, making ovarian cancer the fifth leading contributor to cancer mortality in women. Tumors of the ovary are remarkably varied as they may arise from any of the three cell types in the normal ovary: the multipotent surface (coelomic) epithelium, the totipotent germ cells, and the sex cord–stromal cells. Neoplasms of epithelial origin account for the great majority of ovarian tumors and, in their malignant forms, account for almost 90% of ovarian cancers (Table 19.3). Germ cell and sex cord–stromal cell tumors are much less frequent; although they constitute 20% to 30% of ovarian tumors, they are collectively responsible for less than 10% of malignant tumors of the ovary.

Surface Epithelial Tumors

The majority of ovarian tumors arise from the fallopian tube or epithelial cysts in the cortex of the ovary (Fig. 19.15). As mentioned, studies have shown that many of the tumors thought to arise from the coelomic epithelium that covers the surface of the ovary are now thought to arise from the fimbriated end of the fallopian tube (Fig. 19.15). The epithelium lining the cortical cysts may be derived from displaced ovarian surface epithelium or the lining of fallopian tube. These can become metaplastic or undergo neoplastic transformation to give rise to a number of different epithelial tumors. Benign lesions usually are cystic (cystadenoma) and may have an accompanying stromal component (cystadenofibroma). Malignant tumors also may be cystic (cystadenocarcinoma) or solid (carcinoma).

Table 19.3 Frequency of Major Ovarian Tumors

Type	Percentage of Malignant Ovarian Tumors	Percentage That Are Bilateral
Serous	47	
Benign (60%)		25
Borderline (15%)		30
Malignant (25%)		65
Mucinous	3	
Benign (80%)		5
Borderline (10%)		10
Malignant (10%)		<5
Endometrioid carcinoma	20	30
Undifferentiated carcinoma	10	—
Clear cell carcinoma	6	40
Granulosa cell tumor	5	5
Teratoma	1	
Benign (96%)		15
Malignant (4%)		Rare
Metastatic	5	>50
Others	3	—

Some ovarian epithelial tumors fall into an intermediate category currently referred to as borderline tumors. Although the majority of borderline tumors behave in a benign manner they can recur and some can progress to carcinoma.

Important risk factors for ovarian cancer include nulliparity, family history, and germline mutations in certain tumor suppressor genes. There is a higher incidence of carcinoma in unmarried women and married women with low parity. Of interest, prolonged use of oral contraceptives reduces the risk. Around 5% to 10% of ovarian cancers are familial, and most of these are associated with mutations in the *BRCA1* or *BRCA2* tumor suppressor genes. As will be discussed later, mutations in *BRCA1* and *BRCA2* also are associated with hereditary breast cancer. The average lifetime risk for ovarian cancer is approximately 30% in *BRCA1* carriers; the risk in *BRCA2* carriers is somewhat lower. In contrast with familial ovarian cancer, mutations in *BRCA1* and *BRCA2* are found in only 8% to 10% of sporadic ovarian cancers, which appear to arise through alternative molecular mechanisms.

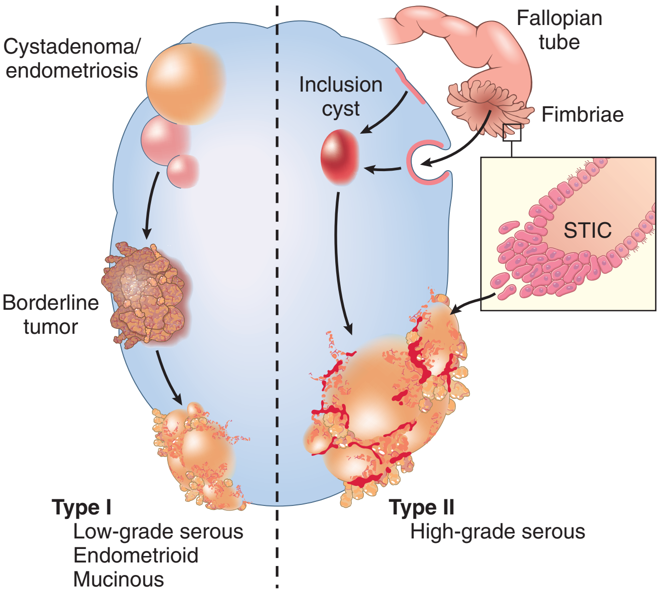

Fig. 19.15 Derivation, of various ovarian neoplasms. Type I tumors progress from benign tumors through borderline tumors that may give rise to a low-grade carcinoma. Type II tumors arise from inclusions cysts/fallopian tube epithelium via intraepithelial precursors that are often not identified. They demonstrate high-grade features and are most commonly of serous histology. STIC, serous tubal intraepithelial carcinoma.

Serous Tumors

Serous tumors are the most common of the ovarian epithelial tumors overall, and also make up the greatest fraction of malignant ovarian tumors. About 60% are benign, 15% are borderline, and 25% are malignant. Benign lesions are usually encountered in patients between 30 and 40 years of age, and malignant serous tumors are more commonly seen between 45 and 65 years of age.

There are two types of serous carcinomas, low-grade and high-grade. The former arise from benign or borderline lesions and progress slowly in a stepwise manner to become invasive carcinoma. These low-grade tumors are associated with mutations in genes encoding signaling proteins, such as *KRAS,* a member of the *RAS* gene family. The high-grade serous tumors develop rapidly. As already mentioned, many of these high-grade lesions arise in the fimbriated end of the fallopian tube via serous tubal intraepithelial carcinoma, rather than ovarian coelomic epithelium. *TP53* mutations are virtually ubiquitous in high-grade serous cancers, being present in over 95% of cases. Other frequently mutated genes include the tumor suppressors *NF1* and *RB,* as well as *BRCA1* and *BRCA2* in familial ovarian cancers.

MORPHOLOGY

Most serous tumors are large, spherical to ovoid, cystic structures up to 30 to 40 cm in diameter. **About 25% of the benign tumors are bilateral.** In the benign tumors, the serosal covering is smooth and glistening. By contrast, the surface of adenocarcinomas often has nodular irregularities representing areas in which the tumor has invaded the serosa. On cut section, small cystic tumors may have a single cavity, but larger ones frequently are divided by multiple septa into multiloculated masses. The cystic spaces usually are filled with a clear serous fluid. Protruding into the cystic cavities are papillary projections, which are more prominent in malignant tumors (Fig. 19.16).

On histologic examination, benign tumors contain a single layer of **columnar epithelial cells** that line the cyst or cysts. The cells often are ciliated. **Psammoma bodies** (concentrically laminated calcified concretions) are common in the tips of papillae. In high-grade carcinoma the cells are markedly atypical, the papillary formations are usually complex and multilayered, and by definition nests or sheets of malignant cells invade the ovarian stroma. Between clearly benign and obviously malignant forms

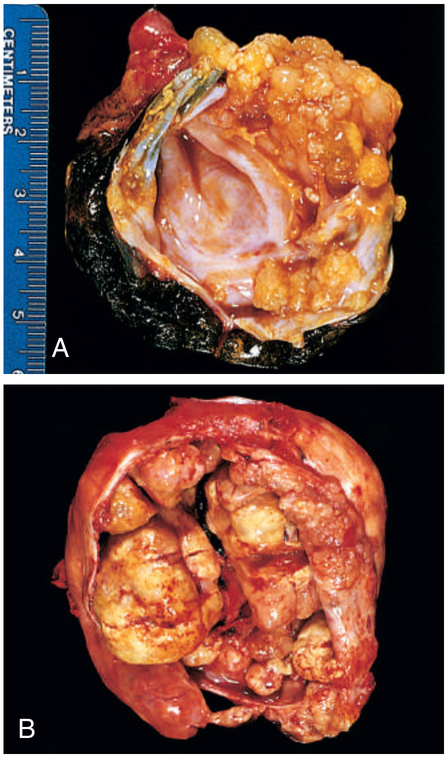

Fig. 19.16 Ovarian serous tumors. (A) Borderline serous cystadenoma opened to display a cyst cavity lined by delicate papillary tumor growths. (B) Cystadenocarcinoma. The cyst is opened to show a large, bulky tumor mass. *(Courtesy of Dr. Christopher Crum, Brigham and Women's Hospital, Boston, Massachusetts.)*

lie **borderline tumors,** which exhibit less cytologic atypia and typically no stromal invasion. Borderline tumors may seed the peritoneum, but fortunately the tumor implants usually are "noninvasive." In general, malignant serous tumors spread throughout the peritoneal cavity and to regional lymph nodes, including periaortic lymph nodes; distant lymphatic and hematogenous metastases are infrequent.

The prognosis for patients with high-grade serous carcinoma is poor, even after surgery and chemotherapy, and depends heavily on the stage of the disease at diagnosis. The 5-year survival for women with carcinoma confined to one ovary is about 90%, but falls precipitously with higher stage tumors to less than 40% depending on the exact stage. In contrast, borderline tumors are associated with nearly 100% survival. Of note, women with tumors containing BRCA1/2 mutations tend to have a better prognosis than women whose tumors lack these genetic abnormalities.

Mucinous Tumors

Mucinous tumors differ from serous tumors in two respects: the neoplastic epithelium consists of mucin-secreting cells; and mucinous tumors are considerably less likely to be malignant. Overall, only 10% of mucinous tumors are malignant; another 10% are borderline, and 80% are benign.

MORPHOLOGY

On gross examination, mucinous tumors produce cystic masses that may be indistinguishable from serous tumors except by the mucinous nature of the cyst contents. However, **they are more likely to be larger and** multicystic (Fig. 19.17A). **Serosal penetration and solid areas of growth are suggestive of malignancy.** Mucin-producing epithelial cells line the cysts (Fig. 19.17B). Malignant tumors are characterized by solid areas of growth, piling up (stratification) of lining cells, cytologic atypia, and stromal invasion.

Compared with serous tumors, mucinous tumors are much less likely to be bilateral. This feature is sometimes useful in differentiating mucinous tumors of the ovary from metastatic mucinous adenocarcinoma from a gastrointestinal tract primary (the so-called "**Krukenberg tumor**"), which more often produces bilateral ovarian masses.

Ruptured ovarian mucinous tumors may seed the peritoneum; however, these deposits typically regress spontaneously. Stable implantation of mucinous tumor cells in the peritoneum with production of copious amounts of mucin is called **pseudomyxoma peritonei;** in most cases, this disorder is caused by metastatic spread of tumors in the gastrointestinal tract, primarily the appendix (Chapter 15).

The prognosis of mucinous cystadenocarcinoma is somewhat better than that of its serous counterpart, although stage rather than histologic type (serous versus mucinous) is the major determinant of outcome. Mutations in *KRAS* are detected in approximately 50% of ovarian mucinous carcinomas, however this does not help distinguish them from metastatic GI tumors, which also have a high frequency of *KRAS* mutations.

Endometrioid Tumors

These tumors may be solid or cystic; they sometimes develop in association with endometriosis. On microscopic examination, they are distinguished by the formation of tubular glands, similar to those of the endometrium, within the lining of cystic spaces. Although benign and borderline forms exist, endometrioid tumors usually are malignant. They are bilateral in about 30% of cases, and 15% to 30% of women with these ovarian tumors have a concomitant endometrial carcinoma. Similar to endometrioid-type carcinoma of the endometrium, endometrioid carcinomas of the ovary frequently have mutations in the *PTEN* tumor suppressor gene as well as mutations in other genes that also act by upregulating PI3K-AKT signaling.

Brenner Tumor

The Brenner tumor is an uncommon, solid, usually unilateral ovarian tumor consisting of abundant stroma containing nests of transitional-type epithelium resembling that of the urinary tract. Occasionally, the nests are cystic and are lined by columnar mucus-secreting cells. Brenner tumors generally are smoothly encapsulated and gray-white on

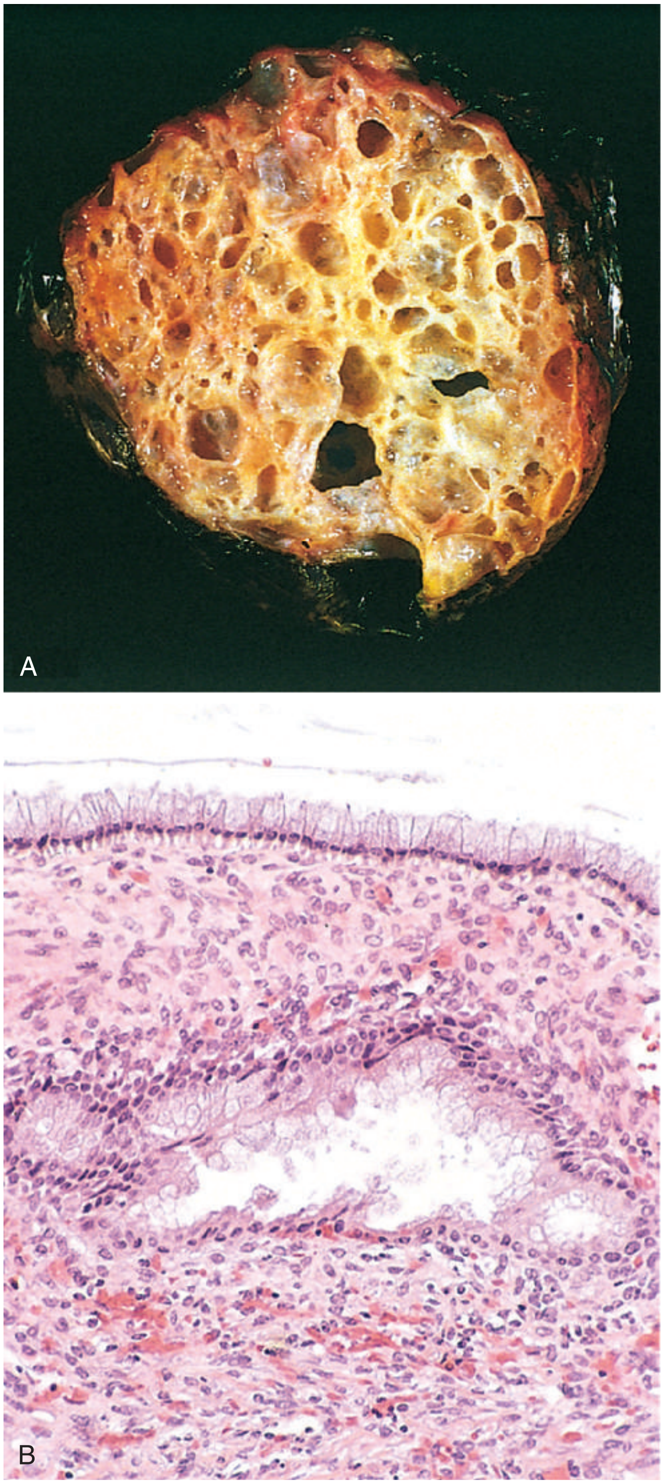

Fig. 19.17 Ovarian mucinous cystadenoma. (A) Mucinous cystadenoma with multicystic appearance and delicate septa. Note the presence of glistening mucin within the cysts. (B) Columnar cell lining of mucinous cystadenoma.

cut section, ranging from a few centimeters to 20 cm in diameter. These tumors may arise from the surface epithelium or from urogenital epithelium trapped within the germinal ridge. Although most are benign, both malignant and borderline tumors have been described.

Other Ovarian Tumors

Many other types of tumors of germ cell and sex cord–stromal origin also arise in the ovary, but only the teratomas of germ cell origin are sufficiently common to merit description. Table 19.4 presents some salient features of other neoplasms of germ cell and sex cord origin.

Teratomas

Teratomas constitute 15% to 20% of ovarian tumors. A distressing feature of these germ cell tumors is their predilection to arise in the first 2 decades of life; to make matters worse, the younger the person, the greater the likelihood of malignancy. More than 90% of these germ cell neoplasms, however, are benign mature cystic teratomas; the immature, malignant variant is rare.

Benign (Mature) Cystic Teratomas

Benign (mature) cystic teratomas are marked by the presence of mature tissues derived from all three germ cell layers: ectoderm, endoderm, and mesoderm. Usually these tumors contain cysts lined by epidermis replete with adnexal appendages—hence the common designation *dermoid cysts.* Most are discovered in young women as ovarian masses or are found incidentally on abdominal radiographs or scans because they contain foci of calcification produced by toothlike structures contained within the tumor. About 90% are unilateral, with the right side more commonly affected. Rarely do these cystic masses exceed 10 cm in diameter. On cut section, they often are filled with sebaceous secretion and matted hair that, when removed, reveal a hair-bearing epidermal lining (Fig. 19.18). Sometimes there is a nodular projection from which teeth protrude. Occasionally, foci of bone and cartilage, nests of bronchial or gastrointestinal epithelium, or other tissues are present.

For unknown reasons, these neoplasms sometimes produce infertility and are prone to undergo torsion (in 10%–15% of cases), which constitutes an acute surgical emergency. A rare, but fascinating, paraneoplastic complication is limbic encephalitis, which may develop in women with teratomas containing mature neural tissue and often remits with tumor resection. Malignant transformation, usually to a squamous cell carcinoma, is seen in about 1% of cases.

Immature Malignant Teratomas

Malignant (immature) teratomas are found early in life, the mean age at clinical detection being 18 years. They typically are bulky and appear solid on cut section, and they often contain areas of necrosis; uncommonly, cystic foci are present that contain sebaceous secretion, hair, and other features similar to those of mature teratomas. On microscopic examination, the distinguishing feature is the presence of immature elements or minimally differentiated cartilage, bone, muscle, nerve, or other tissues. As with other tumors, the prognosis depends on grade and stage.

Specialized Teratomas

A rare subtype of teratoma is composed entirely of specialized tissue. The most common example is struma ovarii,

Table 19.4 Salient Features of Ovarian Germ Cell and Sex Cord Neoplasms

Neoplasm	Peak Incidence	Usual Location	Morphologic Features	Behavior
Germ Cell Origin				
Dysgerminoma	Second to third decade of life Occur with gonadal dysgenesis	Unilateral in 80%–90%	Counterpart of testicular seminoma Sheets or cords of large clear cells Stroma may contain lymphocytes and occasional granulomas	All malignant but only one-third metastasize; all radiosensitive; 80% cure rate
Choriocarcinoma	First 3 decades of life	Unilateral	Identical to placental tumor Two types of epithelial cells: cytotrophoblast and syncytiotrophoblast	Metastasizes early and widely Primary focus may degenerate, leaving only metastases Resistant to chemotherapy
Sex Cord Tumors				
Granulosa-theca cell	Most postmenopausal, but may occur at any age	Unilateral	Composed of mixture of cuboidal granulosa cells and spindled or plump lipid-laden theca cells Granulosa elements may recapitulate ovarian follicle as Call-Exner bodies	May elaborate large amounts of estrogen Granulosa element may be malignant (5%–25%)
Thecoma-fibroma	Any age	Unilateral	Yellow (lipid-laden) plump thecal cells	Most hormonally inactive About 40% produce ascites and hydrothorax (Meigs syndrome) Rarely malignant
Sertoli-Leydig cell	All ages	Unilateral	Recapitulates development of testis with tubules or cords and plump pink Sertoli cells	Many masculinizing or defeminizing Rarely malignant
Metastases to Ovary				
	Older ages	Mostly bilateral	Anaplastic tumor cells, cords, glands, dispersed through fibrous background Cells may be "signet ring" mucin-secreting	Primaries are gastrointestinal tract (Krukenberg tumors), breast, and lung

which is composed entirely of mature thyroid tissue that may actually produce hyperthyroidism. These tumors appear as small, solid, unilateral brown ovarian masses. Other specialized teratomas include ovarian carcinoid, which in rare instances produces carcinoid syndrome.

Clinical Features

With all ovarian neoplasms, management poses a formidable clinical challenge, because symptoms or signs usually appear only when tumors are well advanced. Ovarian tumors of surface epithelial origin usually are asymptomatic until they become large enough to cause local pressure symptoms (e.g., pain, gastrointestinal complaints, urinary frequency). Indeed, about 30% of all ovarian neoplasms are discovered incidentally on routine gynecologic examination. Larger masses, particularly the common epithelial tumors, may cause an increase in abdominal girth. Smaller masses, particularly dermoid cysts, sometimes twist on their pedicles (torsion), producing severe abdominal pain that mimics an acute abdomen. Metastatic seeding of malignant serous tumors often causes ascites, whereas functioning ovarian tumors often come to attention because of the endocrinopathies they produce.

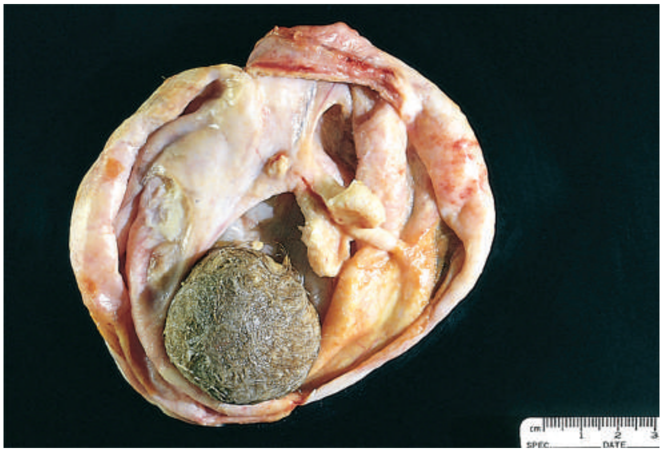

Fig. 19.18 Mature cystic teratoma (dermoid cyst) of the ovary. A ball of hair (bottom) and a mixture of tissues are evident. *(Courtesy of Dr. Christopher Crum, Brigham and Women's Hospital, Boston, Massachusetts.)*

Unfortunately, treatment of ovarian tumors remains unsatisfactory; only a modest increase in survival has been achieved since the mid-1970s. Screening methods that detect early tumors are badly needed, but those evaluated to date are of limited value. One such marker, the protein CA-125, is elevated in the sera of 75% to 90% of women with epithelial ovarian cancer. However, CA-125 is undetectable in up to 50% of women with cancer limited to the ovary; conversely, it often is elevated in a variety of benign conditions and nonovarian cancers. Hence, its usefulness as a screening test in asymptomatic postmenopausal women is limited. Currently, CA-125 measurements are of greatest value in monitoring response to therapy.

SUMMARY

OVARIAN TUMORS

- Tumors may arise from epithelium, sex cord–stromal cells, or germ cells.
- Epithelial tumors are the most common malignant ovarian tumor and are more common in women older than 40 years of age.
- The major types of epithelial tumors are serous, mucinous, and endometrioid. Each has a benign, malignant, and borderline counterpart.
- Serous carcinoma is the most common and many arise in the distal fallopian tube.
- Sex cord–stromal tumors may display differentiation toward granulosa, Sertoli, Leydig, or ovarian stromal cell type. Depending on differentiation, they may produce estrogens or androgens.
- Germ cell tumors (mostly cystic teratomas) are the most common ovarian tumor in young women; the vast majority are benign.
- Germ cell tumors may differentiate toward oogonia (dysgerminoma), primitive embryonal tissue (embryonal), yolk sac (endodermal sinus tumor), placental tissue (choriocarcinoma), or multiple tissue types (teratoma).

Diseases of Pregnancy

Diseases of pregnancy and pathologic conditions of the placenta are important contributors to morbidity and mortality for both mother and child. Discussed in this section are a limited number of disorders in which knowledge of the morphologic lesions contributes to an understanding of clinical disease.

PLACENTAL INFLAMMATIONS AND INFECTIONS

Infections may reach the placenta by either of two paths: (1) ascension through the birth canal or (2) hematogenous (transplacental) spread.

Ascending infections are by far the more common; in most instances they are bacterial and are associated with premature rupture of the fetal membranes. On microscopic examination, the chorioamnion shows neutrophilic infiltration associated with edema and congestion (acute chorioamnionitis). With extension beyond the membranes, the infection may involve the umbilical cord and placental villi, resulting in acute vasculitis of the cord (funisitis). Ascending infections are caused by *Mycoplasma, Candida,* and bacteria of the vaginal flora.

Uncommonly, placental infections may arise by *hematogenous spread* of bacteria and other organisms; on histologic examination, placental villi are the most frequently affected structures (villitis). Syphilis, tuberculosis, listeriosis, toxoplasmosis, and various viruses (rubella, cytomegalovirus, herpes simplex virus) all can cause placental villitis. Transplacental infections can affect the fetus and give rise to the so-called "TORCH" complex (toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes) (Chapter 7).

ECTOPIC PREGNANCY

Ectopic pregnancy is defined as implantation of a fertilized ovum in any site other than the uterus, which may occur in as many as 1% of pregnancies. In more than 90% of these cases, implantation occurs in the fallopian tube (tubal pregnancy); other sites include the ovaries and the abdominal cavity. Any factor that retards passage of the ovum through the fallopian tube predisposes to ectopic pregnancy. In about half of the cases, slowed passage results from chronic inflammation and scarring in the oviduct; intrauterine tumors and endometriosis may also hamper passage of the ovum. In the other 50% of tubal pregnancies, no anatomic cause is evident. Ovarian pregnancies probably result from rare instances in which the ovum is fertilized just as the follicle ruptures. Gestation within the abdominal cavity occurs when the fertilized egg drops out of the fimbriated end of the fallopian tube and implants on the peritoneum.

MORPHOLOGY

In all sites, early development of ectopic pregnancies proceeds normally, with formation of placental tissue, the amniotic sac, and decidual changes. With tubal pregnancies, the invading placenta eventually burrows through the wall of the fallopian tube, causing **intratubal hematoma (hematosalpinx), intraperitoneal hemorrhage,** or both. The tube is usually distended by freshly clotted blood containing bits of gray placental tissue and fetal parts. The histologic diagnosis depends on visualization of placental villi or, rarely, of the embryo.

Until rupture occurs, an ectopic pregnancy may be indistinguishable from a normal pregnancy, with cessation of menstruation and elevation of serum and urinary placental hormones. Under the influence of these hormones, the endometrium (in approximately 50% of cases) undergoes the characteristic hypersecretory and decidual changes of pregnancy. The absence of elevated gonadotropin levels does not exclude the diagnosis because poor attachment and necrosis of the ectopic placenta are common. Rupture of an ectopic pregnancy may be catastrophic, with the sudden onset of intense abdominal pain and signs of an acute abdomen, often followed by shock. Prompt surgical intervention is necessary.

SUMMARY

ECTOPIC PREGNANCY

- Ectopic pregnancy is defined as implantation of the fertilized ovum outside of the uterine corpus. Approximately 1% of pregnancies implant ectopically; the most common site is the fallopian tube.
- Chronic salpingitis with scarring is a major risk factor for tubal ectopic pregnancy.
- Rupture of an ectopic pregnancy is a medical emergency that, if left untreated, may result in exsanguination and death.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease refers to an abnormal proliferation of fetal trophoblast cells. The World Health Organization broadly divides these diseases into two categories: molar lesions and nonmolar lesions. The molar lesions are further divided into partial, complete, and invasive hydatidiform moles. The nonmolar category consists of choriocarcinoma and other more uncommon types of trophoblast-derived malignancies. All elaborate human chorionic gonadotropins (hCG), which is detected in the blood and urine at levels considerably higher than those found during normal pregnancy. In addition to aiding diagnosis, hCG levels in the blood or urine can be used to monitor treatment efficacy. Clinicians prefer the umbrella term gestational trophoblastic disease because the response to therapy, as judged by the hormone levels, is significantly more important than pathologic subtyping of lesions. However, the genetics, pathology, and natural history of these disorders are sufficiently distinct to merit discussion of each.

Hydatidiform Mole: Complete and Partial

The typical hydatidiform mole is a voluminous mass of swollen, sometimes cystically dilated, chorionic villi, appearing grossly as grapelike structures. Varying amounts of normal to highly atypical chorionic epithelium cover the swollen villi. There are two distinctive subtypes of hydatidiform moles: *complete* and *partial*. Complete hydatidiform moles are not compatible with embryogenesis and rarely contain fetal parts. All of the chorionic villi are abnormal, and the chorionic epithelial cells are diploid (46,XX or, uncommonly, 46,XY). The partial hydatidiform mole is compatible with early embryo formation and therefore may contain fetal parts, has some normal chorionic villi, and is almost always triploid (e.g., 69,XXY) (Table 19.5). Both types result from abnormal fertilization with an excess of paternal genetic material. In a complete mole the entire genetic content is supplied by two spermatozoa (or a diploid sperm), yielding diploid cells containing only paternal chromosomes, whereas in a partial mole a normal egg is fertilized by two spermatozoa (or a diploid sperm), resulting in a triploid karyotype with a preponderance of paternal genes.

Table 19.5 Features of Complete and Partial Hydatidiform Mole

Feature	Complete Mole	Partial Mole
Karyotype	46,XX (46,XY)	Triploid (69,XXY)
Villous edema	All villi	Some villi
Trophoblast proliferation	Diffuse; circumferential	Focal; slight
Serum hCG	Elevated	Less elevated
Tissue hCG	++++	+
Risk of subsequent choriocarcinoma	2%	Rare

hCG, Human chorionic gonadotropin.

The incidence of complete hydatidiform mole is about 1 to 1.5 per 2000 pregnancies in the United States and other Western countries. For unknown reasons, the incidence is much higher in Asian countries. Moles are most common before the age of 20 and after the age of 40 years, and a history of the condition increases the risk for molar disease in subsequent pregnancies. Although molar disease formerly was discovered at 12 to 14 weeks of pregnancy during investigation for a gestation that was "too large for dates," early monitoring of pregnancies by ultrasound has lowered the gestational age at detection. In both complete and partial moles, elevation of hCG in the maternal blood and absence of fetal heart sounds are typical.

MORPHOLOGY

In advanced cases the uterine cavity is expanded by a delicate, friable mass of thin-walled, translucent cystic structures (Fig. 19.19). Fetal parts are rarely seen in complete moles but are common in partial moles. On microscopic examination, the **complete mole** shows hydropic swelling of poorly vascularized chorionic villi with a loose, myxomatous, edematous stroma. The chorionic epithelium typically shows a proliferation of both cytotrophoblasts and syncytiotrophoblasts (Fig. 19.20). Histologic grading to predict the clinical outcome of moles has been supplanted by monitoring of hCG levels. In **partial moles,** villous edema involves only a subset of the villi, and the trophoblastic proliferation is focal and slight. In most cases of partial mole, some fetal cells are present, ranging from fetal red cells in placental villi to, in rare cases, a fully formed fetus.

Overall, 80% to 90% of moles do not recur after thorough curettage, but 10% of complete moles are invasive (described next). No more than 2% to 3% give rise to choriocarcinoma.

Invasive Mole

Invasive moles are complete moles that are locally invasive but lack the metastatic potential of choriocarcinoma. An invasive mole retains hydropic villi, which penetrate the uterine wall deeply, possibly causing rupture and sometimes life-threatening hemorrhage. On microscopic examination, the epithelium of the villi shows atypical changes, with proliferation of both trophoblastic and syncytiotrophoblast components.

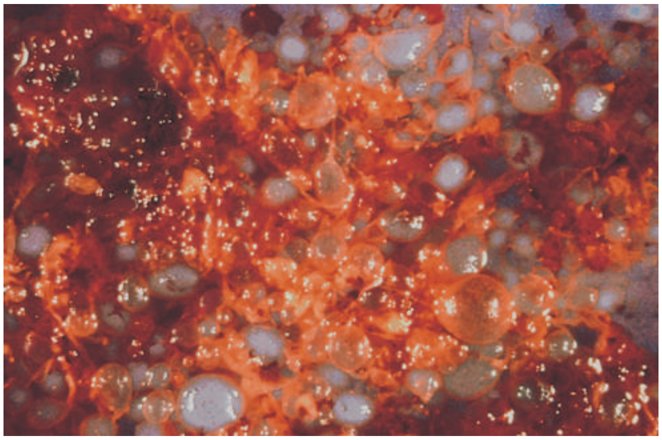

Fig. 19.19 Complete hydatidiform mole, consisting of numerous swollen (hydropic) villi.

Although the marked invasiveness of this lesion makes removal technically difficult, metastases do not occur. Hydropic villi may embolize to distant organs, such as lungs or brain, but these emboli do not behave like true metastases and may regress spontaneously. Because of deeper invasion into the myometrium, an invasive mole is difficult to remove completely by curettage, so if serum β-hCG remains elevated, further treatment is required. Fortunately, in most cases cure is possible with chemotherapy.

Gestational Choriocarcinoma

Choriocarcinoma, a very aggressive malignant tumor, arises from gestational chorionic epithelium or, less frequently, from totipotential cells within the gonads (as a germ cell tumor). These tumors are rare in the Western Hemisphere (they occur in about 1 per 30,000 pregnancies in the United States), but are much more common in Asian and African countries, reaching a frequency of 1 in 2000 pregnancies. Approximately 50% of choriocarcinomas arise from complete hydatidiform moles; about 25% arise after an abortion, while the remainder manifest following an apparently normal pregnancy. In most cases, choriocarcinoma presents as a bloody, brownish discharge accompanied by a rising titer of β-hCG in blood and urine, in the absence of marked uterine enlargement, such as would be seen with a mole. In general, the β-hCG titers are much higher than those associated with a mole.

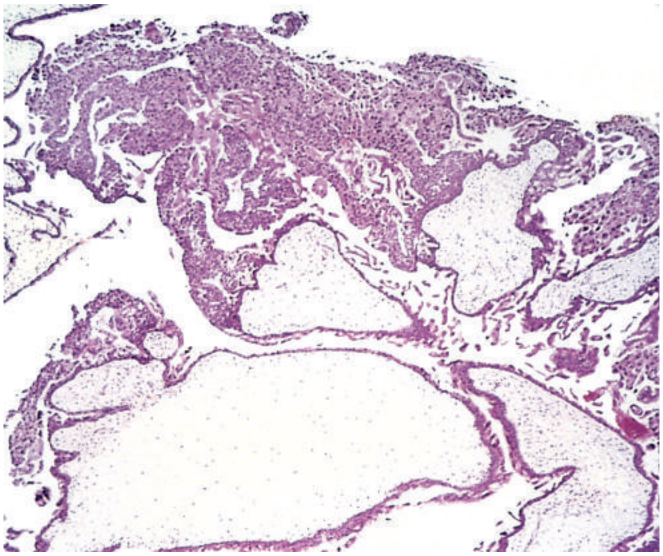

Fig. 19.20 Complete hydatidiform mole. In this microscopic image, distended hydropic villi *(below)* and proliferation of the chorionic epithelium *(above)* are evident. *(Courtesy of Dr. Kyle Molberg, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

MORPHOLOGY

Choriocarcinomas usually appear as hemorrhagic, necrotic uterine masses. Sometimes the necrosis is so extensive that little viable tumor remains. Indeed, the primary lesion may "self-destruct," and only the metastases tell the story. Very early, the tumor insinuates itself into the myometrium and into vessels. **In contrast with hydatidiform moles and invasive moles, chorionic villi are not formed; instead, the tumor is composed of anaplastic cuboidal cytotrophoblasts and syncytiotrophoblasts** (Fig. 19.21).

By the time a choriocarcinoma is discovered, widespread vascular spread usually has occurred to the lungs (50%), vagina (30%–40%), brain, liver, or kidneys. Lymphatic invasion is uncommon.

Clinical Features

Despite the extremely aggressive nature of placental choriocarcinoma, these tumors are remarkably sensitive to chemotherapy. Nearly 100% of affected patients are cured, even those with metastases at distant sites such as the lungs. By contrast, response to chemotherapy with choriocarcinomas that arise in the gonads (ovary or testis) is relatively poor. This striking difference in prognosis may be related to the presence of paternal antigens on placental choriocarcinomas that are lacking in gonadal lesions. Conceivably, a maternal immune response against the foreign (paternal) antigens helps clear the tumor by acting as an adjunct to chemotherapy.

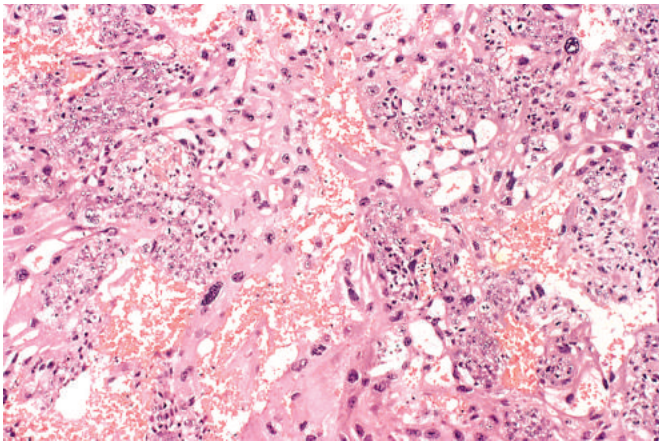

Fig. 19.21 Choriocarcinoma. This field contains both neoplastic cytotrophoblast and multinucleate syncytiotrophoblast. *(Courtesy of Dr. David R. Genest, Brigham and Women's Hospital, Boston, Massachusetts.)*

Placental Site Trophoblastic Tumor

Placental site trophoblastic tumors are derived from the placental site or intermediate trophoblast, a cell that has morphologic and functional features that overlap with those of trophoblasts and syncytiotrophoblasts. These uncommon diploid tumors, often XX in karyotype, typically arise a few months after pregnancy. Because intermediate trophoblasts do not produce hCG in large amounts, hCG concentrations are only slightly elevated. More typically, these tumors produce human placental lactogen. An indolent clinical course is typical, with a generally favorable outcome if the tumor is confined to the endomyometrium. Of note, however, placental site trophoblastic tumors are not as sensitive to chemotherapy as are other trophoblastic tumors, and the prognosis is poor when spread occurs beyond the uterus.

SUMMARY
GESTATIONAL TROPHOBLASTIC DISEASE

- Molar disease is a result of an abnormal contribution of paternal chromosomes to the conceptus.
- Partial moles are triploid and have two sets of paternal chromosomes. They typically are accompanied by fetal tissue. There is a low rate of persistent disease.
- Complete moles are diploid, and all chromosomes are paternal. Rarely are embryonic or fetal tissues associated with a complete mole.
- Among complete moles, 10% to 15% are associated with persistent disease that usually takes the form of an invasive mole. Only 2% of complete moles progress to choriocarcinoma.
- Gestational choriocarcinoma is a highly invasive and frequently metastatic tumor that, in contrast with ovarian choriocarcinoma, is responsive to chemotherapy and curable in most cases.
- Placental site trophoblastic tumor is an indolent tumor of intermediate trophoblast that produces human placental lactogen. It can be cured surgically but once it spreads it does not respond well to chemotherapy.

Preeclampsia/Eclampsia (Toxemia of Pregnancy)

The development of hypertension, accompanied by proteinuria and edema in the third trimester of pregnancy, is referred to as preeclampsia. This syndrome occurs in 5% to 10% of pregnancies, particularly with first pregnancies in women older than 35 years. In those severely affected, seizures may occur, and the symptom complex is then termed *eclampsia*. By long-existing precedent, preeclampsia and eclampsia sometimes are referred to as toxemia of pregnancy. No blood-borne toxin has been identified, and this historically sanctified term is a misnomer. Recognition and early treatment of preeclampsia have now made eclampsia, particularly fatal eclampsia, rare.

While exact triggering events initiating these syndromes are unknown, a common feature underlying all cases is insufficient maternal blood flow to the placenta secondary to inadequate remodeling of the spiral arteries of the uteroplacental vascular bed. In normal pregnancy, the musculoelastic walls of the spiral arteries are invaded by trophoblasts, permitting them to dilate into wide vascular sinusoids. In preeclampsia and eclampsia, this vascular remodeling is impaired, the musculoelastic walls are retained, and the channels remain narrow. Decreased uteroplacental blood flow appears to result in placental hypoxia, placental dysfunction, and the altered release of circulating factors that regulate angiogenesis. Specifically, increases in the anti-angiogenic factors soluble Flt1 (sFlt1) and soluble endoglin (sEng) and reductions in proangiogenic factors, such as VEGF, have been noted. These disturbances are hypothesized to result in endothelial cell dysfunction, vascular hyperreactivity, and end-organ microangiopathy. Although the exact basis of preeclampsia remains to be further defined, several serious consequences have been associated with this condition:

- *Placental infarction,* stemming from chronic hypoperfusion
- *Hypertension,* resulting from reduced endothelial production of the vasodilators prostacyclin and prostaglandin E_2 and from increased production of the vasoconstrictor thromboxane A2
- *Hypercoagulability,* due to endothelial dysfunction and release of tissue factor from the placenta
- *End-organ failure,* most notably of the kidney and the liver, which occurs in patients with full-blown eclampsia. Approximately 10% of the patients with severe preeclampsia develop the so-called "HELLP syndrome", characterized by elevated liver enzymes, microangiopathic hemolytic anemia, thrombocytopenia due to platelet consumption, and sometimes fullblown disseminated intravascular coagulation (DIC).

MORPHOLOGY

The morphologic changes of preeclampsia and eclampsia are variable and correlate to some degree with the severity of the disorder. **Placental abnormalities** include

- **Infarcts,** which can be a feature of normal pregnancy, but are much more numerous with severe preeclampsia or eclampsia
- **Retroplacental hemorrhages**
- **Premature maturation of placental villi** associated with villous edema, hypovascularity, and increased production of syncytial epithelial knots
- **Fibrinoid necrosis** and focal accumulation of lipid-containing macrophages (acute atherosis) of decidual vessels

Clinical Features

Preeclampsia presents insidiously during weeks 24 to 25 of gestation with edema, proteinuria, and rising blood pressure. Should the condition evolve into eclampsia, renal function is impaired, blood pressure rises further, and convulsions may occur. Prompt therapy early in the course aborts the associated organ changes, with all abnormalities resolving promptly after delivery or after cesarean section.

Breast

Three important features distinguish the breast from other organs. First, rather than being essential for survival, the major function is the nutritional support of another individual, the infant. Second, the structure of the organ undergoes marked changes throughout life: expansion of the lobular system after menarche, periodic remodeling during adulthood, especially during and after pregnancy, and ultimately involution and regression of lobules. Finally, breasts are visible and as a result have a social, cultural, and personal significance not shared by other organs. All of these features play a role when considering the origins, presentations, and treatment of breast disease.

The functional unit of the breast is the lobule, which is supported by a specialized intralobular stroma. The inner luminal epithelial cells produce milk during lactation. The basally located myoepithelial cells have contractile function to aid in milk ejection and also help support the basement membrane. The ducts are conduits for milk to reach the nipple. The size of the breast is determined primarily by interlobular stroma, which increases during puberty and involutes with age. Each normal constituent is a source of both benign and malignant lesions (Fig. 19.22).

CLINICAL PRESENTATIONS OF BREAST DISEASE

The predominant symptoms and signs of diseases of the breast are pain, inflammatory changes, nipple discharge, "lumpiness," or a palpable mass (Fig. 19.23A). However, few symptoms are so severe as to require treatment, and the primary reason for investigating their cause is to evaluate the possibility of malignancy. Most symptomatic breast lesions (>90%) are benign. Of women with cancer, about 45% have symptoms, whereas the remainder come to attention through screening tests (Fig. 19.23B).

- *Pain* (mastalgia or mastodynia) is a common symptom often related to menses, possibly due to cyclic edema and swelling. Pain localized in a specific area is usually caused by a ruptured cyst or trauma to adipose tissue (fat necrosis). Almost all painful masses are benign, but for unknown reasons a small fraction of cancers (about 10%) cause pain.
- *Inflammation* causes an edematous and erythematous breast. It is rare and is most often caused by infections, which only occur with any frequency during lactation and breastfeeding. An important mimic of

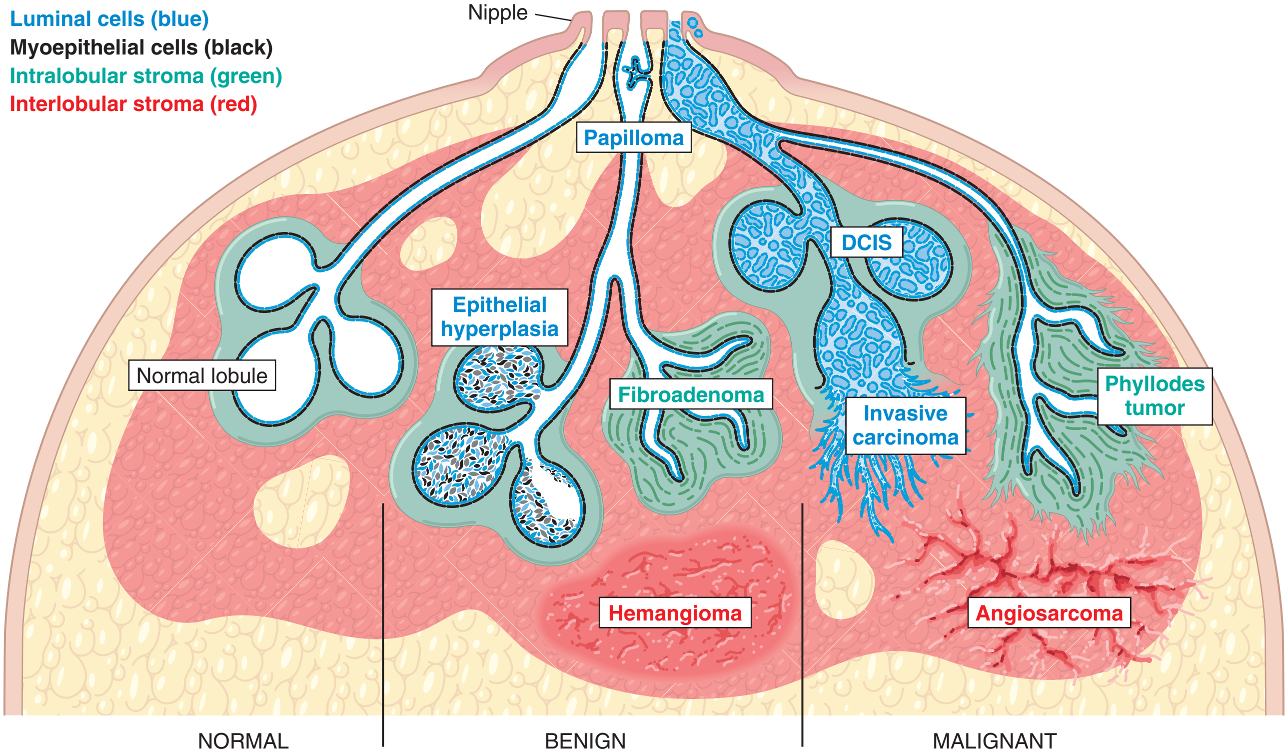

Fig. 19.22 Origins of breast disorders. Benign epithelial lesions include intraductal papillomas that grow in sinuses below the nipple and epithelial hyperplasia that arises in lobules. Malignant epithelial lesions are mainly breast carcinomas, which may remain in situ or invade into the breast and spread by metastasis. Specialized intralobular stroma *(green)* cells may give rise to fibroadenomas and phyllodes tumors, whereas interlobular stroma *(green)* may give rise to a variety of rare benign and malignant tumors.

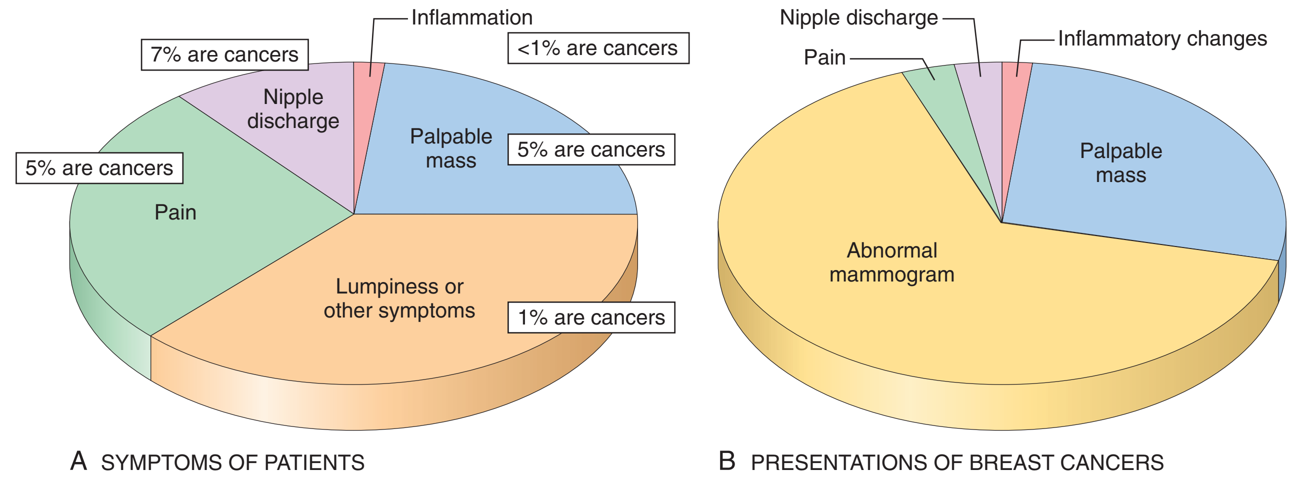

Fig. 19.23 Presenting symptoms of breast disease. (A) Common breast-related symptoms that bring patients to clinical attention. (B) Presentations of breast cancer.

inflammation is "inflammatory" breast carcinoma (discussed later).

- *Nipple discharge* may be normal when small in quantity and bilateral. The most common benign lesion producing a nipple discharge is a papilloma arising in the large ducts below the nipple (Fig. 19.22). Discharges that are spontaneous, unilateral, and bloody are of greatest concern for malignancy.
- *Lumpiness*, or a diffuse nodularity throughout the breast, is usually a result of normal glandular tissue. When pronounced, imaging studies may help to determine whether a discrete mass is present.
- *Palpable masses* can arise from proliferations of stromal cells or epithelial cells and are generally detected when they are 2 to 3 cm in size (Fig. 19.22). Most (~95%) are benign; these tend to be round to oval and to have circumscribed borders. In contrast, malignant tumors usually invade across tissue planes and have irregular borders. However, because some cancers grow deceptively as circumscribed masses, all palpable masses require evaluation.
- *Gynecomastia* is the only common breast symptom in males. There is an increase in both stroma and epithelial cells resulting from an imbalance between estrogens, which stimulate breast tissue, and androgens, which counteract these effects.

Regardless of presenting symptom, the likelihood of malignancy increases with age. For example, the risk of nipple discharge being due to cancer increases from 7% in women younger than 60 years of age to 30% in women older than 60. Similarly, only 10% of palpable masses in women younger than 40 years of age are carcinomas, as compared to 60% in women older than 50.

Mammographic screening was introduced in the 1980s as a means to detect early, nonpalpable asymptomatic breast carcinomas before metastatic spread has occurred. Mammography has met this promise, as the average size of invasive carcinomas detected by mammography is about 1 cm (significantly smaller than cancers identified by palpation), and only 15% will have metastasized to regional lymph nodes at the time of diagnosis. In the United States, most cancers in women more than 50 years of age are now detected by mammography (Fig. 19.23B). As with symptomatic breast lesions, the likelihood that an abnormal mammographic finding is caused by malignancy increases with age, from 10% at age 40 to more than 25% in women older than age 50.

SUMMARY

CLINICAL PRESENTATIONS OF BREAST DISEASE

- Symptoms affecting the breasts are evaluated primarily to determine if malignancy is present.
- Regardless of the symptom, the underlying cause is benign in the majority of cases.
- Breast cancer is most commonly detected by palpation of a mass in younger women and in unscreened populations and by mammographic screening in older women.

INFLAMMATORY PROCESSES

Inflammatory diseases of the breast are rare and may be caused by infections, autoimmune disease, or foreign body–type reactions. Symptoms include erythema and edema, often accompanied by pain and focal tenderness. Because inflammatory diseases are rare, the possibility that the symptoms are caused by inflammatory carcinoma should always be considered (discussed later).

The only infectious agent to cause breast disease with any frequency is *Staphylococcus aureus*, which typically gains entry via fissures in nipple skin during the first weeks of breastfeeding. The invading organisms may lead to the formation of "lactational abscesses," collections of neutrophils and associated bacteria in fibroadipose tissue. If untreated, tissue necrosis may lead to the appearance of fistula tracks opening onto the skin. Most cases are treated adequately with antibiotics and continued expression of milk. Rarely, surgical incision and drainage is required.

STROMAL NEOPLASMS

The two types of stroma in the breast, intralobular and interlobular, give rise to different types of neoplasms (Fig. 19.22). Historically, tumors derived from intralobular stroma have been cleanly divided into benign fibroadenomas and more cellular phyllodes tumors, which sometimes recur following excision and rarely pursue a malignant course. It is now appreciated that these tumors share driver mutations in the same genes and appear to be part of a spectrum of related neoplasms. Nevertheless, the old classification is engrained in the medical lexicon and we will follow it here for simplicity's sake.

MORPHOLOGY

Tumors derived from intralobular stroma are comprised of both stromal cells and epithelial cells (i.e., they are "biphasic"), as the neoplastic proliferation of specialized lobular fibroblasts also stimulates reactive proliferation of lobular epithelial cells. As the intralobular fibroblasts proliferate, they push and distort the epithelial cells so that they form elongated slitlike structures rather than round acini. In benign **fibroadenoma**, the tumor mass has circumscribed borders and low cellularity (Fig. 19.24A); mitoses are rare. By contrast, in **phyllodes tumors** the stromal cells tend to outgrow the epithelial cells, resulting in bulbous nodules of proliferating stromal cells that are covered by epithelium (Fig. 19.24B), the characteristic "phyllodes" (Greek for "leaflike") growth pattern. In high-grade phyllodes tumors epithelium may be scant or absent, producing a sarcomatous appearance. Overall, about 2% of phyllodes tumors metastasize to distant sites.

Lesions of interlobular stroma are monophasic (only comprised of mesenchymal cells) and include benign soft tissue tumors found elsewhere in the body, such as hemangiomas (Chapter 10) and lipomas (Chapter 21). The only malignancy derived from interlobular stromal cells of note is angiosarcoma (Chapter 21), which may arise in the breast after local radiotherapy. The morphologies of these lesions are described elsewhere.

BENIGN EPITHELIAL LESIONS

The majority of benign epithelial lesions are incidental findings detected by mammography. Their major clinical significance is their relationship to the subsequent risk of developing breast cancer. Benign changes are divided into three groups, *nonproliferative disease*, *proliferative disease without atypia*, and *proliferative disease with atypia*, each associated with a different degree of breast cancer risk (Table 19.6).

- Nonproliferative disease is not associated with an increased risk of breast cancer.
- Proliferative disease without atypia encompasses polyclonal hyperplasias that are associated with a slightly increased risk of breast cancer.
- Proliferative disease with atypia includes monoclonal "precancers" that are associated with a modest increase in the risk of breast cancer in both breasts; overall, 13% to 17% of women with these lesions develop breast cancer.

MORPHOLOGY

Nonproliferative disease consists of three major morphologic changes: cysts, fibrosis, and adenosis. It is termed "nonproliferative" because the lesions contain single layers of epithelial cells. The most common nonproliferative breast lesions are simple cysts lined by a layer of luminal cells that often undergo apocrine metaplasia (Fig. 19.25A). The apocrine secretions may calcify and be detected by mammography. When cysts rupture, chronic inflammation and fibrosis in response to the spilled debris may produce palpable nodularity of the breast (so-called "fibrocystic changes"). **Proliferative disease without atypia** includes epithelial hyperplasia, sclerosing adenosis, complex sclerosing lesion, and papilloma. Each is associated with varying degrees of epithelial cell proliferation. For example, in epithelial

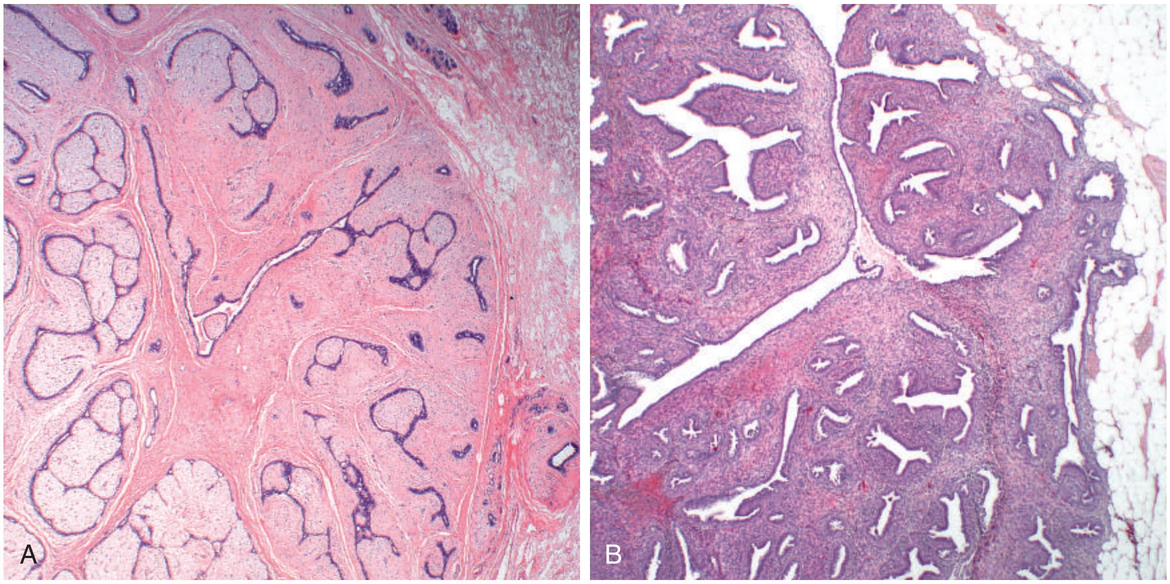

Fig. 19.24 Intralobular stromal neoplasms. (A) Fibroadenoma. This benign tumor has an expansile growth pattern with pushing circumscribed borders. (B) Phyllodes tumors. Proliferating stromal cells distort the glandular tissue, forming cleftlike spaces, and bulge into surrounding stroma.

Table 19.6 Factors Associated With Development of Invasive Carcinoma

Factor	Relative Risk[a]	Absolute Lifetime Risk[a]
Women with no risk factors	1.0	3%
First-degree relative(s) with breast cancer[b]	1.2–9.0	4%–30%
Germline tumor suppressor gene mutation (e.g., *BRCA1* mutation)	2.0–45.0	6% to >90%
Menstrual History		
Age at menarche <12 years	1.3	4%
Age at menopause >55 years	1.5–2.0	5%–6%
Pregnancy		
First live birth <20 years (protective)	0.5	1.6%
First live birth 20–35 years	1.5–2.0	5%–6%
First live birth >35 years	2.0–3.0	6%–10%
Never pregnant (nulliparous)	3.0	10%
Breast-feeding (slightly protective)	0.8	2.6%
Benign Breast Disease		
Proliferative disease without atypia	1.5–2.0	5%–6%
Proliferative disease with atypia (ALH and ADH)	4.0–5.0	13%–17%
Carcinoma in situ (ductal or lobular)	8.0–10.0	25%–30%
Ionizing radiation	1.1–1.4	3.6%–4.6%
Mammographic density	3.0–7.0	10%–23%
Postmenopausal obesity and weight gain	1.1–3.0	3.6%–10%
Postmenopausal hormone replacement	1.1–3.0	3.6%–10%
Alcohol consumption	1.1–1.4	3.6%–4.6%
Alcohol consumption	1.1–1.4	3.6%–4.6%

[a]Relative risk is the likelihood of developing cancer compared to a woman with no risk factors—whose relative risk is 1.0. Absolute lifetime risk is the fraction of women expected to develop invasive carcinoma without a risk reducing intervention. For women with no risk factors, there is about a 3% chance of developing invasive breast cancer.
[b]The most common family history is a mother who developed cancer after menopause. This history does not increase the risk of her daughters.

hyperplasia, increased numbers of both spindled myoepithelial cells and epithelioid luminal cells expand ductal and lobular spaces (Fig. 19.25B).

Proliferative disease with atypia includes atypical lobular hyperplasia (ALH) and atypical ductal hyperplasia (ADH). ALH closely resembles lobular carcinoma in situ (LCIS) and ADH closely resembles ductal carcinoma in situ (DCIS) (both described later), but are more limited in extent. The cells in ADH are uniform in appearance and form sharply marginated spaces or rigid bridges (Fig. 19.25C).

CARCINOMA

Breast carcinoma is the most common malignancy of women globally (excluding nonmelanoma skin cancer) and causes the majority of cancer deaths in women. Although the incidence in the United States decreased slightly in 2002 and then stabilized (changes attributed to a decrease in the use of postmenopausal hormone therapy and a plateau in the number of women undergoing mammographic screening), the worldwide incidence

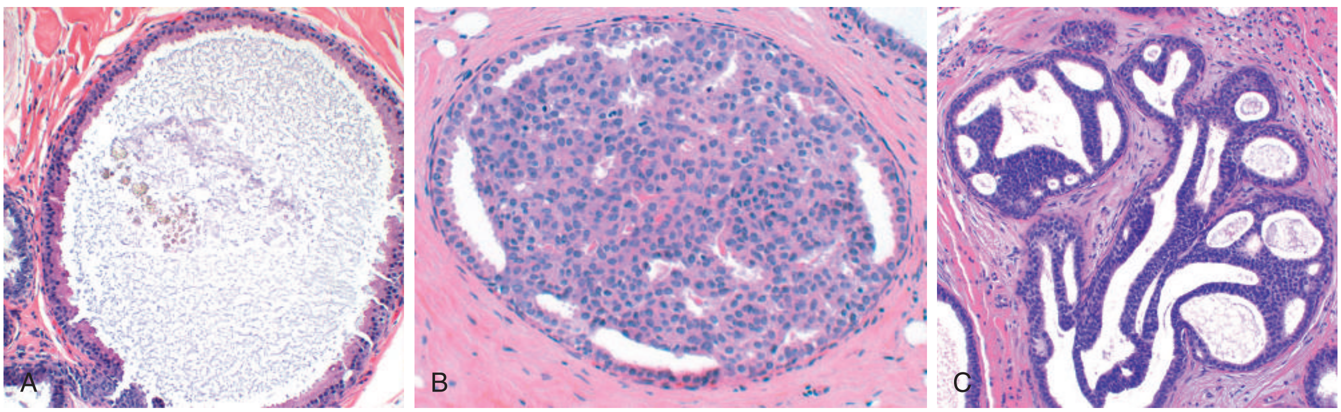

Fig. 19.25 Benign epithelial breast disease. (A) Nonproliferative disease. An apocrine cyst is shown that is a common feature of nonproliferative breast disease. (B) Proliferative breast disease is characterized by increased numbers of epithelial cells, as in this example of epithelial hyperplasia. (C) Proliferative breast disease with atypia. The proliferating epithelial cells are monomorphic in appearance and pile up to form abnormal architectural structures.

and mortality is increasing at an alarming rate. The major factors underlying this trend in developing countries are thought to be social changes that increase breast cancer risk—specifically, delayed childbearing, fewer pregnancies, and reduced breastfeeding—combined with a lack of access to optimal health care.

The lifetime risk of breast cancer is 1 in 8 for women living to age 90 in the United States. It is predicted that about 250,000 breast cancers will be diagnosed in 2016 and about 40,000 women will die of the disease—a toll among cancers second only to lung cancer. Since the mid-1980s the mortality rate has dropped from 30% to less than 20%. The decrease is attributed to both improved screening, which detects some cancers before they have metastasized, and more effective systemic treatment.

Almost all breast malignancies are adenocarcinomas (>95%). In the most clinically useful classification system, breast cancers are divided based on the expression of hormone receptors—estrogen receptor (ER) and progesterone receptor (PR)—and the expression of the human epidermal growth factor receptor 2 (HER2, also known as ERBB2), into three major groups:

- ER positive (HER2 negative; 50%–65% of cancers)
- HER2 positive (ER positive or negative; 10%–20% of cancers)
- Triple negative (ER, PR, and HER2 negative; 10%–20% of cancers)

These three groups show striking differences in patient characteristics, pathologic features, treatment response, metastatic patterns, time to relapse, and outcome (Table 19.7 and Fig. 19.26). Within each group are additional histologic subtypes (discussed later), some of which also have clinical importance.

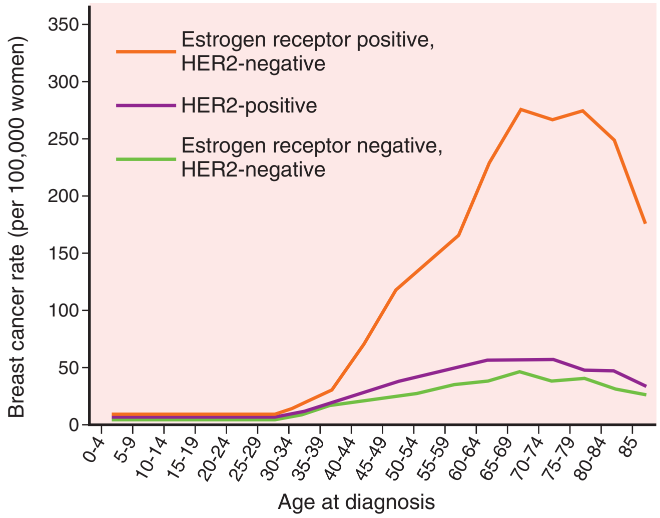

Fig. 19.26 Age and the incidence of breast cancer subtypes.

An alternative classification system with substantial overlap relies on gene expression profiling. This system, which is currently used mainly in the context of clinical research, divides breast cancers into four major types:

- *Luminal A*. The majority are lower-grade ER-positive cancers that are HER2 negative
- *Luminal B*. The majority are higher-grade ER-positive cancers that may be HER2 positive
- *HER2-enriched*. The majority overexpress HER2 and do not express ER
- *Basal-like*. The majority by gene expression profiling resemble basally located myoepithelial cells and are ER-negative, HER2-negative

Table 19.7 Summary of the Major Biologic Types of Breast Cancer

Feature	ER Positive/HER2 Negative	HER2 Positive (ER Positive or Negative)	Triple Negative (ER, PR, and HER2 Negative)
Overall frequency	50%–65%	20%	15%
Typical patient groups	Older women; men; cancers detected by screening; germline *BRCA2* mutation carriers	Young women; germline *TP53* mutation carriers	Young women; germline *BRCA1* mutation carriers
Ethnicity			
European/American	70%	18%	12%
African/American	52%	22%	26%
Hispanic	60%	24%	16%
Asian/Pacific Islander	63%	26%	11%
Grade	Mainly grade 1 and 2	Mainly grade 2 and 3	Mainly grade 3
Complete response to chemotherapy	Low grade (<10%), higher grade (10%)	ER positive (15%), ER negative (>30%)	30%
Timing of relapse	May be late (>10 years after diagnosis)	Usually short (<10 years after diagnosis)	Usually short (<8 years after diagnosis)
Metastatic sites	Bone (70%), viscera (25%), brain (<10%)	Bone (70%), viscera (45%), brain (30%)	Bone (40%), viscera (35%), brain (25%)
Similar group defined by mRNA profiling	Luminal A (low grade), luminal B (high grade)	Luminal B (ER positive), HER2-enriched (ER negative)	Basal-like
Common special histologic types	Lobular, tubular, mucinous, papillary	Apocrine, micropapillary	Carcinoma with medullary features
Common somatic mutations	*PIK3CA* (40%), *TP53* (26%)	*TP53* (75%), *PIK3CA* (40%)	*TP53* (85%)

PIK3CA encodes phosphoinositide 3-kinase (PI3K).

Epidemiology and Risk Factors

A large number of risk factors for breast cancer have been identified (Table 19.6). Some of the more important risk factors are summarized next.

Age and Gender. Breast cancer is rare in women younger than age 25, but increases in incidence rapidly after age 30 (Fig. 19.26); 75% of women with breast cancer are older than 50 years of age, and only 5% are younger than 40. The incidence in men is only 1% of that in women.

Family History of Breast Cancer. The greatest risk is for individuals with multiple affected first-degree relatives with early-onset breast cancer. In most families, it is thought that various combinations of low penetrance, "weak" cancer genes are responsible for increased risk. However, approximately 5% to 10% of breast cancers occur in persons who inherit highly penetrant germline mutations in tumor suppressor genes (discussed later). For these individuals, the lifetime risk of breast cancer may be greater than 90%.

Geographic Factors. Significant differences in the incidence and mortality rates of breast cancer have been reported in various countries. The risk is significantly higher in the Americas and Europe than in Asia and Africa. For example, the incidence and mortality rates are five times higher in the United States than in Japan. Some risk factors must be modifiable because migrants from low-incidence to high-incidence areas tend to acquire the rates of their new home countries. Diet, reproductive patterns, and breastfeeding practices are thought to be involved. In line with this, breast cancer rates appear to be rising in parts of the world that are adopting Western habits.

Race/Ethnicity. The highest rate of breast cancer is in women of European descent, largely because of a higher incidence of ER-positive cancers. Hispanic and African American women tend to develop cancer at a younger age and are more likely to develop aggressive tumors. Such disparities are thought to result from a combination of differences in genetics, social factors, and access to health care and are an area of intense study.

Reproductive History. Early age of menarche, nulliparity, absence of breastfeeding, and older age at first pregnancy are all associated with increased risk, probably because each increases the exposure of "at-risk" breast epithelial cells to estrogenic stimulation.

Ionizing Radiation. Radiation to the chest increases the risk of breast cancer if exposure occurs while the breast is still developing. For example, breast cancer develops in 25% to 30% of women who underwent irradiation for Hodgkin lymphoma in their teens and 20s, but the risk for women treated later in life is not elevated.

Other Risk Factors. Postmenopausal obesity, postmenopausal hormone replacement, mammographic density, and alcohol consumption also have been implicated as risk factors. The risk associated with obesity probably is due to exposure of the breast to estrogen produced by adipose tissue. In keeping with this, obesity is only associated with an increased risk of tumors that express ER.

Pathogenesis

The three major subtypes of breast cancer defined by differential expression of hormone receptors and HER2 arise through more-or-less distinct pathways that involve the stepwise acquisition of driver mutations in the epithelial cells of the duct/lobular system (Fig. 19.27). Factors that contribute directly to the development of breast cancer can be grouped into genetic, hormonal, and environmental categories.

Genetic. Driver mutations in cancer genes that contribute to breast carcinogenesis can be divided into those that are inherited and those that are acquired. **The major germline mutations conferring susceptibility to breast cancer affect genes that regulate genomic stability or that are involved in progrowth signaling pathways.** *BRCA1* and *BRCA2* are classic tumor suppressor genes, in that cancer arises only when both alleles are inactivated or defective (Chapter 6). *BRCA1* and *BRCA2* encode proteins that are required for repair of certain kinds of DNA damage. They are normally expressed in many different cells and tissues, and why germline mutations in these genes lead mainly to an increased risk of breast and serous ovarian cancer (discussed earlier) remains mysterious. The degree of penetrance, age of onset, and susceptibility to other types of cancers differ among the many *BRCA1* and *BRCA2* germline mutations, but most carriers develop breast cancer by the age of 70 years, as compared to about 12% of women with an average risk of breast cancer. For unclear reasons, *BRCA2* mutations are primarily associated with ER-positive tumors, whereas *BRCA1* mutations show a strong association with triple-negative cancers (Fig. 19.27). Other mutated genes associated with familial breast cancer include *TP53* (the so-called "guardian of the genome", Chapter 6) and *PTEN* (an important negative regulator of the pro-growth PI3K-AKT pathway), already mentioned earlier as a risk factor for endometrial carcinoma as part of *Cowden syndrome*.

As might be expected, **the pathways in which familial breast cancer genes function also are often disturbed in sporadic breast cancers**. Somatic mutations in *BRCA1* and *BRCA2* are rare in sporadic cancers, but *BRCA1* is inactivated by methylation in up to 50% of triple-negative cancers. Somatic mutations in *TP53* are common in breast cancer, particularly triple-negative and HER2-positive tumors (Table 19.7), whereas mutations that activate PI3K-AKT signaling are frequently found in sporadic ER-positive and HER2-positive breast cancers (Fig. 19.27).

A common clinically important driver mutation in breast cancer is amplification of the *HER2* gene. HER2 is a receptor tyrosine kinase that promotes cell proliferation and opposes apoptosis by stimulating the RAS- and PI3K-AKT signaling pathways. Cancers that overexpress HER2 are pathogenically distinct and highly proliferative. In the past they had a poor prognosis; however, the availability of therapeutic agents that specifically target HER2 has markedly improved the prognosis for patients with HER2-amplified tumors.

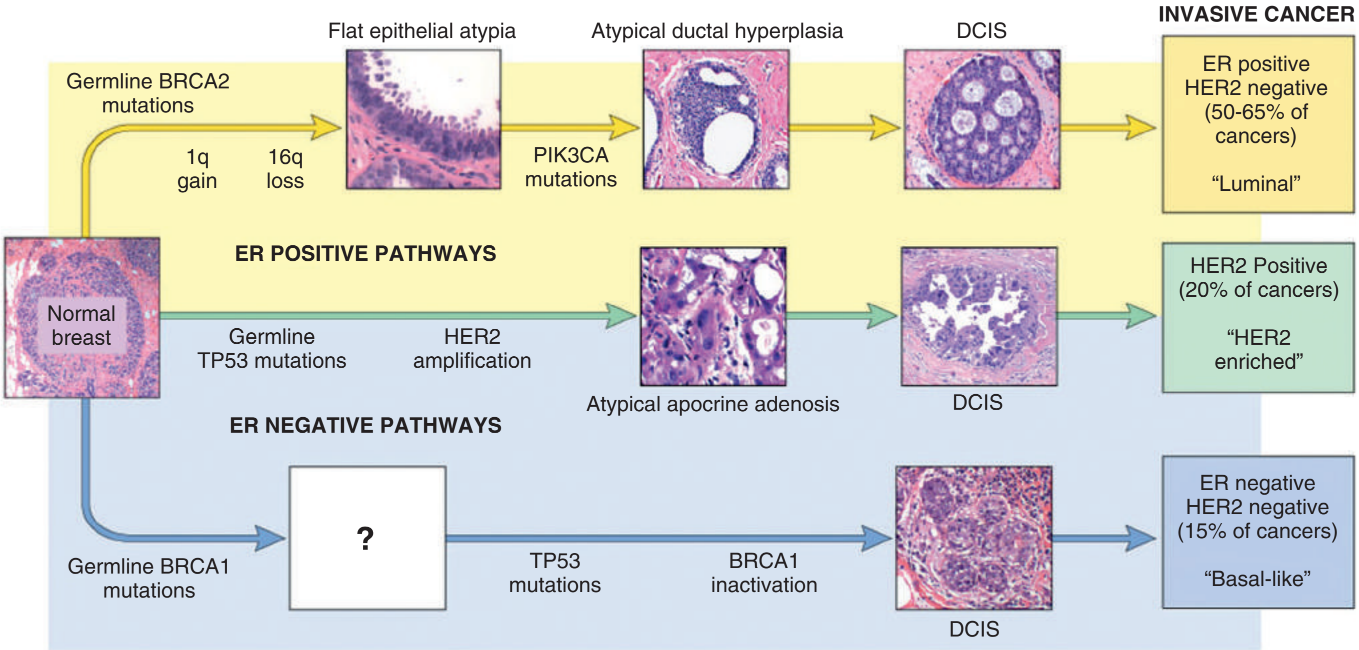

Fig. 19.27 Major pathways of breast cancer development. The most common pathway *(yellow arrow)* leads to ER-positive cancers. Morphologically recognized precursor lesions include flat epithelial atypia, ADH, and DCIS, all of which share certain genomic events with invasive ER-positive carcinomas, such gains of chromosome 1, losses of chromosome 16, and mutations of *PIK3CA* (the gene encoding PI3K). By gene expression profiling, these cancers are classified as "luminal." This is the type of cancer that arises most commonly in individuals with germline *BRCA2* mutations. Less common are cancers that overexpress HER2 because of gene amplification *(green arrow)*. These cancers may be positive or negative for ER and are usually associated with germline *TP53* mutations. A possible precursor lesion is atypical apocrine adenosis, which shares features with apocrine DCIS. The least common but molecularly most distinctive type of breast cancer is negative for ER and HER2 ("triple negative"; *blue arrow*). These cancers have loss of *BRCA1* and *TP53* function and are genomically unstable. The majority of triple-negative cancers are classified as "basal-like" by gene expression profiling.

Hormonal Influences. Estrogens stimulate the production of growth factors, such as transforming growth factor-α, platelet-derived growth factor, fibroblast growth factor, and others, which may promote tumor development through paracrine and autocrine mechanisms. In addition, ER regulates dozens of other genes in an estrogen-dependent fashion, some of which are important for tumor development or growth. Hormonal influences likely drive proliferation during the development of cancers from precursor lesions (which typically strongly express ER) to fully malignant and even metastatic carcinomas. The clearest measure of the importance of estrogen is found in the therapeutic benefits of estrogen antagonists, which reduce the development of ER-positive cancers in women at high risk and are mainstays in the treatment of established ER-positive tumors.

Environmental Factors. Environmental influences are suggested by the variable incidence of breast cancer in genetically homogeneous groups (e.g., Japanese women living in Japan and the United States) and the geographic differences in breast cancer incidence, as discussed earlier.

MORPHOLOGY

The most common location of tumors within the breast is in the upper outer quadrant (50%), followed by the central portion (20%). About 4% of women with breast cancer have bilateral primary tumors or sequential lesions in the same breast.

Breast cancers are classified morphologically according to whether they have penetrated the basement membrane. Those that remain within this boundary are termed *in situ carcinomas*, and those that have spread beyond it are designated *invasive carcinomas*. In this classification, the main forms of breast carcinoma are as follows:

A. Noninvasive
  1. Ductal carcinoma in situ
  2. Lobular carcinoma in situ

B. Invasive
  1. Invasive ductal carcinoma (includes all carcinomas that are not of a special type)—70% to 80%
  2. Invasive lobular carcinoma— ~10% to 15%
  3. Carcinoma with medullary features— ~5%
  4. Mucinous carcinoma (colloid carcinoma) — ~5%
  5. Tubular carcinoma— ~5%
  6. Other types

Noninvasive (in Situ) Carcinoma

There are two morphologic types of noninvasive breast carcinoma: ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). The terms *ductal* and *lobular* are misleading, as both types of CIS are thought to arise from cells in the terminal duct that give rise to lobules. LCIS usually expands involved lobules (Fig. 19.28A), whereas DCIS distorts lobules into ductlike spaces (Fig. 19.28B). By definition, both "respect" the basement membrane and do not invade into stroma or lymphovascular channels.

DCIS has a wide variety of histologic appearances, including solid, comedo, cribriform, papillary, micropapillary, and "clinging"

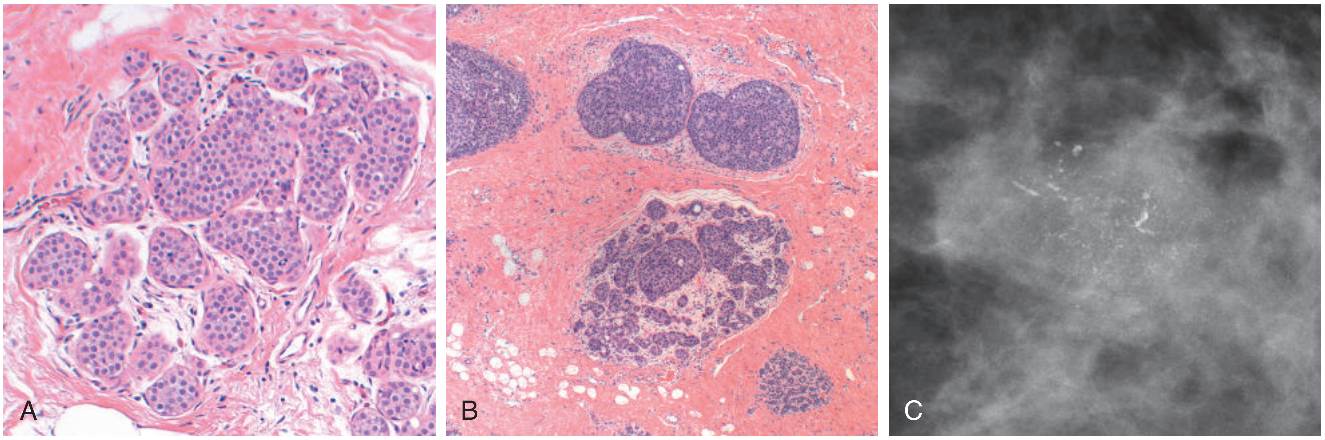

Fig. 19.28 Carcinoma in situ. (A) Lobular carcinoma in situ (LCIS). (B) Ductal carcinoma in situ (DCIS). DCIS partially involves the lobule in the lower half of this photo and has completely effaced the upper lobules, producing a ductlike appearance. (C) Mammographic detection of calcifications associated with DCIS.

types. Nuclear appearances range from bland and monotonous (low nuclear grade) to pleomorphic (high nuclear grade). The distinctive **comedo** subtype is characterized by extensive central necrosis, which produces toothpastelike necrotic tissue that extrudes from transected ducts on application of gentle pressure. **Calcifications frequently are associated with DCIS** (Fig. 19.28C), resulting from calcification of necrotic debris or secretory material. DCIS constitutes only 5% of breast cancers in unscreened populations but up to 30% in screened populations, largely because of the ability of mammography to detect calcifications. Current treatment strategies for DCIS use surgery and irradiation to eradicate the lesion. Treatment with anti-estrogenic agents such as tamoxifen also is used to decrease the risk of recurrence of ER-positive DCIS. The prognosis is excellent, with greater than 97% long-term survival. If untreated, DCIS progresses to invasive cancer in roughly one-third of cases, usually in the same breast and quadrant as the earlier DCIS.

Paget disease of the nipple is caused by the extension of DCIS up the lactiferous ducts and into the contiguous skin of the nipple, producing a unilateral crusting exudate over the nipple and areolar skin. Unlike Paget disease of the vulva (described earlier), Paget disease of the nipple stems from in situ extension of an underlying carcinoma. The prognosis of the carcinoma of origin is affected by the presence of Paget disease and is determined by other factors (discussed under Clinical Features).

LCIS has a uniform appearance. The cells are monomorphic, have bland, round nuclei, and are found in loosely cohesive clusters within the lobules (Fig. 19.28A). LCIS is virtually always an incidental finding because, unlike DCIS, it is only rarely associated with calcifications. Therefore, the incidence of LCIS has remained unchanged in mammographically screened populations. Approximately one-third of women with LCIS eventually develop invasive carcinoma. Unlike DCIS, invasive carcinomas following a diagnosis of LCIS may arise in either breast—⅔ in the same breast and ⅓ in the contralateral breast. Thus, **LCIS is both a marker of an increased risk of carcinoma in both breasts and a direct precursor of some cancers.** Current treatment options include close clinical and radiologic follow-up, chemoprevention with tamoxifen or, less commonly, bilateral prophylactic mastectomy.

Invasive (Infiltrating) Carcinoma

The distinctive histologic patterns of the subtypes of invasive carcinoma are described first, followed by grading, which is used for all.

Invasive ductal carcinoma is a term used for all carcinomas that cannot be subclassified into one of the specialized types described below. A majority (70%–80%) of cancers falls into this group. This type of cancer usually is associated with DCIS. The microscopic appearance varies, ranging from tumors with well-developed tubules and low-grade nuclei (Fig. 19.29A) to tumors consisting of sheets of anaplastic cells. Most invasive ductal carcinomas produce a desmoplastic response, which replaces normal breast fat (resulting in a mammographic density; Fig. 19.29B) and eventually leads to the appearance of a hard, palpable irregular mass. About 50% to 65% of ductal carcinomas are ER positive, 20% are HER2 positive, and 15% are negative for both ER and HER2 (Table 19.7).

Invasive lobular carcinoma consists of infiltrating cells that are morphologically similar to the tumor cells seen in LCIS; indeed, two-thirds of the cases are associated with LCIS. These tumors comprise 10% to 15% of all breast carcinomas. The cells invade stroma individually and often are aligned in "single-file" (Fig. 19.29C). Although most manifest as palpable masses or mammographic densities, a significant subgroup invade without producing a desmoplastic response; such tumors may be clinically occult and difficult to detect by imaging (Fig. 19.29D). The pattern of metastasis of lobular carcinoma is unique among breast cancers, as they frequently spread to cerebrospinal fluid, serosal surfaces, gastrointestinal tract, ovary, uterus, and bone marrow. Almost all lobular carcinomas express hormone receptors, whereas HER2 overexpression is rare.

Carcinomas with medullary features are a special type of triple-negative cancer comprising about 5% of all breast cancers. These carcinomas typically grow as rounded masses that can be difficult to distinguish from benign tumors on imaging (Fig. 19.29F). They consist of sheets of large anaplastic cells associated with pronounced lymphocytic infiltrates composed predominantly of T cells (Fig. 19.29E). The presence of lymphocytes is associated with a favorable prognosis, at least in part due to a better response to chemotherapy compared to poorly differentiated carcinomas without lymphoid infiltrates. This type

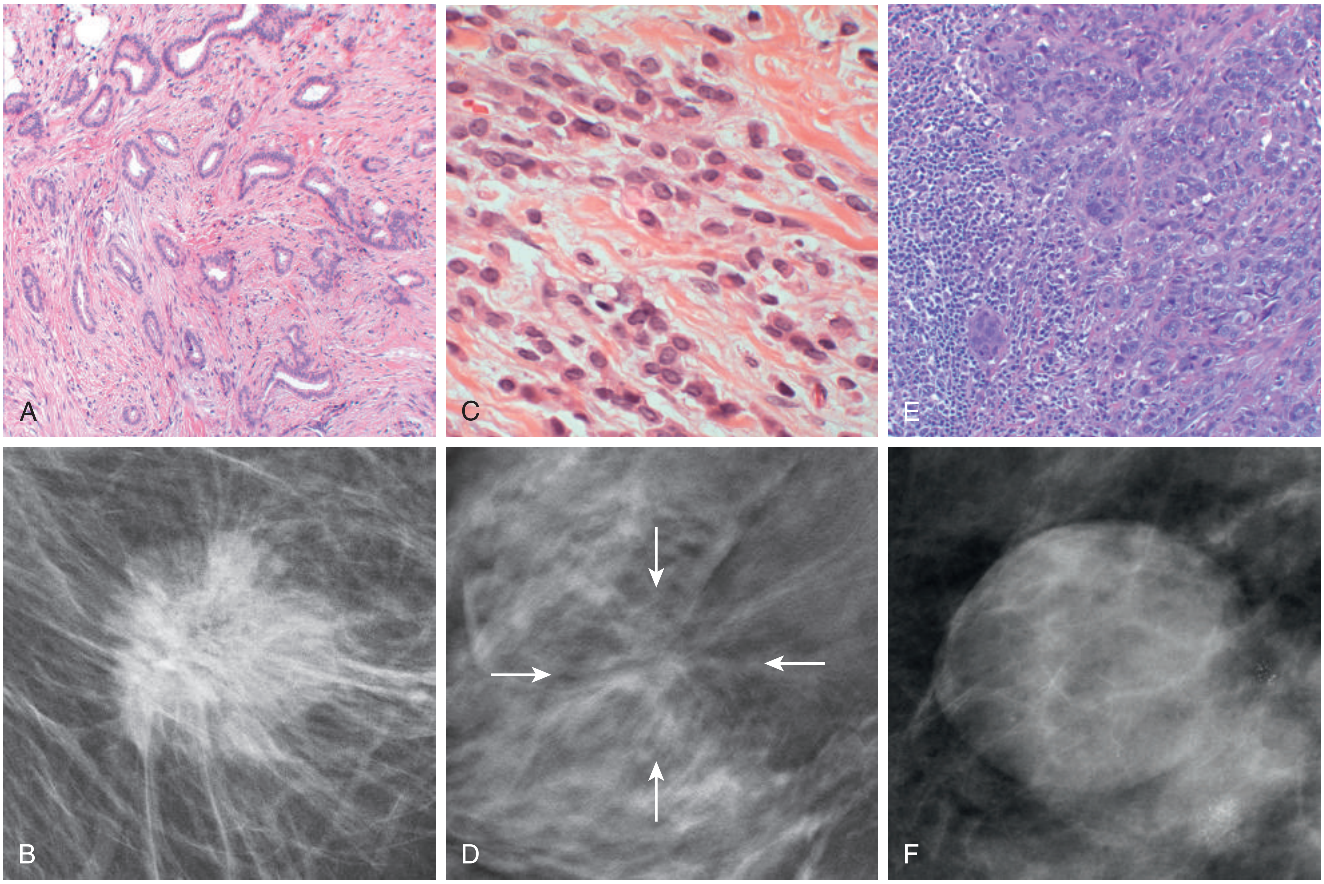

Fig. 19.29 Growth patterns of invasive breast carcinomas. (A) Most grow as tubules ("ductal" carcinoma) and stimulate a reactive desmoplastic stromal proliferation. In mammograms (B), these carcinomas appear as dense masses with spicular margins resulting from invasion of adjacent radiolucent breast tissue. (C) Lobular carcinomas are composed of noncohesive tumor cells that invade as linear cords of cells and induce little stromal response. Accordingly, in mammograms (D) lobular carcinomas often appear as relatively subtle, irregular masses *(arrows)*. (E) Uncommonly, carcinomas consist of tightly adhesive clusters of cells, as in this carcinoma with medullary features, or when there is abundant extracellular mucin production. (F) Such tumors may appear as well-circumscribed masses in mammograms, mimicking the appearance of a benign lesion.

of carcinoma is seen frequently in women with germline *BRCA1* mutations, but most women with these carcinomas are not carriers.

Mucinous (colloid) carcinoma is an ER-positive/HER2-negative tumor that produces abundant amounts of extracellular mucin. The tumors usually are soft and gelatinous because of the presence of mucin pools that create an expansile circumscribed mass.

Tubular carcinoma is another type of ER-positive/HER2-negative cancer and is almost always detected on mammography as a small irregular mass. The tumor cells are arranged in well-formed tubules and have low-grade nuclei. Lymph node metastases are rare, and the prognosis is excellent.

Inflammatory carcinoma is defined by its clinical presentation, rather than a specific morphology. Patients present with a swollen erythematous breast without a palpable mass. The underlying invasive carcinoma is generally poorly differentiated and diffusely infiltrates and obstructs dermal lymphatic spaces, causing the "inflamed" appearance; true inflammation is absent. Many of these tumors metastasize to distant sites; the overall 5-year survival is less than 50%, and understandably even lower in those with metastatic disease at diagnosis. About half express ER and 40% to 60% overexpress HER2.

All types of invasive breast carcinoma are assigned a grade from 1 (low-grade) to 3 (high-grade) based on nuclear pleomorphism, tubule formation, and proliferation. Low-grade nuclei are similar in appearance to the nuclei of normal cells. High-grade nuclei are enlarged and have irregular nuclear contours resulting from abnormal DNA content and structure. Most low-grade carcinomas form well-defined tubules and may be difficult to distinguish from benign lesions, whereas high-grade carcinomas lose this capacity and invade as solid sheets or single cells. Proliferation is evaluated by counting mitotic figures. The majority of HER2-positive and triple-negative carcinomas are highly proliferative, whereas ER-positive cancers show a wide range of proliferation.

Clinical Features

As previously discussed, in unscreened populations (including young women, for whom screening is not indicated) most breast cancers are detected as a palpable mass by the affected patient. Such carcinomas are almost all invasive and are typically at least 2 to 3 cm in size. At least half of these cancers will already have spread to regional lymph nodes. In older screened populations,

approximately 60% of breast cancers are discovered before symptoms are present. About 20% are in situ carcinomas. Invasive carcinomas detected by screening in older women are 1 to 2 cm in size and only 15% will have metastasized to lymph nodes. Palpable cancers in the older age group are often "interval" cancers—cancers that appear suddenly between screening intervals. Understandably, interval cancers generally are highly proliferative and usually are high grade.

The clinical outcome for a woman with breast cancer can be predicted based on the molecular and morphologic features of the cancer and its stage at the time of diagnosis. Factors that influence outcome include the following:

- *Biologic type.* The biologic type of cancer is evaluated by a combination of histologic appearance, grade (including proliferative rate), expression of hormone receptors, and expression of HER2.

  Proliferation is evaluated by mitotic count and is closely tied to responsiveness to cytotoxic chemotherapy. This is because rapidly growing cancer cells are more sensitive to agents that damage DNA or otherwise interfere with cell division.

  Expression of estrogen or progesterone receptors predicts response to anti-estrogen therapy. The growth of hormone receptor–positive cancers can be inhibited for many years with therapy and it is possible for patients to survive for long periods with distant metastases. However, resistance often eventually develops—in some cancers because of mutations in the gene for ER. In contrast, there is no targeted therapy available for triple-negative cancers, which are treated with chemotherapy. Cancers that do not respond to initial therapy metastasize and usually cause the death of the patient.

  Overexpression of HER2 is seen in about 20% of breast cancers. HER2 remains one of the best-characterized examples of an effective therapy that is directed against a tumor-specific molecular lesion. Before targeted therapy, which may take the form of blocking antibodies or small molecular inhibitors of HER2, outcomes were similar to patients with triple-negative carcinomas. However, complete response rates exceed 60% when targeted therapy is combined with chemotherapy, and the outlook for these patients has been markedly improved.
- *RNA expression profiling* is a newer method of subclassifying cancers. For breast cancers, many of the genes that predict prognosis are involved in proliferation. The greatest clinical value of these assays is their ability to identify patients with slow-growing, anti-estrogen-responsive cancers who can be spared the toxicity of chemotherapy.
- *Tumor stage.* "Stage" is a measure of the extent of tumor at the time of diagnosis and is important for all biologic types of carcinoma. It is based on features of the primary tumor (T), involvement of regional lymph nodes (N), and the presence of distant metastases (M) (Fig. 19.30). The AJCC/UICC staging system, used in the United States and Europe, classifies tumors as T1, T2, and T3 based on the tumor size, whereas T4 tumors have ulceration of the skin, involvement of the deep muscles of the chest wall, or are clinically diagnosed as inflammatory carcinoma. *The majority of cancers first metastasize to regional nodes*, and nodal involvement is a very strong prognostic factor. Lymphatic drainage goes to one or two sentinel lymph nodes in the axilla in most patients. If these nodes are not involved, the remaining axillary nodes are usually free of carcinoma. *Sentinel node biopsy* has become the standard for assessing nodal involvement, replacing more extensive lymph node dissections, which are associated with significant morbidity. *Distant metastases* (M) are only detected in 5% of newly diagnosed women. Stage 0 is CIS, which is associated with survival rates greater than 95%. Stage I includes women with smaller cancers and nodes either free of carcinoma or with only very small micrometastases. Survival is ~86% at 10 years. Carcinomas are classified as Stage II either because of larger tumor size or because of up to

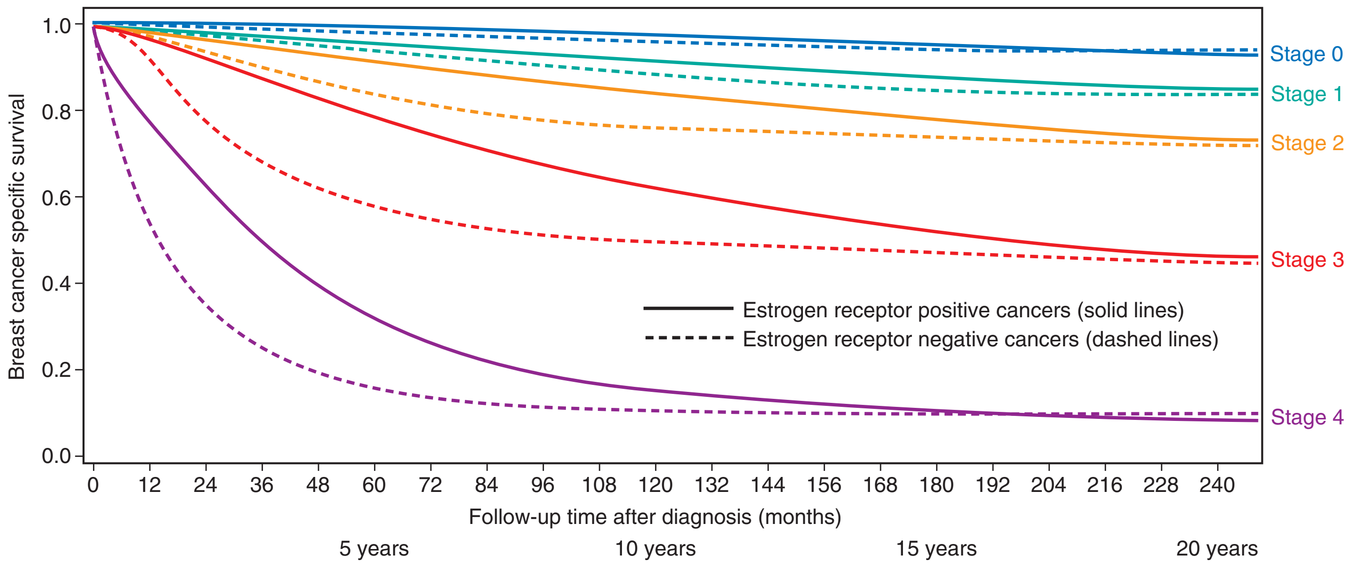

Fig. 19.30 Ten-year breast cancer specific survival according to AJCC stage for ER-positive and ER-negative cancers. Both stage and biologic type of cancer are important determinants of survival. ER-positive invasive cancers have improved survival over ER-negative cancers at all stages, but this advantage diminishes after 5 years because of late recurrences of ER-positive tumors. *(Graph courtesy of Dr. Stephanie Wong; data from* SEER-18, 1992–2012. *http://seer.cancer.gov.)*

three positive nodes. Survival declines to ~71% at Stage II. Stage III is the group of locally advanced cancers defined by large size, involvement of skin or chest wall, or by four or more positive nodes. Only ~54% of patients survive 10 years. Stage IV is reserved for patients with distant metastases, and survival is very poor (~11%). The most likely site of a distant recurrence varies with the biologic type of cancer. Triple-negative cancers and HER2 cancers are more likely to metastasize to the brain and viscera, in contrast to ER-positive cancers, which most often metastasize to bones (Table 19.7).

Combining stage and biologic factors may provide a more accurate assessment of outcome. For example, for each cancer stage, the survival of patients with ER-positive cancers is higher than patients with ER-negative cancers 5 years postdiagnosis, especially for Stages III and IV (Fig. 19.30). It must be noted, however, this advantage diminishes with time, with progressively smaller differences being seen at 10 years post-diagnosis and beyond (Fig. 19.30). This narrowing of survival differences is explained by two factors. First, most deaths from ER-negative cancers happen within 5 years of diagnosis (Fig. 19.31). Women who live beyond this point are those whose tumors have had excellent responses to treatment, and many of these women may be cured. Second, although the growth of ER-positive cancers is held in check for years by antiestrogen therapy, this therapy is not curative and these cancers may eventually become resistant to treatment.

Historically, virtually all women with untreated breast cancer died within 3 to 4 years. However, great strides have been made in treatment and now 80% of women with breast cancer who receive optimal therapy will survive.

Endocrine therapy with tamoxifen and aromatase inhibitors is very effective for ER-positive cancers, which may remain dormant for many years.

Targeted therapy has the promise of being more effective and less toxic than conventional chemotherapy (Table 19.8), as already proven by marked improvement in survival of women with HER2-positive carcinomas following the introduction of therapies that target HER2. Newer approaches to targeted therapy include inhibition of alternative DNA repair pathways in *BRCA*-mutated cancers and blockage of the PI3K-AKT-signaling pathway. Immune checkpoint blockade therapy (Chapter 6), is under evaluation in patients with breast cancer. It is hoped that such new approaches will improve outcomes in subtypes that currently have a generally poor prognosis, such as triple negative breast cancer.

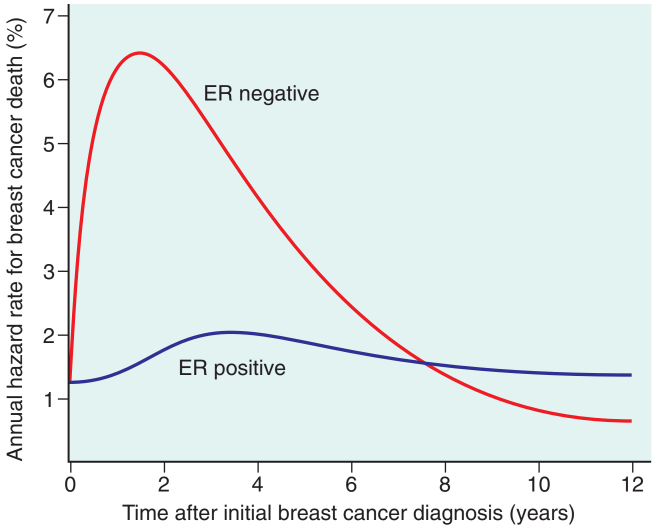

Fig. 19.31 Time to recurrence of breast cancers. The hazard ratio reflects the risk of recurrence of each molecular type of breast cancer at various points in time after diagnosis. ER-negative cancers usually recur within the first 8 years. Patients who survive beyond this interval are likely cured. In contrast, ER-positive cancers have a lower rate of recurrence, but remain at risk decades after the primary diagnosis.

Table 19.8 Targeted Treatment of Breast Cancer

Target	Treatment	Assay	Comments
ER	Estrogen deprivation (oophorectomy, aromatase inhibitors) Blockage of ER (tamoxifen)	IHC for nuclear ER	Effective cytostatic (but not cytotoxic) therapy for ER-positive cancer
HER2	Antibodies to HER2 Cytotoxic therapy linked to HER2 antibody Tyrosine kinase inhibitors	IHC for membrane HER2 ISH for HER2 gene amplification	Effective for HER2-positive cancers
Susceptibility to DNA damage resulting from BRCA 1 and BRCA2 mutations that cause defects in HRR	Chemotherapy with agents causing DNA damage that requires HRR (e.g., platinum agents) Inhibition of alternative DNA repair pathway (poly-ADP ribose polymerase or PARP inhibitors)	Sequencing of *BRCA1* and *BRCA2*	May be effective for carcinomas arising in patients with germline *BRCA1* or 2 mutations or cancers with somatic loss of BRCA function
PI3K/AKT pathway	Inhibition of proteins in the pathway	Activating mutations or pathway activation—not yet validated	>80% of breast cancers have alterations in this pathway Effectiveness of treatment not yet demonstrated
Immune checkpoint proteins	Blocking antibodies to PD-L1, PD-1, and other immune checkpoint proteins	IHC for immune checkpoint proteins—not yet validated	Under investigation in patients with triple-negative breast cancer

ER, Estrogen receptor; *HRR*, homologous recombination repair; *IHC*, immunohistochemistry; *ISH*, in situ hybridization.

SUMMARY

BREAST CARCINOMA

- The lifetime risk of developing breast cancer for an American woman is 1 in 8.
- A majority (75%) of breast cancers are diagnosed after the age of 50.
- The major risk factors for developing breast cancer are related to hormonal factors and inherited susceptibility.
- About 12% of all breast cancers are caused by identified germ-line mutations; *BRCA1* and *BRCA2* genes account for one-half of the cases associated with single-gene mutations.
- DCIS is a precursor to invasive ductal carcinoma and is most often found on mammographic screening as calcifications. When carcinoma develops in a woman with a previous diagnosis of untreated DCIS, it is usually is an invasive ductal carcinoma in the same breast.
- LCIS is both a marker of increased risk and a precursor lesion. When carcinoma develops in a woman with a previous diagnosis of LCIS, two-thirds are in the same breast and one-third is in the contralateral breast.
- Invasive carcinomas are classified according to histologic type and biologic type: ER-positive/HER2-negative, HER2-positive, and ER/PR/HER2-negative (triple-negative). The biologic types of cancer have important differences in patient characteristics, grade, mutation profile, metastatic pattern, response to therapy, time to recurrence, and prognosis.
- Prognosis is dependent on the biologic type of tumor, stage, and the availability of treatment modalities.

CHAPTER

Endocrine System 20

CHAPTER OUTLINE

The endocrine system is comprised of a widely distributed group of organs that work together to maintain the body's metabolic equilibrium, or homeostasis. The cells of the endocrine system achieve this by secreting molecules, which are frequently called *hormones,* that act on target cells distant from their site of synthesis. A hormone typically is carried by the blood from the endocrine gland to its target tissues. Most hormones are secreted in response to other, so-called trophic, hormones, which are produced in response to particular metabolic needs. Production of a hormone often downregulates the activity of the gland that secretes the stimulating trophic hormone, a process known as *feedback inhibition.*

Hormones can be classified into several broad categories, based on the nature of their receptors:

- *Hormones that act by binding to cell surface receptors:* This large class of compounds is composed of two groups: (1) peptide hormones, such as *growth hormone* and *insulin,* and (2) small molecules, such as *epinephrine.* Binding of these hormones to cell surface receptors leads to an increase in intracellular *second messengers,* such as cyclic adenosine monophosphate (cAMP), inositol 1,4,5-trisphosphate (IP3), and ionized calcium. Elevated levels of one or more of these compounds can activate intracellular signaling pathways that may stimulate cell growth or differentiation, or alter cell function.
- *Hormones that act by binding to intracellular receptors:* Many lipid-soluble hormones pass through the plasma membrane by diffusion to interact with receptors in the cytosol or the nucleus. The resulting hormone-receptor complexes bind specifically to regulatory elements in DNA, thereby affecting the expression of specific target genes. Hormones of this type include *steroids* (e.g., estrogen, progesterone, glucocorticoids), *retinoids* (vitamin A), and *thyroxine.*

Endocrine diseases generally are caused by: (1) *underproduction or overproduction* of hormones, with associated biochemical and clinical consequences; (2) *end-organ resistance* to the effects of a hormone; or (3) *neoplasms,* which may be nonfunctional or may be associated with overproduction or underproduction of hormones. In many settings, the study of endocrine diseases relies heavily on biochemical measurements of the levels of hormones, their regulators, and other metabolites.

Pituitary

The pituitary gland is a small, bean-shaped structure that lies at the base of the brain within the confines of the sella turcica. It is intimately related to the hypothalamus, with which it is connected by a stalk, composed of axons extending from the hypothalamus, and a rich venous plexus constituting a portal circulation. Along with the hypothalamus, the pituitary has a central role in the regulation of most of the other endocrine glands. The pituitary is composed of two morphologically and functionally distinct components: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). Diseases of the pituitary, accordingly, can be divided into those that primarily affect the anterior lobe and those that primarily affect the posterior lobe.

The anterior pituitary, or adenohypophysis, produces trophic hormones that stimulate the production of hormones from the thyroid, adrenal, and other glands. The anterior pituitary is composed of epithelial cells derived embryologically from the developing oral cavity. In routine histologic sections, a colorful array of cells containing basophilic cytoplasm, eosinophilic cytoplasm, or poorly staining (chromophobic) cytoplasm is present (Fig. 20.1). Detailed studies using electron microscopy and immunohistochemical techniques have demonstrated that the staining properties of these cells are related to the presence of different polypeptide hormones within their cytoplasm that control the activity of other endocrine glands. The release of these pituitary hormones is under the control of factors produced in the hypothalamus; while most hypothalamic factors are stimulatory and promote pituitary hormone release, others (e.g., somatostatin and dopamine) are inhibitory (Fig. 20.2). Rarely, signs and symptoms of pituitary disease may be caused by overproduction or underproduction of hypothalamic factors, rather than a primary pituitary abnormality.

Symptoms and signs of pituitary disease fall into the following categories:

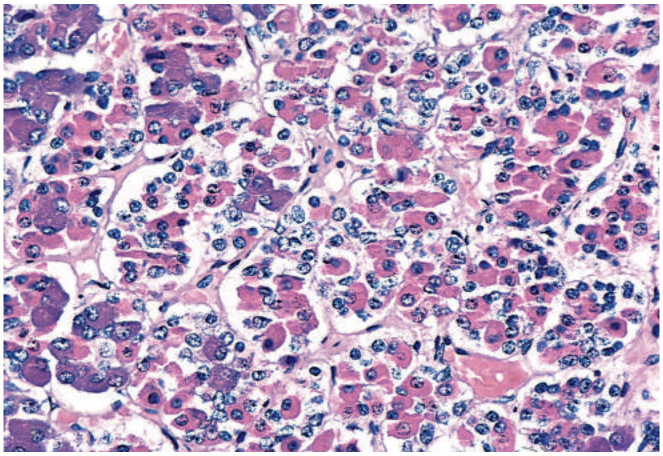

Fig. 20.1 Normal anterior pituitary gland. The gland is populated by several distinct cell types that express different peptide hormones. These hormones are basophilic (blue), eosinophilic (red), or nonstaining in routine sections stained with hematoxylin and eosin, which allows the various cell types to be identified. Note also the presence of a fine reticulin network between the cells.

- *Hyperpituitarism* related effects: Hyperpituitarism arises from excessive secretion of trophic hormones. It most often results from an *anterior pituitary adenoma* but also may be caused by other pituitary and extrapituitary lesions, as discussed later. The symptoms and signs of hyperpituitarism are discussed in the context of individual tumors later in the chapter (see Table 20.1).
- *Hypopituitarism* related effects: Hypopituitarism is caused by deficiency of trophic hormones and results from a variety of destructive processes that may damage the pituitary, including ischemic injury, surgery, radiation, and inflammatory reactions. In addition, nonfunctional pituitary adenomas may encroach upon and destroy the normal anterior pituitary, causing hypopituitarism.
- *Local mass effects:* Among the earliest changes associated with pituitary neoplasms are radiographic abnormalities of the sella turcica, including sellar expansion, bony erosion, and disruption of the diaphragma sellae. Because of the close proximity of the optic nerves and chiasm to the sella, expanding pituitary lesions often compress decussating fibers in the optic chiasm. This can give rise to visual field abnormalities, classically in the form of defects in the lateral (temporal) visual fields—a so-called "bitemporal hemianopsia". As in the case of any expanding intracranial mass, pituitary tumors may produce signs and symptoms of elevated intracranial pressure, including headache, nausea, and vomiting. Pituitary neoplasms that extend beyond the sella turcica into the base of the brain produce seizures or obstructive hydrocephalus; involvement of cranial nerves can result in *cranial nerve palsy.* On occasion, acute hemorrhage into a pituitary neoplasm is associated with rapid enlargement of the lesion and loss of consciousness, a situation termed *pituitary apoplexy.* Acute pituitary apoplexy may be rapidly fatal and is therefore considered to be a neurosurgical emergency.

ANTERIOR PITUITARY TUMORS

The most common cause of anterior pituitary disorders are pituitary tumors, most of which are benign adenomas. Some of these produce hormones and result in endocrine abnormalities, and others are nonfunctional and produce mass effects. We discuss first the general features of pituitary adenomas, then specific tumors.

Pituitary Adenomas: General Features

The most common cause of hyperpituitarism is a hormone-producing adenoma arising in the anterior lobe. Other, less common, causes include hyperplasia and carcinomas of the anterior pituitary, secretion of hormones by some extrapituitary tumors, and certain hypothalamic disorders. Some salient features of pituitary adenomas are as follows:

- *Pituitary adenomas are classified on the basis of hormone(s) produced by the neoplastic cells*, which are detected by immunohistochemical stains performed on tissue sections (Table 20.1).

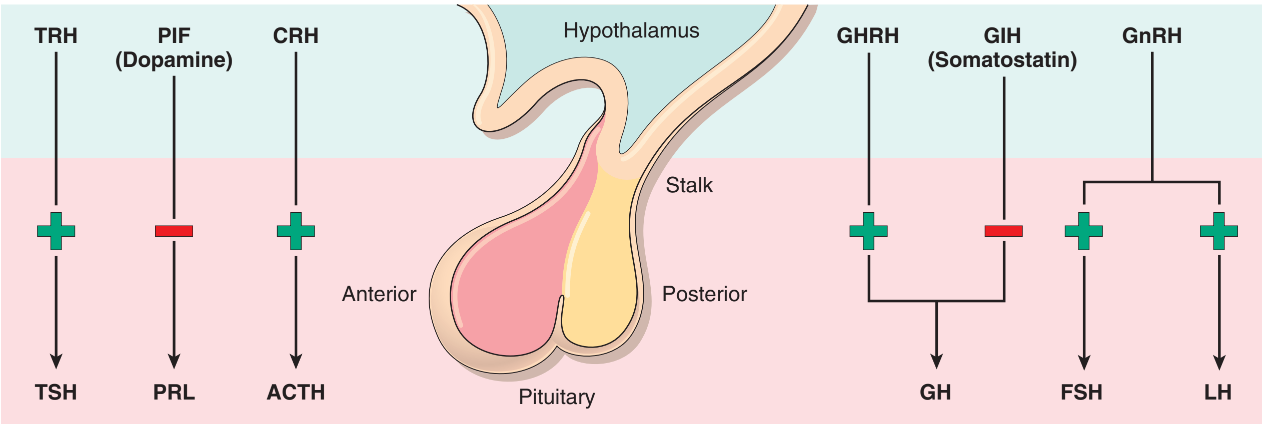

Fig. 20.2 The hypothalamic/pituitary axis. The hypothalamus regulates the secretion of hormones from the adenohypophysis (anterior pituitary gland) by releasing stimulatory (corticotropin-releasing hormone, CRH; growth hormone–releasing hormone, GHRH; gonadotropin-releasing hormone, GnRH; thyrotropin-releasing hormone (TRH) and inhibitory factors (growth hormone inhibitory hormone, GIH or somatostatin; prolactin inhibitory factor, PIF or dopamine). These in turn modulate the release of six hormones from the anterior pituitary: adrenocorticotropic hormone (ACTH or corticotropin); follicle-stimulating hormone (FSH); growth hormone (GH, or somatotropin); luteinizing hormone (LH); prolactin (PRL); and thyroid-stimulating hormone (TSH, or thyrotropin).

- Pituitary adenomas can be *functional* (hormone producing) or *nonfunctioning* (not producing hormone), or *silent* (i.e., demonstration of hormone production at the tissue level only, without clinical manifestations of hormone excess). Both functional and nonfunctioning pituitary adenomas usually are composed of a single cell type and produce at most a single predominant hormone, but there are exceptions. Some pituitary adenomas secrete two different hormones (growth hormone and prolactin being the most common combination); rarely, pituitary adenomas are plurihormonal.
- Pituitary adenomas are designated as *microadenomas* if they are less than 1 cm in diameter and *macroadenomas* if they exceed 1 cm in diameter.
- Nonfunctioning adenomas are likely to come to clinical attention at a later stage and are, therefore, more likely to be macroadenomas. Because of their larger size, nonfunctioning adenomas may encroach upon and destroy adjacent anterior pituitary parenchyma, leading to hypopituitarism.

Pathogenesis

Several genetic abnormalities associated with pituitary adenomas have been identified:

- **G-protein mutations are one of the most common genomic alterations in pituitary adenomas.** G-proteins play a critical role in signal transduction, transmitting signals from cell surface receptors e.g. growth

Table 20.1 Classification of Pituitary Adenomas

Pituitary Cell Type	Hormone	Adenoma Subtypes	Associated Syndrome*
Lactotroph	Prolactin	Lactotroph adenoma Silent lactotroph adenoma	Galactorrhea and amenorrhea (in females) Sexual dysfunction, infertility
Somatotroph	GH	Densely granulated somatotroph adenoma Sparsely granulated somatotroph adenoma Silent somatotroph adenoma	Gigantism (children) Acromegaly (adults)
Mammosomatotroph	Prolactin, GH	Mammosomatotroph adenomas	Combined features of GH and prolactin excess
Corticotroph	ACTH and other POMC-derived peptides	Densely granulated corticotroph adenoma Sparsely granulated corticotroph adenoma Silent corticotroph adenoma	Cushing syndrome Nelson syndrome
Thyrotroph	TSH	Thyrotroph adenomas Silent thyrotroph adenomas	Hyperthyroidism
Gonadotroph	FSH, LH	Gonadotroph adenomas Silent gonadotroph adenomas ("null cell," oncocytic adenomas)	Hypogonadism, mass effects, and hypopituitarism

ACTH, Adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; POMC, pro-opiomelanocortin; TSH, thyroid-stimulating hormone.

*Note that nonfunctional (silent) adenomas in each category express the corresponding hormone(s) within the neoplastic cells, as determined by special immunohistochemical staining on tissues. However, these adenomas do not produce the associated clinical syndrome, and typically present with *mass effects* accompanied by *hypopituitarism* due to destruction of normal pituitary parenchyma. These features are particularly common with gonadotroph adenomas. Partially adapted from Asa SL, Essat S: The pathogenesis of pituitary tumors. Annu Rev Pathol 4:97, 2009.

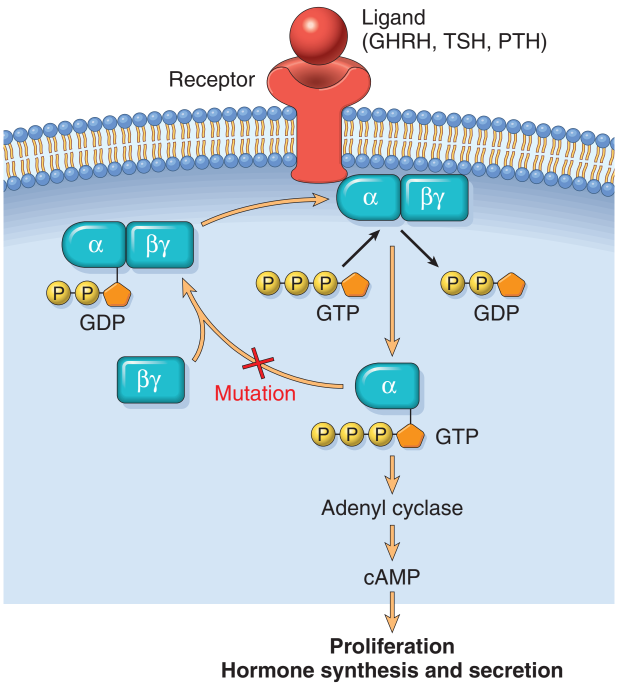

Fig. 20.3 G-protein signaling in endocrine neoplasia. Mutations that lead to G-protein hyperactivity are seen in a variety of endocrine neoplasms, including pituitary, thyroid, and parathyroid adenomas. G proteins play a critical role in signal transduction, transmitting signals from cell surface receptors (GHRH, TSH, or PTH receptor) to intracellular effectors (e.g., adenyl cyclase), which then generate second messengers (cAMP, cyclic adenosine monophosphate). *GDP,* Guanosine diphosphate; *GTP,* guanosine triphosphate; *P,* inorganic phosphate.

hormone–releasing hormone (GHRH) receptor, to intracellular effectors (e.g., adenyl cyclase), which then generate second messengers (e.g., cAMP). G-proteins are heterotrimeric proteins, composed of a specific α-subunit that binds guanine nucleotides and interacts with both cell surface receptors and intracellular effectors (Fig. 20.3); the β- and γ-subunits are noncovalently bound to the α-subunit. Gs is a stimulatory G protein that has a pivotal role in signal transduction in several endocrine organs, including the pituitary. The α-subunit of Gs (Gsα) is encoded by the *GNAS* gene. In the basal state, Gs exists in an inactive state, with guanosine diphosphate (GDP) bound to the guanine nucleotide-binding site of Gsα. On interaction with the ligand-bound cell surface receptor, GDP dissociates, and guanosine triphosphate (GTP) binds to Gsα, activating the G protein. The activation of Gsα results in the generation of cAMP, which is a potent mitogenic stimulus in several endocrine cells (e.g., pituitary somatotrophs and corticotrophs, thyroid follicular cells, parathyroid cells), promoting cellular proliferation and hormone synthesis and secretion. Normally, Gsα activation is transient because of an intrinsic GTPase activity in the α-subunit, which hydrolyzes GTP into GDP. *Approximately 40% of somatotroph cell adenomas bear GNAS mutations that abrogate the GTPase activity of Gsα, leading to constitutive activation of Gsα, persistent generation of cAMP, and unchecked cellular proliferation. GNAS* mutations also have been described in a minority of corticotroph adenomas; but are absent in thyrotroph, lactotroph, and gonadotroph adenomas, which arise from cells whose hypothalamic release hormones do not signal via cAMP-dependent pathways.

- *Approximately 5% of pituitary adenomas arise as a result of an inherited predisposition*. Four genes have been identified thus far as a cause of familial pituitary adenomas: *MEN1*, *CDKN1B*, *PRKAR1A*, and *AIP*. These genes regulate transcription and the cell cycle. Of note, somatic mutations of these four genes are rarely encountered in sporadic pituitary adenomas.
- *Molecular abnormalities associated with aggressive behavior include aberrations in cell cycle checkpoint genes*, such as overexpression of cyclin D1, mutations of *TP53,* and epigenetic silencing of the retinoblastoma gene *(RB)*. In addition, activating mutations of the *RAS* oncogene are observed in rare *pituitary carcinomas*. The functions of these genes were discussed in Chapter 6.

MORPHOLOGY

The usual pituitary adenoma is a well-circumscribed, soft lesion. Small tumors may be confined to the sella turcica, while larger lesions may compress the optic chiasm and adjacent structures (Fig. 20.4), erode the sella turcica and anterior clinoid processes, and extend locally into the cavernous and sphenoidal sinuses. In as many as 30% of cases, the adenomas are nonencapsulated and infiltrate adjacent bone, dura, and (uncommonly) brain. Foci of hemorrhage and/or necrosis are common in larger adenomas.

Pituitary adenomas are composed of relatively uniform, polygonal cells arrayed in sheets, cords, or papillae. Supporting connective tissue, or reticulin, is sparse. The nuclei of the neoplastic cells may be uniform or pleomorphic. **This cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from**

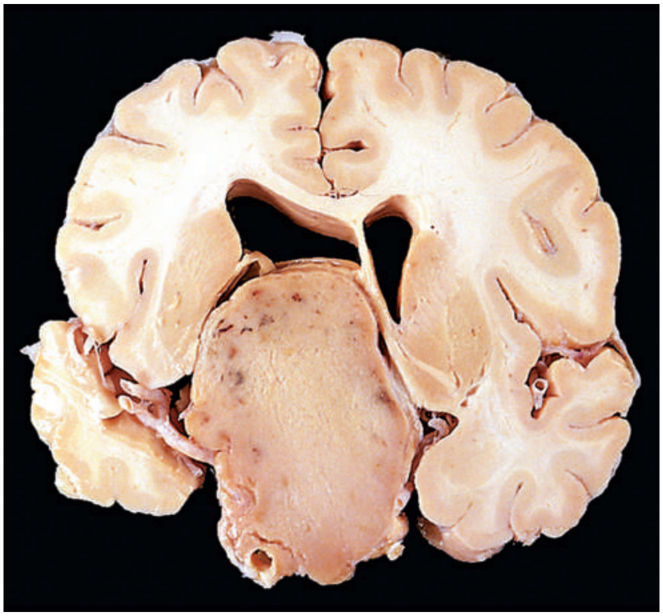

Fig. 20.4 Pituitary adenoma. This massive, nonfunctioning adenoma has grown far beyond the confines of the sella turcica and has distorted the overlying brain. Nonfunctioning adenomas tend to be larger at the time of diagnosis than those that secrete a hormone.

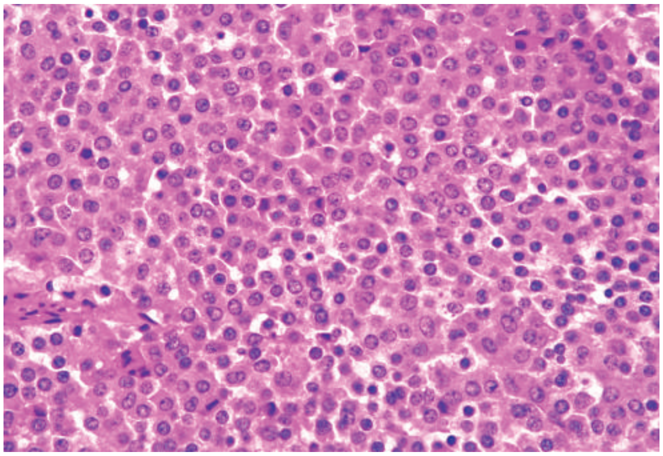

Fig. 20.5 Pituitary adenoma. The monomorphism of these cells contrasts with the admixture of cells seen in the normal anterior pituitary gland in Fig. 20.1. Note also the absence of the reticulin network.

non-neoplastic anterior pituitary parenchyma (Fig. 20.5). Mitotic activity usually is scanty. The cytoplasm of the constituent cells may be acidophilic, basophilic, or chromophobic, depending on the type and amount of secretory product within the cell, but it is fairly uniform throughout the neoplasm. The functional status of the adenoma cannot be predicted from its histologic appearance. Adenomas that harbor *TP53* mutations often demonstrate brisk mitotic activity and higher proliferation rates and are designated **atypical adenomas** because of their potential for aggressive behavior.

SUMMARY

PITUITARY ADENOMAS: GENERAL FEATURES

- The most common cause of hyperpituitarism is an anterior lobe pituitary adenoma.
- Pituitary adenomas can be macroadenomas (>1 cm in diameter) or microadenomas (<1 cm across), and on clinical evaluation, they can be functional or nonfunctioning.
- Macroadenomas may potentially lead to mass effects, including visual disturbances.
- Functioning adenomas are associated with distinct endocrine signs and symptoms.
- Mutation of the *GNAS* gene, which results in constitutive activation of a stimulatory G protein, is one of the more common genetic alterations.
- The two distinctive morphologic features of most adenomas are their cellular monomorphism and absence of a reticulin network.

Functioning Adenomas and Hyperpituatarism

Adenomas arising from different pituitary cells produce hormones characteristic of that cell type and cause clinical syndromes that reflect the activity of the hormones.

Lactotroph Adenomas

Prolactin-secreting lactotroph adenomas are the most frequent type of hyperfunctioning pituitary adenoma, accounting for about 30% of all clinically recognized cases. They range in size from microadenomas to large, expansile tumors associated with considerable mass effect. Prolactin is demonstrable within the cytoplasm of the neoplastic cells by immunohistochemical techniques. Prolactin secretion by lactotroph adenomas is highly efficient, such that even microadenomas can secrete sufficient hormone to induce systemic symptoms.

Hyperprolactinemia causes amenorrhea, galactorrhea, loss of libido, and infertility. Because manifestations of hyperprolactinemia (e.g., amenorrhea) are obvious in premenopausal women, prolactinomas are diagnosed at an earlier stage in women of reproductive age than in others with these tumors. By contrast, the effects of hyperprolactinemia are subtle in men and older women, in whom the tumor may reach a large size before coming to clinical attention. Hyperprolactinemia also is a feature of other conditions, including pregnancy, high-dose estrogen therapy, renal failure, hypothyroidism, hypothalamic lesions, and dopamine-inhibiting drugs (e.g., reserpine). In addition, any mass in the suprasellar compartment may disturb the normal inhibitory influence of hypothalamus on prolactin secretion, resulting in hyperprolactinemia—a mechanism known as the *stalk effect.* Thus, mild elevations of serum prolactin (<200 μg/L) in a patient with a pituitary adenoma do not necessarily indicate a prolactin-secreting neoplasm.

Somatotroph Adenomas

Growth hormone–secreting somatotroph adenomas are the second most common type of functioning pituitary adenoma, and cause gigantism in children or acromegaly in adults. Because the clinical manifestations of excess growth hormone may be subtle, somatotroph cell adenomas may be quite large by the time they come to clinical attention. On microscopic examination, growth hormone–producing adenomas are composed of densely or sparsely granulated cells, and immunohistochemical staining demonstrates growth hormone within the cytoplasm of the neoplastic cells. Small amounts of immunoreactive prolactin often are present as well.

Persistent growth hormone excess stimulates the hepatic secretion of insulin-like growth factor 1 (IGF1), which acts in conjunction with growth hormone to induce overgrowth of bones and muscle. If a growth hormone–secreting adenoma develops before the epiphyses close, as is the case in prepubertal children, excessive levels of growth hormone and IGF1 result in *gigantism.* This condition is characterized by a generalized increase in body size, with disproportionately long arms and legs. If elevated levels of growth hormone and IGF1 persist or develop after closure of the epiphyses, affected individuals develop *acromegaly,* in which growth is most conspicuous in soft tissues, skin, viscera, and the bones of the face, hands, and feet. Enlargement of the jaw results in its protrusion (*prognathism*), broadening of the lower face, and separation of the teeth. The hands and feet are enlarged, and the fingers are broad and sausage-like. In most instances gigantism is accompanied by evidence of acromegaly. These changes may develop slowly over decades before being recognized, hence the adenoma may be quite large before it is detected.

Persistent growth hormone excess also is associated with metabolic abnormalities, the most important of

which is diabetes mellitus. This arises because of growth hormone–induced peripheral insulin resistance, which "blunts" the body's response to elevated glucose levels (see "Diabetes Mellitus", later). Failure to suppress growth hormone production in response to an oral load of glucose is one of the most sensitive tests for acromegaly. Other manifestations of growth hormone excess include gonadal dysfunction, generalized muscle weakness, hypertension, arthritis, congestive heart failure, and an increased risk for gastrointestinal cancers.

Corticotroph Adenomas

Excess production of ACTH by functioning corticotroph adenomas leads to adrenal hypersecretion of cortisol and the development of hypercortisolism (also known as *Cushing syndrome*). Cushing syndrome (discussed later with diseases of the adrenal gland) may be caused by other conditions as well. When the hypercortisolism is caused by excessive production of ACTH by the pituitary, it is called *Cushing disease* after the neurosurgeon Harvey Cushing who first described the disorder.

Most corticotroph adenomas are small (microadenomas) at the time of diagnosis. These adenomas stain positively with periodic acid–Schiff (PAS) stains, as a result of the accumulation of glycosylated ACTH protein. ACTH also can be specifically detected by immunohistochemical methods. Large, clinically aggressive corticotroph cell adenomas may develop after surgical removal of the adrenal glands for treatment of Cushing syndrome. In most instances this condition, known as *Nelson syndrome,* results from loss of the inhibitory effect of adrenal corticosteroids on a preexisting corticotroph microadenoma. Because the adrenals are absent in individuals with Nelson syndrome, hypercortisolism does not develop. Instead, patients present with the mass effects of the pituitary tumor. Patients with Cushing syndrome often have hyperpigmented skin because of increased production of melanocyte stimulating hormone (MSH), which is derived from the same precursor as ACTH so its synthesis accompanies that of ACTH.

Other Anterior Pituitary Neoplasms

Other pituitary adenomas are associated with hormonal disorders not considered part of hyperpituitarism, or are nonfunctional and do not produce hormonal disturbances.

- *Gonadotroph adenomas* are so named because they produce hormones *(luteinizing hormone [LH]* and *follicle-stimulating hormone [FSH])* that act on reproductive organs (gonads). These adenomas can be difficult to recognize because they secrete hormones inefficiently and variably and the secretory products usually do not cause a recognizable clinical syndrome. They are typically detected when the tumors become large enough to cause signs and symptoms related to local mass effects, such as impaired vision, headaches, diplopia, or pituitary apoplexy. The neoplastic cells usually demonstrate immunoreactivity for the common gonadotropin α-subunit and the specific β-FSH and β-LH subunits; FSH usually is the predominant secreted hormone.
- *Thyrotroph (thyroid-stimulating hormone [TSH]–producing) adenomas* account for about 1% of all pituitary adenomas and constitute a rare cause of hyperthyroidism.
- *Nonfunctioning pituitary adenomas* are a heterogeneous group that constitutes 25% to 30% of all pituitary tumors. Not surprisingly, the typical presentation is characterized by mass effects. These lesions also may impinge on the residual anterior pituitary and produce hypopituitarism, which may appear slowly due to gradual enlargement of the adenoma or abruptly because of acute intratumoral hemorrhage (pituitary apoplexy).
- *Pituitary carcinomas are exceedingly rare.* In addition to local extension beyond the sella turcica, these tumors virtually always metastasize to distant sites.

SUMMARY

HYPERPITUITARISM-ASSOCIATED ADENOMAS

- *Prolactinomas:* amenorrhea, galactorrhea, loss of libido, and infertility
- *Growth hormone (somatotroph cell) adenomas:* gigantism (children), acromegaly (adults), and impaired glucose tolerance and diabetes mellitus
- *Corticotroph cell adenomas:* Cushing syndrome, hyperpigmentation
- All pituitary adenomas, particularly nonfunctioning adenomas, may be associated with mass effects and hypopituitarism.

HYPOPITUITARISM

Clinically significant hypopituitarism may occur with loss or absence of 75% or more of the anterior pituitary parenchyma. It may be ***congenital*** (exceedingly rare) or result from a wide range of ***acquired*** intrinsic abnormalities of the pituitary. Less frequently, disorders that interfere with the delivery of pituitary hormone–releasing factors from the hypothalamus, such as hypothalamic tumors, cause hypofunction of the anterior pituitary. ***Hypopituitarism accompanied by evidence of posterior pituitary dysfunction in the form of diabetes insipidus*** (discussed later) ***is almost always of hypothalamic origin.*** Most cases of anterior pituitary hypofunction are caused by the following:

- *Tumors and other mass lesions* (especially nonfunctioning pituitary adenomas)
- *Ischemic necrosis of the anterior pituitary,* called *Sheehan syndrome,* or postpartum necrosis of the anterior pituitary, is the most common form of clinically significant necrosis of the anterior pituitary. During pregnancy, the anterior pituitary enlarges, mainly because of an increase in the size and number of prolactin-secreting cells. This hyperplasia is not accompanied by an increase in blood supply from the low-pressure hypophyseal portal venous system. The enlarged gland is thus vulnerable to ischemic injury, especially in women who experience hypotension during the peripartal period. By contrast, the posterior pituitary receives its blood directly from arterial branches and is much less susceptible to ischemic injury. Pituitary necrosis also may occur in the setting of disseminated intravascular coagulation, sickle cell anemia, elevated intracranial pressure, traumatic injury, and shock of any origin.
- *Iatrogenic causes* include ablation of the pituitary by surgery or radiation

- Other, less common causes of anterior pituitary hypofunction include inflammatory lesions such as sarcoidosis or tuberculosis, trauma, and metastatic tumors involving the pituitary

The clinical manifestations of anterior pituitary hypofunction depend on the specific hormones that are lacking. In children, growth failure (*pituitary dwarfism*) may occur as a result of growth hormone deficiency. Gonadotropin or gonadotropin-releasing hormone (GnRH) deficiency leads to amenorrhea and infertility in women and to decreased libido, impotence, and loss of pubic and axillary hair in men. TSH and ACTH deficiencies result in hypothyroidism and hypoadrenalism, respectively (discussed later). Prolactin deficiency results in failure of postpartum lactation. The anterior pituitary also is a rich source of MSH, synthesized from the same precursor molecule that produces ACTH; therefore, one of the manifestations of hypopituitarism is pallor of skin from loss of stimulatory effects of MSH on melanocytes.

POSTERIOR PITUITARY SYNDROMES

The posterior pituitary, or neurohypophysis, is composed of modified glial cells (termed *pituicytes*) and axonal processes extending from nerve cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus. The hypothalamic neurons produce two peptides: anti-diuretic hormone (ADH) and oxytocin. They are stored in axon terminals in the neurohypophysis and released into the circulation in response to appropriate stimuli. ADH is a nonapeptide hormone synthesized predominantly in the supraoptic nucleus. In response to several different stimuli, including increased plasma osmotic pressure, left atrial distention, exercise, and certain emotional states, ADH is released from axon terminals in the neurohypophysis into the general circulation. The hormone acts on the collecting tubules of the kidney to promote the resorption of free water. Oxytocin stimulates the contraction of smooth muscle in the pregnant uterus and of muscle surrounding the lactiferous ducts of the mammary glands. Impairment of oxytocin synthesis and release has not been associated with significant clinical abnormalities.

The clinically important posterior pituitary syndromes involve ADH under- or overproduction.

- **ADH deficiency causes *diabetes insipidus*, a condition characterized by excessive urination (polyuria) due to an inability of the kidney to resorb water properly from the urine.** Diabetes insipidus can result from several causes, including head trauma, neoplasms, and inflammatory disorders of the hypothalamus and pituitary, and from surgical procedures involving the hypothalamus or pituitary. The condition sometimes arises spontaneously *(idiopathic)*. Diabetes insipidus from ADH deficiency is designated *central,* to differentiate it from *nephrogenic* diabetes insipidus, which is caused by renal tubular unresponsiveness to circulating ADH. The clinical manifestations of both diseases are similar and include the excretion of large volumes of dilute urine with an inappropriately low specific gravity. Serum sodium and osmolality are increased as a result of excessive renal loss of free water, resulting in thirst and polydipsia. Patients who can drink water generally compensate for urinary losses, but patients who are obtunded, bedridden, or otherwise limited in their ability to obtain water may develop life-threatening dehydration.
- **The syndrome of inappropriate ADH (SIADH) secretion is typically associated with ADH excess, which causes resorption of excessive amounts of free water, resulting in hyponatremia**. Causes of SIADH include the secretion of ectopic ADH by malignant neoplasms (particularly small-cell carcinomas of the lung), non-neoplastic diseases of the lung, and local injury to the hypothalamus or neurohypophysis. The clinical manifestations of SIADH are dominated by hyponatremia, cerebral edema, and resultant neurologic dysfunction. Although total body water is increased, blood volume remains normal, and peripheral edema does not develop.

Thyroid

The thyroid gland consists of two bulky lateral lobes connected by a relatively thin isthmus, usually located below and anterior to the larynx. The thyroid gland develops embryologically from an evagination of the developing pharyngeal epithelium that descends from the foramen cecum at the base of the tongue to its normal position in the anterior neck. This pattern of descent explains the occasional presence of ectopic thyroid tissue, most commonly located at the base of the tongue (lingual thyroid) or at other sites abnormally high in the neck.

The thyroid is divided into lobules, each composed of about 20 to 40 evenly dispersed follicles. The follicles are lined by cuboidal to low columnar epithelium, which is filled with thyroglobulin, the iodinated precursor protein of active thyroid hormone. In response to trophic factors from the hypothalamus, TSH (also called *thyrotropin*) is released by thyrotrophs in the anterior pituitary into the circulation. The binding of TSH to its receptor on thyroid follicular epithelial cells results in activation and conformational change in the receptor, allowing it to associate with a stimulatory G-protein (Fig. 20.6). As illustrated in Fig. 20.3, activation of stimulatory G-protein results in an increase in intracellular cAMP levels, which stimulates thyroid hormone synthesis and release. Thyroid follicular epithelial cells convert thyroglobulin into *thyroxine* (T_4) and lesser amounts of *triiodothyronine* (T_3). T_4 and T_3 are released into the systemic circulation, where most of these peptides are bound to circulating plasma proteins, such as T_4-binding globulin, for transport to peripheral tissues. The binding proteins maintain the serum unbound (free) T_3 and T_4 concentrations within narrow limits while ensuring that the hormones are readily available to the tissues.

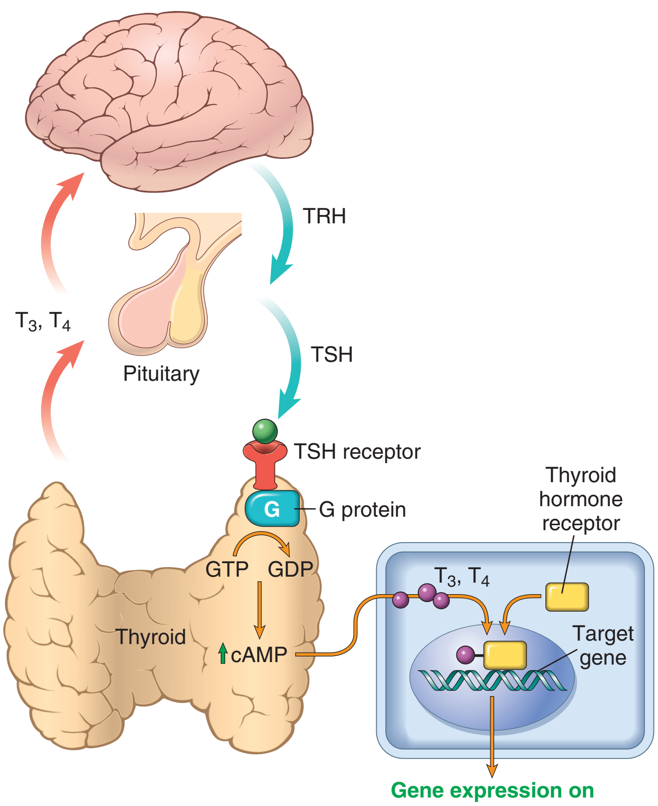

Fig. 20.6 Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones (T_3 and T_4) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary gland. Decreased levels of T_3 and T_4 stimulate the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary, causing T_3 and T_4 levels to rise. Elevated T_3 and T_4 levels, in turn, suppress the secretion of both TRH and TSH. This relationship is termed a *negative-feedback loop.* TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G proteins, release of cyclic AMP (cAMP), and cAMP-mediated synthesis and release of thyroid hormones (i.e., T_3 and T_4). In the periphery, T_3 and T_4 interact with the thyroid hormone receptor (TR) and form a complex that translocates to the nucleus and binds to so-called "thyroid response elements" (TREs) on target genes, thereby initiating transcription.

In the periphery, the majority of free T_4 is deiodinated to T_3; the latter binds to thyroid hormone nuclear receptors in target cells with 10-fold greater affinity than T_4 and has proportionately greater activity. Binding of thyroid hormone to its nuclear thyroid hormone receptor (TR) creates a hormone-receptor complex that regulates the transcription of a subset of cellular genes. This produces diverse cellular effects, including increased carbohydrate and lipid catabolism and protein synthesis in a wide range of cell types. The net result of these processes is an increase in the basal metabolic rate.

Clinical recognition of diseases of the thyroid is important, because most are amenable to medical or surgical management. Such diseases include conditions associated with excessive release of thyroid hormones (hyperthyroidism), thyroid hormone deficiency (hypothyroidism), and mass lesions of the thyroid. Considered next are the clinical consequences of disturbed thyroid function, followed by an overview of the disorders that generate these problems.

HYPERTHYROIDISM

Thyrotoxicosis is a hypermetabolic state caused by elevated circulating levels of free T_3 and T_4. Because it is caused most commonly by hyperfunction of the thyroid gland, thyrotoxicosis often is referred to as *hyperthyroidism*. In certain conditions, however, the oversupply either is related to excessive release of preformed thyroid hormone (e.g., in thyroiditis) or comes from an extrathyroidal source, rather than a hyperfunctioning gland (Table 20.2). *Thus, strictly speaking, hyperthyroidism is only one (albeit the most common) category of thyrotoxicosis.* Despite this clear distinction, the following discussion adheres to the common practice of using the terms *thyrotoxicosis* and *hyperthyroidism* interchangeably.

The three most common causes of thyrotoxicosis are associated with hyperfunction of the gland:

- Diffuse hyperplasia of the thyroid associated with Graves disease, a form of autoimmune thyroid disease (accounts for 85% of cases)
- Hyperfunctioning ("toxic") multinodular goiter
- Hyperfunctional ("toxic") adenoma of the thyroid

The clinical manifestations of thyrotoxicosis are protean and are mainly attributable to the *hypermetabolic state* induced by thyroid hormone and *overactivity of the sympathetic nervous system:*

- *Constitutional symptoms:* The skin of thyrotoxic individuals tends to be soft, warm, and flushed because of increased blood flow and peripheral vasodilation to increase heat loss; heat intolerance and excessive sweating are common. Increased sympathetic activity and hypermetabolism result in weight loss despite increased appetite.
- *Gastrointestinal:* Stimulation of the gut results in rapid transit time (hypermotility), which can cause fat malabsorption and steatorrhea.
- *Cardiac:* Palpitations and tachycardia are common due to both increased cardiac contractility and increased

Table 20.2 Causes of Thyrotoxicosis

Associated With Hyperthyroidism
Primary
Diffuse toxic hyperplasia (Graves disease)
Hyperfunctioning ("toxic") multinodular goiter
Hyperfunctioning ("toxic") adenoma
Iodine-induced hyperthyroidism
Secondary
TSH-secreting pituitary adenoma (rare)*
Not Associated With Hyperthyroidism
Granulomatous (de Quervain) thyroiditis *(painful)*
Subacute lymphocytic thyroiditis *(painless)*
Struma ovarii (ovarian teratoma with thyroid)
Factitious thyrotoxicosis (exogenous thyroxine intake)

TSH, Thyroid-stimulating hormone.
*Associated with increased TSH; all other causes of thyrotoxicosis associated with decreased TSH.

Fig. 20.7 A patient with hyperthyroidism. A wide-eyed, staring gaze, caused by overactivity of the sympathetic nervous system, is one of the classic features of this disorder. In Graves disease, one of the most important causes of hyperthyroidism, accumulation of loose connective tissue behind the orbits also adds to the protuberant appearance of the eyes.

peripheral oxygen requirements. Older adult patients with preexisting heart disease may develop congestive heart failure.

- *Neuromuscular:* Patients frequently experience nervousness, tremor, and irritability due to the sympathetic overactivity. Nearly 50% develop proximal muscle weakness *(thyroid myopathy).*
- *Ocular changes* often call attention to hyperthyroidism. A wide, staring gaze and lid lag are present because of sympathetic overstimulation of the superior tarsal muscle (*Müller's muscle*), which functions alongside the levator palpebrae superioris muscle to raise the upper eyelid (Fig. 20.7). However, fullblown *thyroid ophthalmopathy* associated with proptosis is a feature seen only in Graves disease (discussed later).
- *Thyroid storm* designates the abrupt onset of severe hyperthyroidism. It occurs most often in patients with Graves disease and probably results from an acute elevation in catecholamine levels, as might be encountered during infection, surgery, cessation of anti-thyroid medication, or any form of stress. Thyroid storm is a medical emergency, as a significant number of untreated patients die of cardiac arrhythmias.
- *Apathetic hyperthyroidism* refers to thyrotoxicosis occurring in older adults, in whom the typical features of thyroid hormone excess often are blunted. The underlying thyroid disease is usually detected during laboratory workup for unexplained weight loss or worsening cardiovascular disease.

The diagnosis of hyperthyroidism is based on clinical features and laboratory data. *The measurement of serum TSH is the most useful single screening test for hyperthyroidism,* because TSH levels are decreased even at the earliest stages, when the disease may still be subclinical. In rare cases of pituitary- or hypothalamus-associated (secondary) hyperthyroidism, TSH levels are either normal or raised. A low TSH value usually is associated with increased levels of free T_4. In the occasional patient, hyperthyroidism results predominantly from increased circulating levels of T_3 (T_3 toxicosis). In such cases, free T_4 levels may be decreased, and direct measurement of serum T_3 may be useful. Once the diagnosis of thyrotoxicosis has been confirmed by a combination of TSH and free thyroid hormone assays, measurement of radioactive iodine uptake by the thyroid gland can be valuable in determining the etiology. For example, such scans may show diffusely increased uptake in Graves disease, increased uptake in a solitary nodule in toxic adenoma, or decreased uptake in thyroiditis.

HYPOTHYROIDISM

Hypothyroidism is caused by structural or functional derangements that interfere with thyroid hormone production. This disorder may be divided into primary and secondary categories, depending on whether it arises from an intrinsic abnormality in the thyroid or from hypothalamic or pituitary disease (Table 20.3). Primary hypothyroidism can be secondary to *congenital, autoimmune,* or *iatrogenic* causes.

- *Genetic defects* that perturb thyroid development (thyroid dysgenesis) or the synthesis of thyroid hormone (dyshormonogenetic goiter) are rare overall but the most common cause of congenital hypothyroidism in the U.S.
- *Endemic deficiency of dietary iodine* is typically manifested by hyothryoidism early in childhood and has been also called congenital, but is not caused by genetic defects. It is a common cause of hypothyroidism in infants and children worldwide.
- *Autoimmune thyroid disease* is a common cause of hypothyroidism in regions of the world where iodine is supplemented in dietary salt products. The vast majority of cases of autoimmune hypothyroidism are due to Hashimoto thyroiditis (discussed later).
- *Iatrogenic hypothyroidism* can be caused by either surgical or radiation-induced ablation of thyroid parenchyma, or as an unintended adverse effect of certain drugs.

The clinical manifestations of hypothyroidism include cretinism and myxedema.

- *Cretinism* refers to hypothyroidism developing in infancy or early childhood. This disorder formerly was

Table 20.3 Causes of Hypothyroidism

Primary
Postablative
Surgery, radioiodine therapy, or external irradiation
Autoimmune hypothyroidism
Hashimoto thyroiditis*
Iodine deficiency*
Drugs (lithium, iodides, p-aminosalicylic acid)*
Congenital biosynthetic defect (dyshormonogenetic goiter) (rare)*
Genetic defects in thyroid development (rare)
Thyroid hormone resistance syndrome (rare)
Secondary (Central)
Pituitary failure (rare)
Hypothalamic failure (rare)

*Associated with enlargement of thyroid ("goitrous hypothyroidism"). Hashimoto thyroiditis and postablative hypothyroidism account for the majority of cases of hypothyroidism in developed countries.

fairly common in areas of the world where dietary iodine deficiency is endemic, including mountainous areas such as the Himalayas and the Andes *(endemic cretinism).* It is now much less frequent because of the widespread supplementation of salt with iodine. By contrast, enzyme defects that interfere with thyroid hormone synthesis are a cause of *sporadic cretinism.* Clinical features of cretinism include impaired development of the skeletal system and central nervous system, severe mental retardation, short stature, coarse facial features, a protruding tongue, and umbilical hernia. The severity of the mental impairment in cretinism seems to be influenced by the time of onset of the deficient state in utero. Normally, maternal hormones that are critical to fetal brain development, including T_3 and T_4, cross the placenta. If maternal thyroid deficiency is present before the development of the fetal thyroid gland, mental retardation is severe. By contrast, reduction in maternal thyroid hormones later in pregnancy, after the fetal thyroid has developed, allows normal brain development.

- Hypothyroidism in older children and adults results in a condition known as *myxedema.* The initial symptoms include generalized fatigue, apathy, and mental sluggishness, which may mimic depression. Decreased sympathetic activity results in constipation and decreased sweating. The skin is cool and pale because of decreased blood flow. Reduced cardiac output contributes to shortness of breath and decreased exercise capacity, two frequent complaints. Thyroid hormones regulate the transcription of several sarcolemmal genes, such as calcium ATPases, whose encoded products are critical in maintaining efficient cardiac output. In addition, hypothyroidism promotes an atherogenic lipid profile—an increase in total cholesterol and low-density lipoprotein (LDL) levels—that may contribute to the adverse cardiovascular mortality rates in this disease. Histologically, there is an accumulation of matrix substances, such as glycosaminoglycans and hyaluronic acid, in skin, subcutaneous tissue, and viscera. This results in nonpitting edema, broadening and coarsening of facial features, enlargement of the tongue, and deepening of the voice.

The diagnosis of hypothyroidism is based on laboratory evaluation. As in the case of hyperthyroidism, *measurement of serum TSH is the most sensitive screening test.* The serum TSH concentration is increased in primary hypothyroidism because of a loss of feedback inhibition of thyrotropin-releasing hormone (TRH) and TSH production by the hypothalamus and pituitary, respectively. The TSH concentration is not increased in individuals with hypothyroidism caused by primary hypothalamic or pituitary disease. Serum T_4 is decreased in patients with hypothyroidism of any origin.

AUTOIMMUNE THYROID DISEASE

Autoimmunity is the underlying cause of a variety of thyroid diseases, which are collectively referred to as *autoimmune thyroid disease (AITD)*. These disorders include thyroiditis, and antibody-mediated disturbances in thyroid function that are not necessarily associated with inflammation (exemplified by Graves disease). We discuss first the various forms of thyroiditis.

Thyroiditis encompasses a diverse group of disorders characterized by some form of thyroid inflammation. This discussion focuses on the three most common and clinically significant subtypes: (1) Hashimoto thyroiditis, (2) granulomatous (de Quervain) thyroiditis, and (3) subacute lymphocytic thyroiditis.

Chronic Lymphocytic (Hashimoto) Thyroiditis

Hashimoto thyroiditis is the most common cause of hypothyroidism in areas of the world where iodine levels are sufficient. It is characterized by gradual thyroid failure secondary to autoimmune destruction of the thyroid gland. It is most prevalent between 45 and 65 years of age and is more common in women with a female to male ratio of 10:1 to 20:1. Although it is primarily a disease of older women, it can occur at any age, including childhood.

Pathogenesis

Hashimoto thyroiditis is an autoimmune disease caused by an immune response to thyroid autoantigens (Chapter 5). Circulating autoantibodies against thyroid antigens are present in the vast majority of patients. The immune response leads to progressive depletion of thyroid epithelial cells associated with lymphocytic infiltrates and fibrosis. The inciting events leading to the autoimmune response have not been fully elucidated, but multiple immunologic mechanisms that may contribute to thyroid cell damage have been identified (Fig. 20.8), including the following:

- CD8+ cytotoxic T-cell–mediated killing of thyroid epithelial cells.
- Cytokine-mediated cell death. T-cell activation leads to the production of inflammatory cytokines such as interferon-γ in the thyroid gland, with resultant recruitment and activation of macrophages and damage to follicles.
- Binding of anti-thyroid antibodies (anti-thyroglobulin, and anti-thyroid peroxidase antibodies), followed by antibody-dependent cell–mediated cytotoxicity (Chapter 5).

The disease appears to have a significant genetic component, based on a concordance rate of about 40% in monozygotic twins and the presence of anti-thyroid antibodies in approximately 50% of asymptomatic siblings of affected patients. Increased susceptibility to Hashimoto thyroiditis is associated with polymorphisms in immune regulation–associated genes, the most significant of which is the cytotoxic T lymphocyte–associated antigen-4 gene *(CTLA4)*, which codes for a negative regulator of T-cell responses (Chapter 5).

MORPHOLOGY

The thyroid usually is diffusely and symmetrically enlarged. Microscopic examination reveals widespread infiltration of the parenchyma by a **mononuclear inflammatory infiltrate** containing small lymphocytes, plasma cells, and well-developed

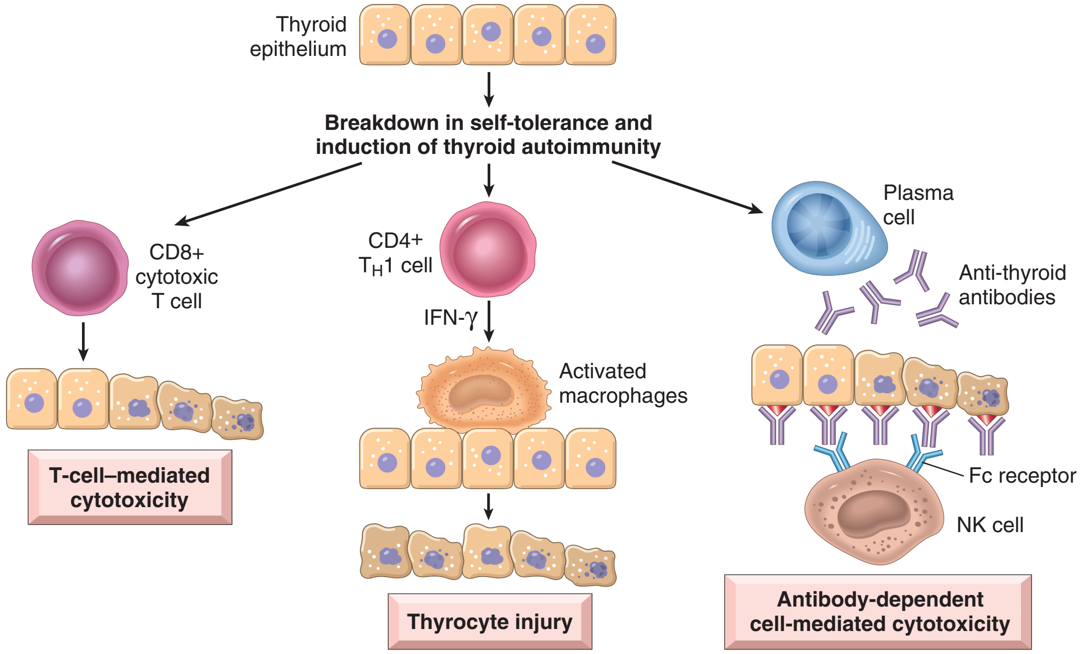

Fig. 20.8 Pathogenesis of Hashimoto thyroiditis. Breakdown of immune tolerance to thyroid autoantigens results in progressive autoimmune destruction of thyrocytes by infiltrating cytotoxic T cells, locally released cytokines, or antibody-dependent cytotoxicity.

germinal centers (Fig. 20.9). The thyroid follicles are atrophic and are lined in many areas by epithelial cells distinguished by the presence of abundant eosinophilic, granular cytoplasm, termed **Hürthle, or oxyphil, cells.** This is a metaplastic response of the normal low cuboidal follicular epithelium to ongoing injury; on ultrastructural examination, the Hürthle cells are characterized by numerous prominent mitochondria. Interstitial connective tissue is increased and may be abundant. Less commonly, the thyroid is small and atrophic as a result of more extensive fibrosis **(fibrosing variant).**

Clinical Features

Hashimoto thyroiditis comes to clinical attention as *painless enlargement of the thyroid, usually associated with some degree of hypothyroidism,* often in a middle-age woman.

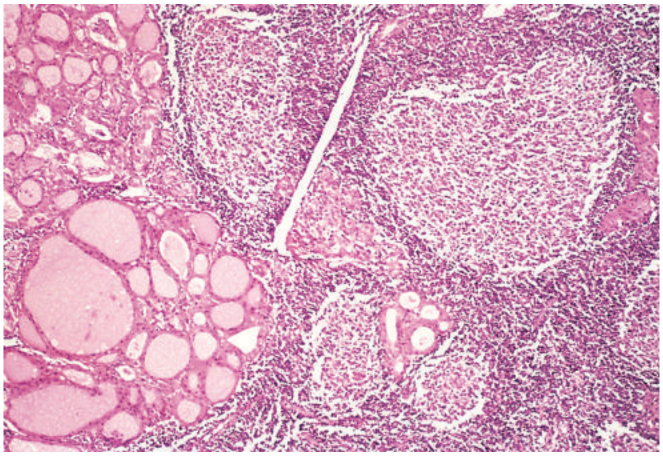

Fig. 20.9 Hashimoto thyroiditis. The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centers. Residual thyroid follicles lined by deeply eosinophilic Hürthle cells also are seen.

The enlargement of the gland usually is symmetric and diffuse, but in some cases it may be sufficiently localized to raise suspicion for neoplasm. In the usual clinical course, hypothyroidism develops gradually. In some cases, however, it may be preceded by transient thyrotoxicosis caused by disruption of thyroid follicles, with secondary release of thyroid hormones *(hashitoxicosis).* During this phase, free T_4 and T_3 concentrations are elevated, TSH is diminished, and radioactive iodine uptake is decreased. As hypothyroidism supervenes, T_4 and T_3 levels progressively fall, accompanied by a compensatory increase in TSH. Patients with Hashimoto thyroiditis often have *other autoimmune diseases* and are at *increased risk for the development of B-cell non-Hodgkin lymphomas* (Chapter 12), which typically arise within the thyroid gland. The relationship between Hashimoto disease and thyroid epithelial cancers remains controversial, with some morphologic and molecular studies suggesting a predisposition to papillary carcinomas.

Subacute Granulomatous (de Quervain) Thyroiditis

Subacute granulomatous thyroiditis, also known as *de Quervain thyroiditis,* is much less common than Hashimoto disease. De Quervain thyroiditis is most common between 30 and 50 years of age and, like other forms of thyroiditis, occurs more frequently in women than in men. Subacute thyroiditis is believed to be caused by a viral infection or an inflammatory process triggered by viral infections, and not by an autoimmune process. A majority of patients have a history of an upper-respiratory infection shortly before the onset of thyroiditis. Unlike in autoimmune thyroid disease, the immune response in subacute granulomatous thyroiditis is not self-perpetuating, so the process spontaneously remits.

MORPHOLOGY

The gland is firm, with an intact capsule, and may be unilaterally or bilaterally enlarged. Histologic examination reveals disruption of thyroid follicles, extravasation of colloid, and infiltrating neutrophils, which are replaced over time by lymphocytes, plasma cells, and macrophages. The extravasated colloid provokes an exuberant granulomatous reaction with giant cells, some containing fragments of colloid. Healing occurs by resolution of inflammation and fibrosis.

Clinical Features

The onset of this form of thyroiditis often is acute. It is characterized by *neck pain* (particularly with swallowing), fever, malaise, and variable enlargement of the thyroid. Transient hyperthyroidism may occur, as in other cases of thyroiditis, as a result of disruption of thyroid follicles and release of excessive thyroid hormone. The leukocyte count and erythrocyte sedimentation rates are increased. With progression of the gland destruction, a transient hypothyroid phase may ensue. The condition typically is self-limited, with most patients returning to a euthyroid state within 6 to 8 weeks.

Subacute Lymphocytic Thyroiditis

Subacute lymphocytic thyroiditis also is known as *silent* or *painless* thyroiditis; in a subset of patients, the onset follows pregnancy *(postpartum thyroiditis)*. This disease is most likely autoimmune in etiology, as circulating antithyroid antibodies are found in a majority of patients. It mostly affects middle-aged women, who present with a painless neck mass or features of thyroid hormone excess. The initial phase of thyrotoxicosis (which is likely to be secondary to thyroid tissue damage) is followed by return to a euthyroid state within a few months. In a minority of affected individuals, the condition eventually progresses to hypothyroidism. Except for possible mild symmetric enlargement, the thyroid appears normal on gross inspection. The histologic features consist of lymphocytic infiltration and hyperplastic germinal centers within the thyroid parenchyma.

Other Forms of Thyroiditis

Riedel thyroiditis, a rare disorder that is a manifestation of IgG4-related disease (Chapter 5), is characterized by extensive fibrosis involving the thyroid and contiguous neck structures. Clinical evaluation demonstrates a hard and fixed thyroid mass, simulating a thyroid neoplasm. It may be associated with idiopathic fibrosis in other sites in the body, such as the retroperitoneum.

SUMMARY

THYROIDITIS

- Chronic lymphocytic (Hashimoto) thyroiditis is the most common cause of hypothyroidism in regions where dietary iodine levels are sufficient.
- Hashimoto thyroiditis is an autoimmune disease characterized by progressive destruction of thyroid parenchyma, Hürthle cell change, and mononuclear (lymphoplasmacytic) infiltrates, with or without extensive fibrosis.
- Multiple autoimmune mechanisms account for thyroid injury in Hashimoto disease, including cytotoxicity mediated by CD8+ T cells, cytokines (IFN-γ), and anti-thyroid antibodies.
- Subacute granulomatous (de Quervain) thyroiditis is a self-limited disease, probably secondary to a viral infection, and is characterized by pain and the presence of a granulomatous inflammation in the thyroid.
- Subacute lymphocytic thyroiditis is a self-limited disease that often occurs after a pregnancy (postpartum thyroiditis), typically is painless, and is characterized by lymphocytic inflammation in the thyroid.

Graves Disease

In 1835, Robert Graves reported on his observations of a disease characterized by "violent and long continued palpitations in females" associated with enlargement of the thyroid gland. **Graves disease is the most common cause of endogenous hyperthyroidism.** It is characterized by a triad of manifestations:

- *Thyrotoxicosis,* caused by a diffusely enlarged, hyperfunctional thyroid
- An infiltrative *ophthalmopathy* with resultant exophthalmos, noted in as many as 40% of patients
- A localized, infiltrative *dermopathy* (sometimes designated *pretibial myxedema*), seen in a minority of cases

Graves disease has a peak incidence between 20 and 40 years of age, with women being affected up to seven times more commonly than men. This is a common disorder, estimated to affect 1.5% to 2% of women in the United States. Genetic factors are important in Graves disease; the incidence is increased in relatives of affected patients, and the concordance rate in monozygotic twins is as high as 60%. As with other autoimmune disorders, a genetic susceptibility to Graves disease is associated with the presence of certain human leukocyte antigen (HLA) haplotypes, specifically HLA-DR3, and polymorphisms in genes whose products regulate T-cell responses, including the inhibitory T-cell receptor CTLA-4 and the tyrosine phosphatase PTPN22.

Pathogenesis

Many manifestations of Graves disease are caused by autoantibodies against the TSH receptor that bind to, and stimulate, thyroid follicular cells independent of endogenous trophic hormones. Multiple autoantibodies are produced in Graves disease, including the following:

- *Thyroid-stimulating immunoglobulin (TSI).* This IgG antibody binds to the TSH receptor and mimics the action of TSH, stimulating adenyl cyclase, with resultant increased release of thyroid hormones. Almost all individuals with Graves disease have detectable amounts of this autoantibody, which is relatively specific for Graves disease.

- *Thyroid growth-stimulating immunoglobulins.* Also directed against the TSH receptor, these antibodies have been implicated in the proliferation of thyroid follicular epithelium.
- *TSH-binding inhibitor immunoglobulins.* These anti-TSH receptor antibodies prevent TSH from binding to its receptor on thyroid epithelial cells and in so doing may inhibit thyroid cell function. The coexistence of stimulating and inhibiting immunoglobulins in the serum of the same patient is not unusual, and may explain why some patients develop episodes of hypothyroidism.

A T-cell–mediated autoimmune phenomenon also is involved in the development of the *infiltrative ophthalmopathy* characteristic of Graves disease. In Graves ophthalmopathy, the volume of the retroorbital connective tissues and extraocular muscles is increased due to (1) marked infiltration of the retroorbital space by mononuclear cells, predominantly T cells; (2) inflammatory edema and swelling of extraocular muscles; (3) accumulation of extracellular matrix components, specifically hydrophilic glycosaminoglycans such as hyaluronic acid and chondroitin sulfate; and (4) increased numbers of adipocytes (fatty infiltration). These changes displace the eyeball forward, potentially interfering with the function of the extraocular muscles.

Autoimmune thyroid diseases thus span a continuum in which Graves disease, characterized by hyperfunction of the thyroid, lies at one extreme and Hashimoto disease, manifesting as hypothyroidism, occupies the other end. Sometimes hyperthyroidism may supervene on preexisting Hashimoto thyroiditis, while at other times individuals with Graves disease may spontaneously develop thyroid hypofunction; occasionally, Hashimoto thyroiditis and Graves disease may coexist within an affected kindred. Not surprisingly, there is also an element of histologic overlap between the autoimmune thyroid disorders (most characteristically, prominent intrathyroidal lymphoid cell infiltrates with germinal center formation). In both disorders, the frequency of other autoimmune diseases, such as systemic lupus erythematosus, pernicious anemia, type 1 diabetes, and Addison disease, is increased.

MORPHOLOGY

In the typical case of Graves disease, the thyroid gland is enlarged (usually symmetrically) due to **diffuse hypertrophy and hyperplasia** of thyroid follicular epithelial cells. The gland is usually smooth and soft, and its capsule is intact. On microscopic examination, the follicular epithelial cells in untreated cases are tall, columnar, and more crowded than usual. This crowding often results in the formation of small papillae, which project into the follicular lumen (Fig. 20.10). Such papillae lack fibrovascular cores, in contrast with those of papillary carcinoma. The colloid within the follicular lumen is pale, with scalloped margins. Lymphoid infiltrates, consisting predominantly of T cells, with fewer B cells and mature plasma cells, are present throughout the interstitium; germinal centers are common.

Changes in extrathyroidal tissues include generalized lymphoid hyperplasia. In individuals with ophthalmopathy, the tissues of the orbit are edematous because of the presence of hydrophilic glycosaminoglycans. In addition, there is infiltration by lymphocytes, mostly T cells. Orbital muscles initially are edematous but may undergo fibrosis late in the course of the disease. The dermopathy, if present, is characterized by thickening of the dermis, as a result of deposition of glycosaminoglycans and lymphocyte infiltration.

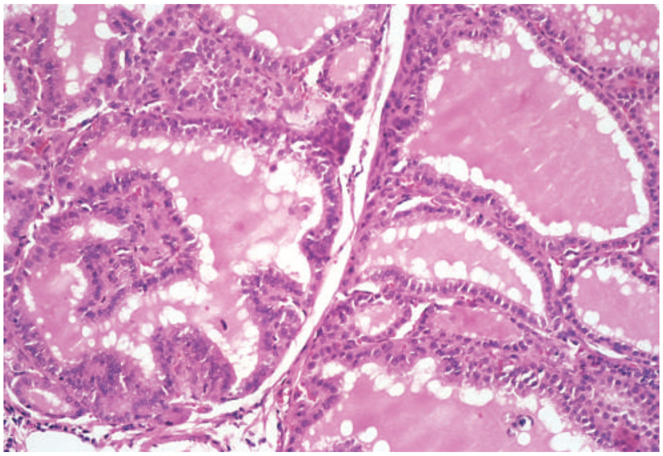

Fig. 20.10 Graves disease. The follicles are lined by tall columnar epithelial cells that are actively resorbing the colloid in the centers of the follicles, resulting in a "scalloped" appearance of the colloid.

Clinical Features

The clinical manifestations of Graves disease include those common to all forms of thyrotoxicosis (discussed earlier), as well as those associated uniquely with Graves disease: *diffuse hyperplasia of the thyroid, ophthalmopathy,* and *dermopathy.* The degree of thyrotoxicosis varies from case to case, and the related changes may sometimes be less conspicuous than other manifestations of the disease. Increased flow of blood through the hyperactive gland often produces an audible bruit. Sympathetic overactivity produces a characteristic wide, staring gaze and lid lag. The ophthalmopathy of Graves disease results in abnormal protrusion of the eyeball *(exophthalmos).* The exophthalmos may persist or progress despite successful treatment of the thyrotoxicosis, sometimes resulting in corneal injury. The extraocular muscles often are weak. The infiltrative dermopathy most commonly involves the skin overlying the shins, where it manifests as scaly thickening and induration of the skin (pretibial myxedema). The skin lesions may be slightly pigmented papules or nodules and often have an orange peel texture. Laboratory findings in Graves disease include elevated serum free T_4 and T_3 and depressed serum TSH. Because of ongoing stimulation of the thyroid follicles by TSIs, radioactive iodine uptake is increased diffusely.

SUMMARY

GRAVES DISEASE

- Graves disease, the most common cause of endogenous hyperthyroidism, is characterized by the triad of thyrotoxicosis, ophthalmopathy, and dermopathy.

- Graves disease is an autoimmune disorder caused by autoantibodies to the TSH receptor that mimic TSH action and activate TSH receptors on thyroid epithelial cells.
- The thyroid in Graves disease is characterized by diffuse hypertrophy and hyperplasia of follicles and lymphoid infiltrates; glycosaminoglycan deposition and lymphoid infiltrates are responsible for the ophthalmopathy and dermopathy.
- Laboratory features include elevations in serum free T_3 and T_4 and decreased serum TSH.

DIFFUSE AND MULTINODULAR GOITER

Enlargement of the thyroid, or *goiter,* is the most common manifestation of thyroid disease. **Diffuse and multinodular goiters are the result of impaired synthesis of thyroid hormone,** most often caused by dietary iodine deficiency. Impairment of thyroid hormone synthesis leads to a compensatory rise in the serum TSH, which drives the hypertrophy and hyperplasia of thyroid follicular cells and, ultimately, enlargement of the thyroid gland. The degree of thyroid enlargement is proportional to the level and duration of thyroid hormone deficiency. These compensatory changes overcome the hormone deficiency and maintain a *euthyroid* metabolic state in the vast majority of affected individuals. However, if the underlying disorder is severe (e.g., a congenital biosynthetic defect), the compensatory responses may be inadequate, resulting in *goitrous hypothyroidism*.

Pathogenesis

Goiters can be endemic or sporadic.

- *Endemic goiter* occurs in geographic areas where the diet contains little iodine. The designation *endemic* is used when goiters are present in more than 10% of the population in a given region. Such conditions are particularly common in mountainous areas of the world, including the Himalayas and the Andes. With increased availability of dietary iodine supplementation, the frequency and severity of endemic goiter have declined significantly.
- *Sporadic goiter* occurs less frequently than endemic goiter. The condition is more common in females than in males, with a peak incidence in puberty or young adulthood, when there is an increased physiologic demand for T_4. Sporadic goiter may be caused by several conditions, including the excessive ingestion of substances that interfere with thyroid hormone synthesis, such as calcium and vegetables belonging to the *Brassicaceae* (also called *Cruciferae*) family (e.g., cabbage, cauliflower, Brussels sprouts, turnips). In other instances goiter may result from inherited enzymatic defects that interfere with thyroid hormone synthesis *(dyshormonogenetic goiter).* In most cases, however, the cause of sporadic goiter is not apparent.

MORPHOLOGY

Early in its development, TSH-induced hypertrophy and hyperplasia of thyroid follicular cells usually result in diffuse, symmetric enlargement of the gland **(diffuse goiter).** The follicles are lined by crowded columnar cells, which may pile up and form projections similar to those seen in Graves disease. If dietary iodine subsequently increases, or if the demands for thyroid hormone decrease, the follicular epithelium involutes to form an enlarged, colloid-rich gland **(colloid goiter).** The cut surface of the thyroid in such cases usually is brown, glassy-appearing, and translucent. On microscopic examination, the follicular epithelium may be hyperplastic in the early stages of disease or flattened and cuboidal during periods of involution. Colloid is abundant during the latter periods.

With time, recurrent episodes of hyperplasia and involution combine to produce a more irregular enlargement of the thyroid, termed **multinodular goiter.** Virtually all long-standing diffuse goiters convert into multinodular goiters. Multinodular goiters are multilobulate, asymmetrically enlarged glands that may attain a massive size. On cut surface, irregular nodules containing variable amounts of brown, gelatinous colloid are

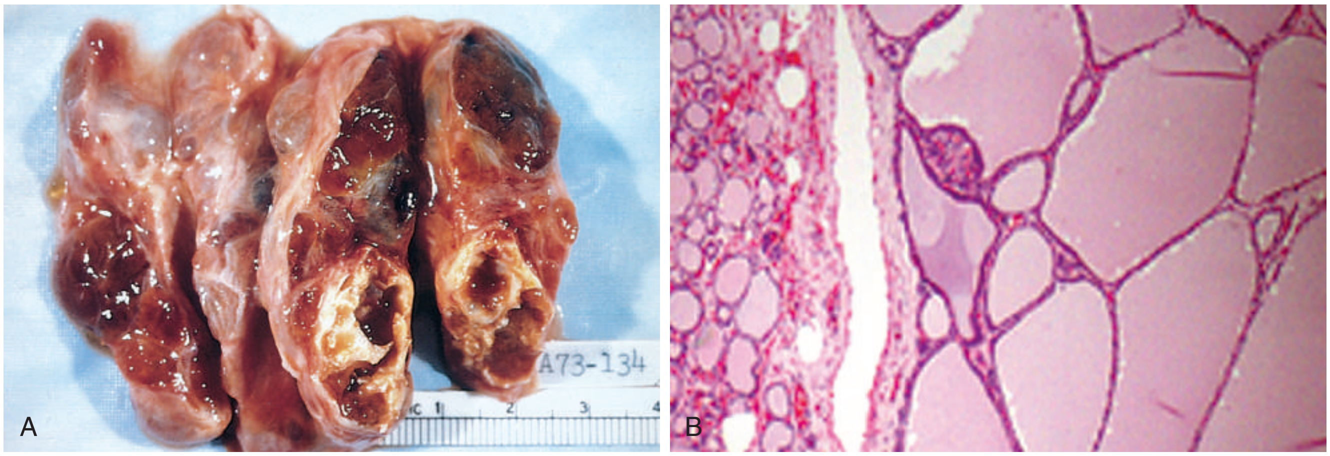

Fig. 20.11 Multinodular goiter. (A) Gross morphologic appearance. The coarsely nodular gland contains areas of fibrosis and cystic change. (B) Photomicrograph of a specimen from a hyperplastic nodule, with compressed residual thyroid parenchyma on the periphery. The hyperplastic follicles contain abundant pink "colloid" within their lumina. Note the absence of a prominent capsule, a feature distinguishing such lesions from neoplasms of the thyroid. *(B, Courtesy of Dr. William Westra, Department of Pathology, Johns Hopkins University, Baltimore, Maryland.)*

evident (Fig. 20.11A). Older lesions often show areas of fibrosis, hemorrhage, calcification, and cystic change. The microscopic appearance includes colloid-rich follicles lined by flattened, inactive epithelium and areas of follicular epithelial hypertrophy and hyperplasia, accompanied by the regressive changes just noted (see Fig. 20.11B).

Clinical Features

The dominant clinical features of goiter are those caused by the mass effects of the enlarged gland. In addition to the obvious cosmetic problem of a large neck mass, goiters also may cause airway obstruction, dysphagia, and compression of large vessels in the neck and upper thorax (so-called "superior vena cava syndrome").

Multinodular goiters typically are hormonally silent, but a minority (approximately 10% over 10 years) manifest with thyrotoxicosis secondary to the development of autonomous nodules that produce thyroid hormone independent of TSH stimulation. This condition, known as *toxic multinodular goiter* or *Plummer syndrome,* is not accompanied by the infiltrative ophthalmopathy and dermopathy of Graves disease–associated thyrotoxicosis. The incidence of malignancy in long-standing multinodular goiters is low (<5%) but not zero, and concern for malignancy arises with goiters that demonstrate sudden changes in size or associated symptoms (e.g., hoarseness).

THYROID NEOPLASMS

Thyroid tumors range from circumscribed, benign adenomas to highly aggressive, anaplastic carcinomas. From a clinical standpoint, the possibility of a tumor is of major concern in patients who present with thyroid nodules. Fortunately, the overwhelming majority of solitary nodules of the thyroid prove to be either benign adenomas or localized, non-neoplastic conditions (e.g., a dominant nodule in multinodular goiter, simple cysts, or foci of thyroiditis). Carcinomas of the thyroid, by contrast, are uncommon, accounting for less than 1% of solitary thyroid nodules. Several clinical criteria provide a clue to the nature of a given thyroid nodule:

- *Solitary nodules,* in general, are more likely to be neoplastic than are multiple nodules.
- *Nodules in very young (<20 years) or very old (>70 years) individuals* are more likely to be neoplastic.
- *Nodules in males* are more likely to be neoplastic than are those in females.
- A history of *radiation* exposure is associated with an increased incidence of thyroid malignancy.
- Nodules that take up radioactive iodine in imaging studies *(hot nodules)* are more likely to be benign.

Such associations, however, are of little significance in the evaluation of a given patient, in whom the timely recognition of a malignancy may be lifesaving. Ultimately, morphologic evaluation of a thyroid nodule by fine-needle aspiration, combined with the histologic study of surgically resected thyroid tissue, provide the most definitive information about the nature of the nodule.

Adenomas

Adenomas of the thyroid are benign neoplasms derived from follicular epithelium. Follicular adenomas usually are solitary. On clinical and morphologic grounds, they may be difficult to distinguish from a dominant nodule in multinodular goiter, for example, or from less common follicular carcinomas. Although the vast majority of adenomas are nonfunctional, a small proportion produce thyroid hormones *(toxic adenomas),* causing clinically apparent thyrotoxicosis. In general, follicular adenomas are not forerunners to carcinomas; nevertheless, shared genetic alterations support the possibility that at least a subset of follicular carcinomas arise in preexisting adenomas.

Pathogenesis

Driver mutations in the TSH receptor signaling pathway play an important role in the pathogenesis of toxic adenomas (see Fig. 20.6). Activating (gain-of-function) somatic mutations in one of two components of this signaling system—most often the gene encoding the TSH receptor itself *(TSHR)* and, less commonly, the α-subunit of Gs *(GNAS)*—allow follicular cells to secrete thyroid hormone independent of TSH stimulation (thyroid autonomy). The result of this overabundance is symptomatic hyperthyroidism, with a "hot" thyroid nodule seen on imaging studies. Overall, somatic mutations in the TSH receptor signaling pathway are present in slightly over half of toxic adenomas. Not surprisingly, such mutations also are observed in a subset of autonomous nodules that give rise to toxic multinodular goiters, discussed earlier. Thus, autonomy in both toxic goiter and toxic adenomas stems from the ability of follicular cells to release thyroid hormone independent of trophic factors (i.e., TSH). A minority of nonfunctioning follicular adenomas (<20%) exhibit mutations in *RAS* or other other genes, genetic alterations that are shared with follicular carcinomas (discussed later).

MORPHOLOGY

The typical thyroid adenoma is a **solitary,** spherical lesion that compresses the adjacent nonneoplastic thyroid. The neoplastic cells are demarcated from the adjacent parenchyma by a **well-defined, intact capsule** (Fig. 20.12A). On microscopic examination, the constituent cells are arranged in uniform follicles that contain colloid (see Fig. 20.12B). Occasionally, the neoplastic cells acquire brightly eosinophilic granular cytoplasm (oxyphil or Hürthle cell change) (Fig. 20.13). Similar to endocrine tumors at other anatomic sites, even benign follicular adenomas occasionally exhibit focal nuclear pleomorphism, atypia, and prominent nucleoli **(endocrine atypia);** by themselves, these features do not constitute evidence of malignancy. The hallmark of all follicular adenomas is the presence of an intact well-formed capsule encircling the tumor. **Careful evaluation of the integrity of the capsule is therefore critical in distinguishing follicular adenomas from follicular carcinomas,** which demonstrate capsular and/or vascular invasion (discussed later).

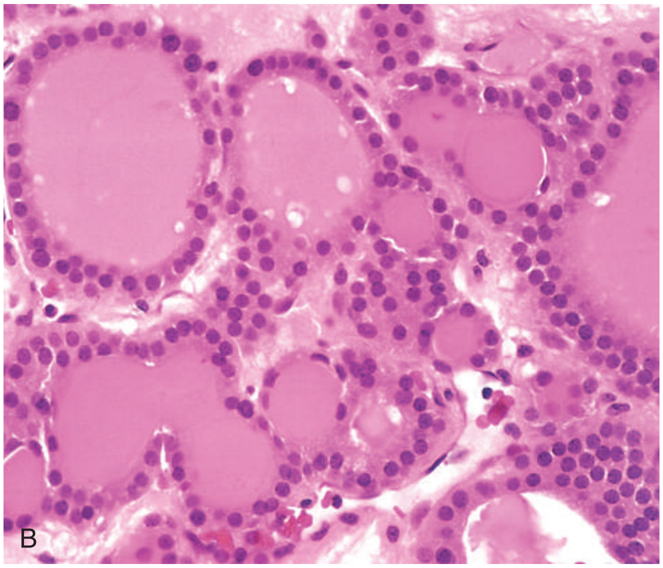

Fig. 20.12 Follicular adenoma of the thyroid gland. (A) A solitary, well-circumscribed nodule is visible in this gross specimen. (B) The photomicrograph shows well-differentiated follicles resembling those of normal thyroid parenchyma.

Clinical Features

Most adenomas of the thyroid manifest as painless nodules, often discovered during a routine physical examination. Larger masses may produce local symptoms such as difficulty in swallowing. Individuals with toxic adenomas may present with features of thyrotoxicosis. After injection of radioactive iodine, most adenomas take up iodine less avidly than normal thyroid parenchyma. On radionuclide scanning, therefore, adenomas appear as *cold* nodules relative to the adjacent normal thyroid gland. Toxic adenomas, however, appear as *warm* or *hot* nodules in the scan. As many as 10% of *cold* nodules eventually prove to be malignant. By contrast, malignancy is uncommon in *hot* nodules. Essential techniques used in the preoperative evaluation of suspected adenomas are ultrasonography and fine-needle aspiration biopsy. Because of the need for evaluating capsular integrity, *the definitive diagnosis of thyroid adenoma can be made only after careful microscopic examination of the resected specimen.* Suspected adenomas of the thyroid are therefore removed surgically to exclude malignancy. Thyroid adenomas carry an excellent prognosis and do not recur or metastasize.

Carcinomas

The detection of small , clinically asymptomatic cancerous nodules of the thyroid gland has increased dramatically in the United States over the last few years, largely due to the increasing use of thyroid ultrasound and other imaging studies. Nonetheless, deaths from thyroid cancer have remained relatively stable during this period, underscoring the favorable outcome for such incidentally detected thyroid carcinomas (and also raising questions about the value of detecting clinically insignificant cancers). A female predominance has been noted among patients who develop thyroid carcinoma in the early and middle adult years. By contrast, cases seen in childhood and late adult life are distributed equally between males and females. Most thyroid carcinomas (except medullary carcinomas) are derived from the thyroid follicular epithelium, and of these, the vast majority are well-differentiated lesions. The major subtypes of thyroid carcinoma and their relative frequencies are as follows:

- *Papillary carcinoma* (accounting for more than 85% of cases)
- *Follicular carcinoma* (5% to 15% of cases)
- *Anaplastic (undifferentiated) carcinoma* (<5% of cases)
- *Medullary carcinoma* (5% of cases)

Because of the unique clinical and biologic features associated with each type of thyroid carcinoma, these are described separately. Presented next is an overview of the molecular pathogenesis of all thyroid cancers.

Pathogenesis

Distinct molecular events are involved in the pathogenesis of the four major variants of thyroid cancer. Genetic alterations in the three follicular cell–derived malignancies are clustered along two oncogenic pathways that lie downstream of growth factor receptors and RAS—the mitogen-activated protein (MAP) kinase pathway and the phosphatidylinositol-3-kinase (PI-3K)/AKT pathway

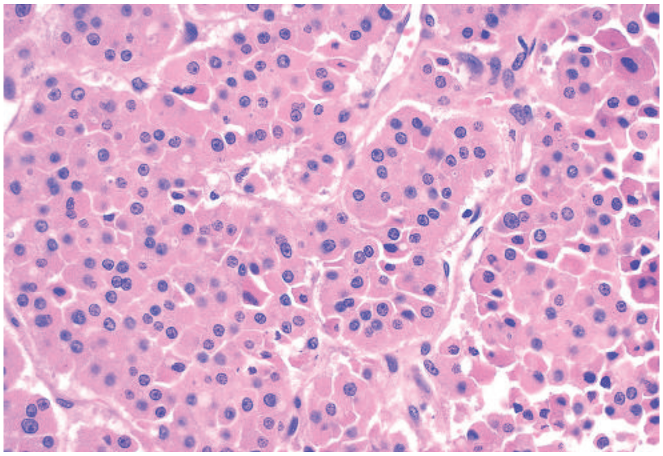

Fig. 20.13 Hürthle cell adenoma. On this high-power view, the tumor is composed of cells with abundant eosinophilic cytoplasm and small regular nuclei. *(Courtesy of Dr. Mary Sunday, Brigham and Women's Hospital, Boston, Massachusetts.)*

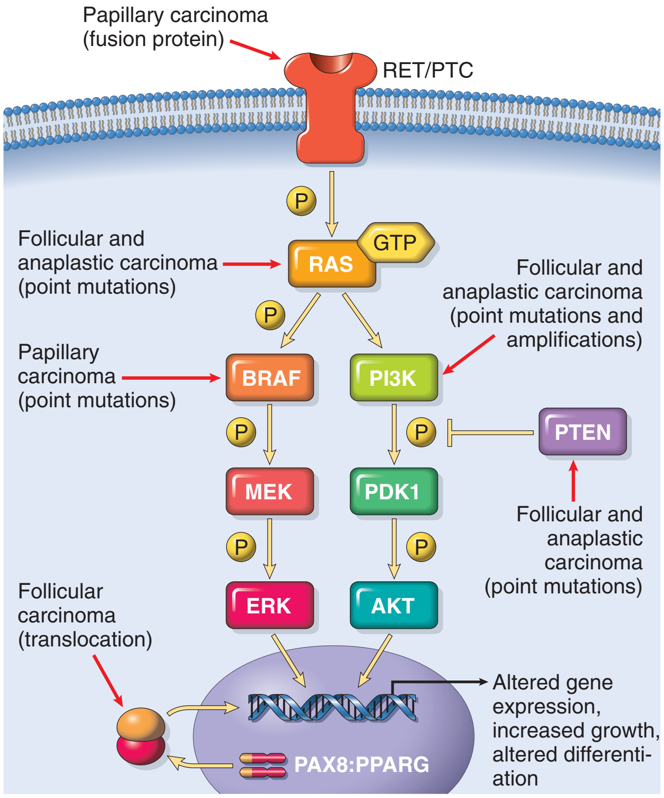

Fig. 20.14 Genetic alterations in follicular cell–derived malignancies of the thyroid gland.

(Fig. 20.14). In normal cells, these pathways are transiently activated by binding of growth factors to receptor tyrosine kinases, which results in signal transduction. In thyroid carcinomas, as with many solid cancers (Chapter 6), gain-of-function mutations in components of these pathways lead to constitutive activation, even in the absence of growth factors, thus promoting carcinogenesis.

- *Papillary thyroid carcinomas*. **Activation of the MAP kinase pathway is a feature of most papillary carcinomas.** The most common mechanisms of MAP kinase signaling are: (1) rearrangements in genes that encode the receptor tyrosine kinases RET and NTRK1 (neurotrophic tyrosine kinase receptor 1); and (2) activating point mutations in *BRAF,* whose product is a component of the MAP kinase pathway (see Fig. 20.14). One third to one half of papillary thyroid carcinomas harbor a gain-of-function mutation in *BRAF,* which is the most common driver mutation in this neoplasm. Since chromosomal rearrangements of the *RET* or *NTRK1* genes and mutations of *BRAF* have redundant effects, papillary thyroid carcinomas demonstrate either one or the other molecular abnormality, but not both.
- *Follicular thyroid carcinomas*. **Follicular thyroid carcinomas frequently harbor driver mutations in RAS or in components of the PI3K/AKT signaling pathway**. Both gain-of-function mutation in PI3K and loss-of-function mutations in PTEN, a negative regulator of PI3K, are seen. RAS and PI3K mutations also are found in benign follicular adenomas to and anaplastic carcinomas (see next) suggesting a shared histogenesis. One third to one half of follicular carcinomas also have a unique (2;3)(q13;p25) translocation that disrupts *PAX8*, a paired homeobox gene that is important in thyroid development, and the peroxisome proliferator–activated receptor gene *(PPARG)*, whose gene product is a nuclear hormone receptor implicated in terminal differentiation of cells.
- *Anaplastic carcinomas*. **These highly aggressive tumors can arise de novo or, more commonly, by progression of a well-differentiated papillary or follicular carcinoma.** Molecular alterations present in anaplastic carcinomas include those also seen in well-differentiated carcinomas (e.g., *RAS* or *PIK3CA* mutations), as well as additional mutations that are specific to anaplastic carcinoma. The most common of these unique mutations are loss-of-function mutations in *TP53*, which are believed to have an important role in the development of anaplastic carcinomas.
- *Medullary thyroid carcinomas*. In contrast with the subtypes described earlier, these neoplasms arise from the parafollicular C cells, rather than the follicular epithelium. Familial medullary thyroid carcinomas occur in *multiple endocrine neoplasia type 2* (MEN-2) (see later) and are associated with germ line *RET* proto-oncogene mutations that lead to constitutive activation of the RET tyrosine kinase receptor. *RET* mutations are also seen in approximately one-half of nonfamilial (sporadic) medullary thyroid cancers.

Environmental Factors. **The major risk factor predisposing to thyroid cancer is exposure to ionizing radiation, particularly during the first 2 decades of life.** In keeping with this finding, there was a marked increase in the incidence of papillary carcinomas among children exposed to ionizing radiation after the Chernobyl nuclear disaster in 1986. Deficiency of dietary iodine (and by extension, an association with goiter) is linked with a higher frequency of follicular carcinomas.

Papillary Carcinoma

As mentioned earlier, papillary carcinomas are the most common form of thyroid cancer. These tumors may occur at any age, and they account for the vast majority of thyroid carcinomas associated with previous exposure to ionizing radiation.

MORPHOLOGY

Papillary carcinomas are solitary or multifocal lesions. Some tumors may be well circumscribed and encapsulated; others infiltrate the adjacent parenchyma and have ill-defined margins. The cut surface sometimes reveals papillary foci that point to the diagnosis (Fig. 20.15A). The microscopic hallmarks of papillary neoplasms include the following:

- Branching **papillae** having a fibrovascular stalk covered by a single to multiple layers of cuboidal epithelial cells (see Fig. 20.15B). In most cases, the epithelium covering the papillae has well-differentiated, uniform, orderly cuboidal cells, but more pleomorphic or even anaplastic morphologies may be seen.

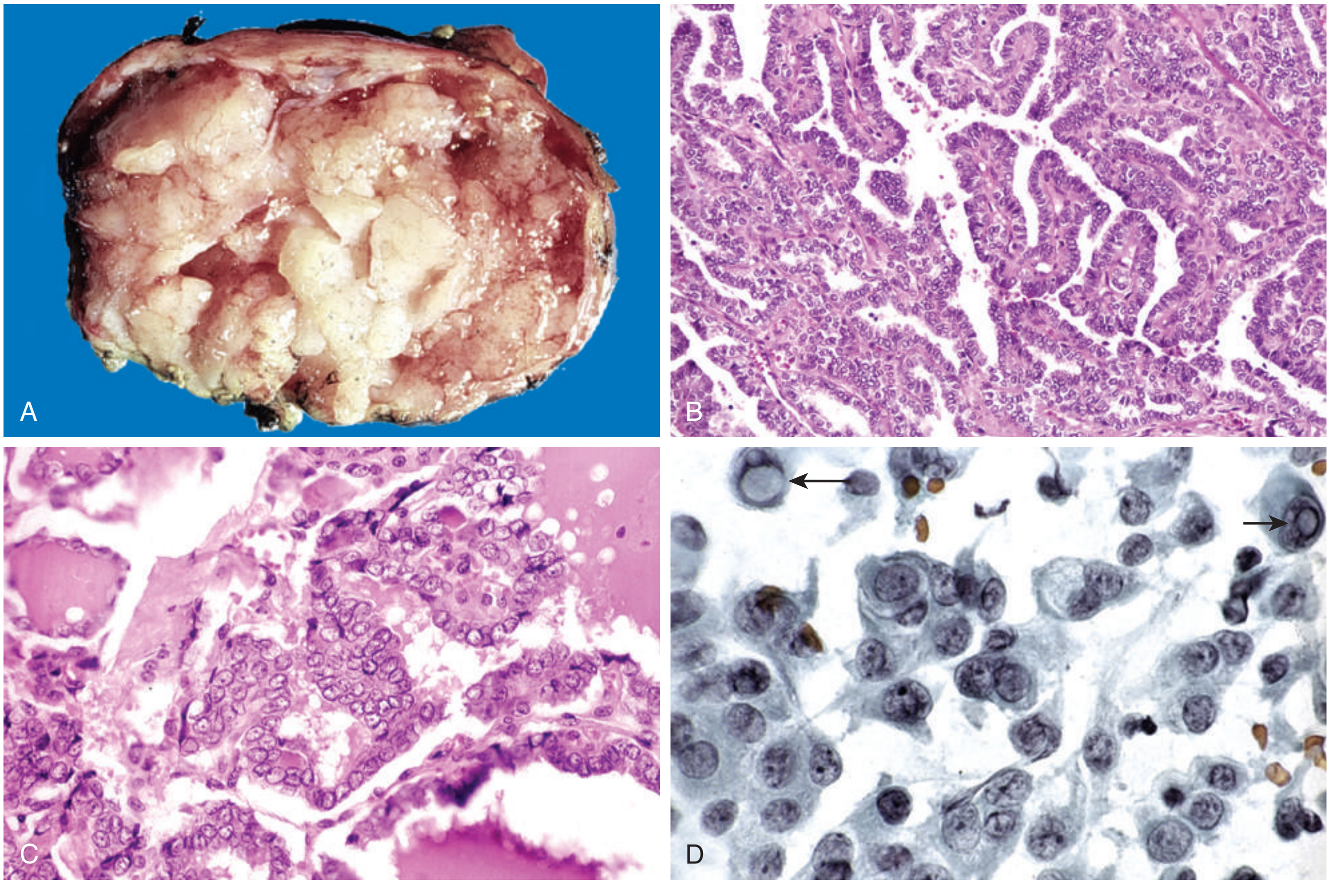

Fig. 20.15 Papillary carcinoma of the thyroid gland. (A to C) A papillary carcinoma with grossly discernible papillary structures. In this particular example, well-formed papillae (B) are lined by cells with characteristic empty-appearing nuclei, sometimes termed *Orphan Annie eye* nuclei (C). (D) Cells obtained by fine-needle aspiration of a papillary carcinoma. Characteristic intranuclear inclusions are visible in some of the aspirated cells *(arrows)*. *(Courtesy of Dr. S. Gokasalan, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

- Nuclei with finely dispersed chromatin, which imparts an optically clear or empty appearance, giving rise to the designation **ground-glass** or **Orphan Annie eye nuclei** (see Fig. 20.15B). In addition, invaginations of the cytoplasm often give the appearance of intranuclear inclusions ("pseudo-inclusions") or intranuclear grooves (see Fig. 20.15D). **These nuclear features are sufficient for the diagnosis of papillary carcinoma,** even in the absence of papillary architecture.
- Concentrically calcified structures termed **psammoma bodies** are often present within the lesion, usually within the cores of papillae. These structures are almost never found in follicular and medullary carcinomas.
- Foci of lymphatic invasion by tumor are often present, but involvement of blood vessels is relatively uncommon, particularly in smaller lesions. Metastases to adjacent cervical lymph nodes occur in up to one-half of cases.
- There are over a dozen variants of papillary thyroid carcinoma, the most common of which is the so-called **encapsulated follicular variant,** comprised of follicles lined by cells harboring nuclear features of papillary cancers (discussed earlier).

Clinical Features

Papillary carcinomas are nonfunctional tumors, so they manifest most often as a painless mass in the neck, either within the thyroid or as a metastasis in a cervical lymph node. A preoperative diagnosis usually can be established by fine-needle aspiration based on the characteristic nuclear features described earlier. Papillary carcinomas are indolent lesions, with 10-year survival rates in excess of 95%. Of interest, the presence of isolated cervical node metastases does not have a significant influence on prognosis. In a minority of patients, hematogenous metastases are present at the time of diagnosis, most commonly to the lung. The long-term survival of patients with papillary thyroid cancer is dependent on several factors, including age (in general, the prognosis is less favorable among patients older than 40 years of age), presence of extrathyroidal extension, and presence of distant metastases (stage).

Recent studies have shown that follicular variants of papillary carcinoma that lack evidence of invasion have essentially no potential for malignant behavior. In recognition of this, forthcoming recommendations from the World Health Organization suggest the name carcinoma should be stripped from these tumors, which will henceforth be classified as benign neoplasms to prevent overtreatment.

Follicular Carcinoma

Follicular carcinomas account for 5% to 15% of primary thyroid cancers. They are more common in women (occurring in a ratio of 3:1) and manifest at an older age than papillary carcinomas, with a peak incidence between 40 and 60

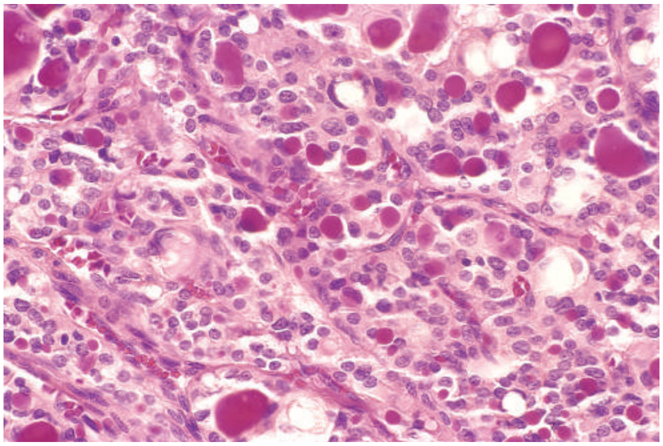

Fig. 20.16 Follicular carcinoma of the thyroid gland. A few of the glandular lumina contain recognizable colloid.

years of age. Follicular carcinoma is more frequent in areas with dietary iodine deficiency (accounting for 25%–40% of thyroid cancers), while its incidence has either decreased or remained stable in iodine-sufficient areas of the world.

MORPHOLOGY

On microscopic examination, most follicular carcinomas are composed of uniform cells forming small follicles, reminiscent of normal thyroid (Fig. 20.16); in other cases, follicular differentiation may be less apparent. As with follicular adenomas, Hürthle cell variants of follicular carcinomas may be seen. Follicular carcinomas may be widely invasive, infiltrating the thyroid parenchyma and extrathyroidal soft tissues, or minimally invasive. The latter type are sharply demarcated lesions that may be impossible to distinguish from follicular adenomas on gross examination. **The distinction between follicular adenoma and carcinoma requires extensive histologic sampling of the tumor capsule–thyroid interface, to exclude capsular and/or vascular invasion** (Fig. 20.17). As discussed earlier, invasive follicular lesions in which the nuclear features are typical of papillary carcinomas are regarded as follicular variants of papillary cancers.

Clinical Features

Follicular carcinomas manifest most frequently as *solitary cold thyroid nodules.* In rare cases, they may be hyperfunctional. These neoplasms tend to metastasize through the bloodstream *(hematogenous dissemination)* to the lungs, bone, and liver. In contrast with papillary carcinomas, regional nodal metastases are uncommon. As many as one-half of patients with widely invasive carcinomas succumb to their disease within 10 years, while less than 10% of patients with minimally invasive follicular carcinomas die within the same time span. Follicular carcinomas are treated with surgical excision. Well-differentiated metastases may take up radioactive iodine, which can be used to identify and also ablate such lesions.

Anaplastic Carcinoma

Anaplastic carcinomas are undifferentiated tumors of the thyroid follicular epithelium, accounting for less than 5% of thyroid tumors. They are aggressive, with a mortality rate approaching 100%. Patients with anaplastic carcinoma are older than those with other types of thyroid cancer, with a mean age of 65 years. Approximately one-fourth of patients with anaplastic thyroid carcinomas have a history of a well-differentiated thyroid carcinoma, and another one-fourth harbor a concurrent well-differentiated tumor in the resected specimen.

MORPHOLOGY

Anaplastic carcinomas manifest as bulky masses that typically grow rapidly beyond the thyroid capsule into adjacent neck structures. On microscopic examination, these neoplasms are composed of highly anaplastic cells, which may be large and pleomorphic or spindle shaped and in some cases mixture of the two cell types.

Foci of papillary or follicular differentiation may be present in some tumors, suggesting origin from a better-differentiated carcinoma.

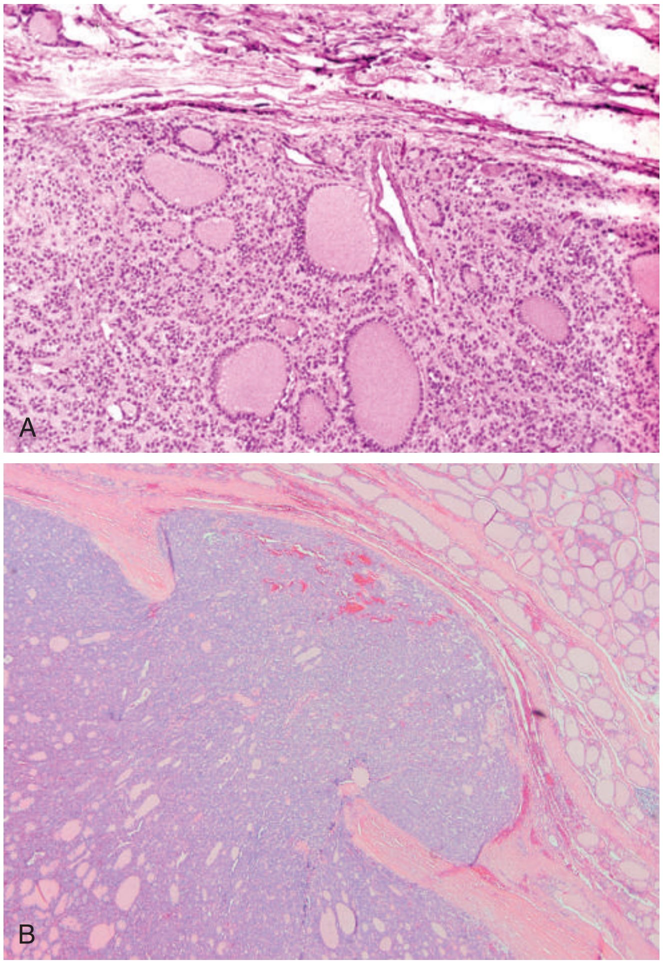

Fig. 20.17 Capsular invasion in follicular carcinoma. Evaluating the integrity of the capsule is critical in distinguishing follicular adenomas from follicular carcinomas. (A) In adenomas, a fibrous capsule, usually thin but occasionally more prominent, surrounds the neoplastic follicles and no capsular invasion is seen; compressed normal thyroid parenchyma usually is present external to the capsule *(top)*. (B) By contrast, follicular carcinomas demonstrate capsular invasion that may be minimal, as in this case, or widespread, with extension into local structures of the neck.

Clinical Features

Anaplastic carcinomas grow with wild abandon despite therapy. Metastases to distant sites are common, but in most cases death occurs in less than 1 year as a result of aggressive local growth and compromise of vital structures in the neck.

Medullary Carcinoma

Medullary carcinomas of the thyroid are *neuroendocrine tumors* derived from the parafollicular cells, or C cells, of the thyroid. Like normal C cells, medullary carcinomas secrete calcitonin, measurement of which plays an important role in the diagnosis and postoperative follow-up of patients. In some cases, the tumor cells elaborate other polypeptide hormones such as somatostatin, serotonin, and vasoactive intestinal peptide. Medullary carcinomas arise *sporadically* in about 70% of cases. The remaining 30% are *familial*, occurring in the setting of multiple endocrine neoplasia (MEN) syndrome 2A or 2B, or familial medullary thyroid carcinoma without an associated MEN syndrome, as discussed later. Both familial and sporadic medullary forms are associated with gain-of-function driver mutations in the RET receptor tyrosine kinase. Sporadic medullary carcinomas, as well as familial cases without an associated MEN syndrome, occur in adults, with a peak incidence in the fifth and sixth decades. Cases associated with MEN-2A or MEN-2B, by contrast, tend to occur in younger patients, including children.

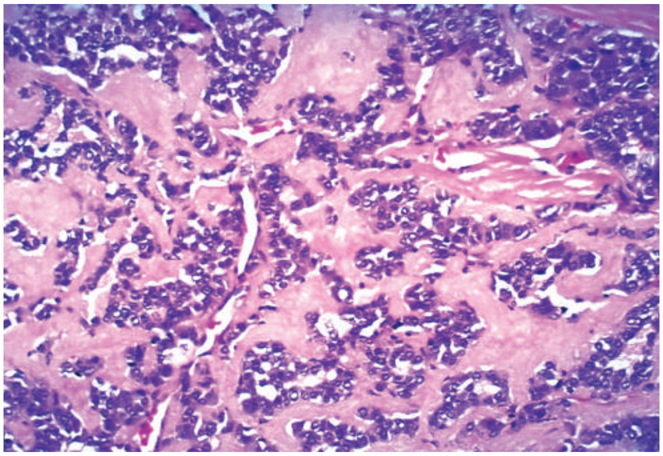

Fig. 20.18 Medullary carcinoma of the thyroid gland. These tumors typically contain amyloid, visible here as homogeneous extracellular material, derived from calcitonin molecules secreted by the neoplastic cells.

MORPHOLOGY

Medullary carcinomas may arise as a solitary nodule or may manifest as multiple lesions involving both lobes of the thyroid. **Multicentricity** is particularly common in familial cases. Larger lesions often contain areas of necrosis and hemorrhage and may extend through the capsule of the thyroid. On microscopic examination, medullary carcinomas are composed of polygonal to spindle-shaped cells, which may form nests, trabeculae, and even follicles. **Amyloid deposits**, derived from altered calcitonin molecules, are present in the adjacent stroma in many cases (Fig. 20.18) and are a distinctive feature. Calcitonin is readily demonstrable both within the cytoplasm of the tumor cells and in the stromal amyloid by immunohistochemical methods. One of the characteristic features of familial medullary carcinomas is the presence of **multicentric C cell hyperplasia** in the surrounding thyroid parenchyma, a feature usually absent in sporadic lesions. Foci of C cell hyperplasia are believed to represent the precursor lesions from which medullary carcinomas arise.

Clinical Features

In sporadic cases, medullary carcinoma manifests most often as a mass in the neck, sometimes associated with compression effects such as dysphagia or hoarseness. In some instances the initial manifestations are caused by the secretion of a peptide hormone (e.g., diarrhea caused by the secretion of vasoactive intestinal peptide). Screening of the patient's relatives for elevated calcitonin levels or *RET* mutations permits early detection of tumors in familial cases. As discussed later, all members of MEN-2 kindreds carrying *RET* mutations are offered prophylactic thyroidectomies to preempt the development of medullary carcinomas; often, the only histologic finding in the resected thyroid of these asymptomatic carriers is the presence of C cell hyperplasia or small (<1 cm) *micromedullary carcinomas*.

SUMMARY

THYROID NEOPLASMS

- Most thyroid neoplasms manifest as *solitary thyroid nodules*, but only 1% of all thyroid nodules are neoplastic.
- *Follicular adenomas* are the most common benign neoplasms, while papillary carcinoma is the most common malignancy.
- Multiple genetic pathways are involved in *thyroid carcinogenesis*. Some of the driver mutations that are fairly unique to thyroid cancers include *PAX8/PPARG* fusion (in follicular carcinoma), chromosomal rearrangements involving the *RET* oncogene (in papillary cancers), and mutations of *RET* (in medullary carcinomas).
- *Follicular adenomas and carcinomas* both are composed of well-differentiated follicular epithelial cells; the latter are distinguished by presence of capsular and/or vascular invasion.
- *Papillary carcinomas* are recognized by nuclear features (ground-glass nuclei, pseudoinclusions), even in the absence of papillae. These neoplasms typically metastasize by way of the lymphatics, but the prognosis is excellent.
- *Anaplastic carcinomas* are thought to arise by progression of more differentiated neoplasms. They are highly aggressive, uniformly lethal cancers.
- *Medullary cancers* are nonepithelial neoplasms arising from the parafollicular C cells and can occur in either sporadic (70%) or familial (30%) settings. Multicentricity and C cell hyperplasia are features of familial cases. Amyloid deposits are a characteristic histologic finding.

Parathyroid Glands

The parathyroid glands are derived developmentally from pharyngeal pouches that also give rise to the thymus. They are most commonly located in close proximity to the upper and lower poles of each thyroid lobe but may be found anywhere along the pathway of descent of the pharyngeal pouches, including the carotid sheath, the thymus, and elsewhere in the anterior mediastinum. Most of the gland is composed of *chief cells* which have secretory granules containing *parathyroid hormone (PTH). Oxyphil cells* are found throughout the normal parathyroid either singly or in small clusters. They are slightly larger than the chief cells, have acidophilic cytoplasm, and are tightly packed with mitochondria.

Parathyroid glands are key regulators of calcium homeostasis. The activity of the parathyroid glands is controlled by the level of free (ionized) calcium in the blood, rather than by trophic hormones secreted by the hypothalamus and pituitary. Normally, decreased levels of free calcium stimulate the synthesis and secretion of PTH, which has the following effects on its target tissues, the kidneys and the bones:

- Increased renal tubular reabsorption of calcium
- Increased urinary phosphate excretion, thereby lowering serum phosphate levels (since phosphate binds to ionized calcium)
- Increased conversion of vitamin D to its active dihydroxy form in the kidneys, which in turn augments gastrointestinal calcium absorption
- Enhanced osteoclastic activity (i.e., bone resorption, thus releasing ionized calcium), mediated indirectly by promoting the differentiation of osteoclast progenitor cells into mature osteoclasts

The net result of these activities is an increase in the level of free calcium in the blood, which inhibits PTH secretion from chief cells. Abnormalities of the parathyroids include both hyperfunction and hypofunction. *Tumors of the parathyroid glands, unlike thyroid tumors, usually come to attention because of excessive secretion of PTH, rather than mass effects.*

HYPERPARATHYROIDISM

Hyperparathyroidism occurs in two major forms, *primary* and *secondary,* and, less commonly, as *tertiary* hyperparathyroidism. The first condition represents an autonomous, spontaneous overproduction of PTH, while the latter two conditions typically occur as secondary phenomena in patients with chronic renal insufficiency.

Primary Hyperparathyroidism

Primary hyperparathyroidism is a common endocrine disorder and an important cause of hypercalcemia. There was a dramatic increase in the detection of cases in the latter half of the 20th century, mainly due to routine performance of serum calcium assays in hospitalized patients. The frequency of occurrence of the various parathyroid lesions underlying primary hyperparathyroidism is as follows:

- Adenoma—85% to 95%
- Primary hyperplasia (diffuse or nodular)—5% to 10%
- Parathyroid carcinoma—1%

Pathogenesis

Abnormalities in two genes are commonly associated with parathyroid tumors:

- *Cyclin D1 gene rearrangements*. Cyclin D1 is a positive regulator of the cell cycle. An inversion on chromosome 11 repositions the *cyclin D1* gene (normally on 11q), so that it resides adjacent to genomic elements that regulate the *PTH* gene (on 11p). These elements drive abnormal expression of cyclin D1 in PTH-producing cells, leading to increased proliferation of these cells. Between 10% and 20% of adenomas have this acquired genetic defect. Cyclin D1 is overexpressed in approximately 40% of parathyroid adenomas, indicating the existence of additional mechanisms that lead to its dysregulation.
- *MEN1 mutations*. Approximately 20% to 30% of sporadic parathyroid tumors have mutations in both copies of the *MEN1* tumor suppressor gene (see later). The spectrum of *MEN1* mutations in the sporadic tumors is virtually identical to that in familial parathyroid adenomas.

MORPHOLOGY

The morphologic changes in primary hyperparathyroidism include those in the parathyroid glands and in other organs affected by hypercalcemia. In 75% to 80% of cases, one of the parathyroid glands harbors a solitary **adenoma.** The typical parathyroid adenoma is a well-circumscribed, soft, tan nodule, invested by a delicate capsule. **By definition, parathyroid adenomas are confined to a single gland** (Fig. 20.19). The other glands are normal in size or somewhat shrunken, as a result of feedback

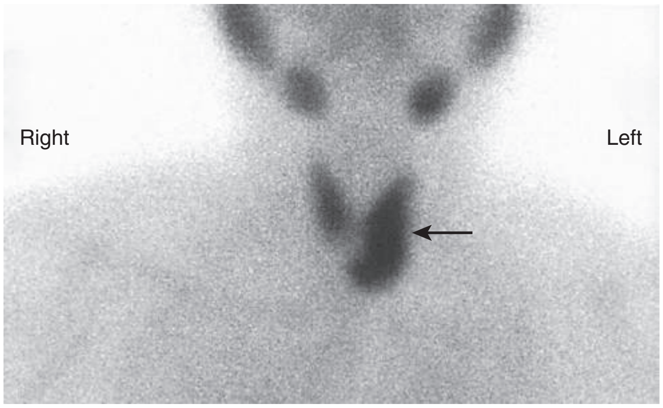

Fig. 20.19 Technetium-99 radionuclide scan demonstrates an area of increased uptake corresponding to the left inferior parathyroid gland *(arrow)*. This proved to be a parathyroid adenoma. Preoperative scintigraphy is useful in localizing and distinguishing adenomas from parathyroid hyperplasia, in which more than one gland will demonstrate increased uptake.

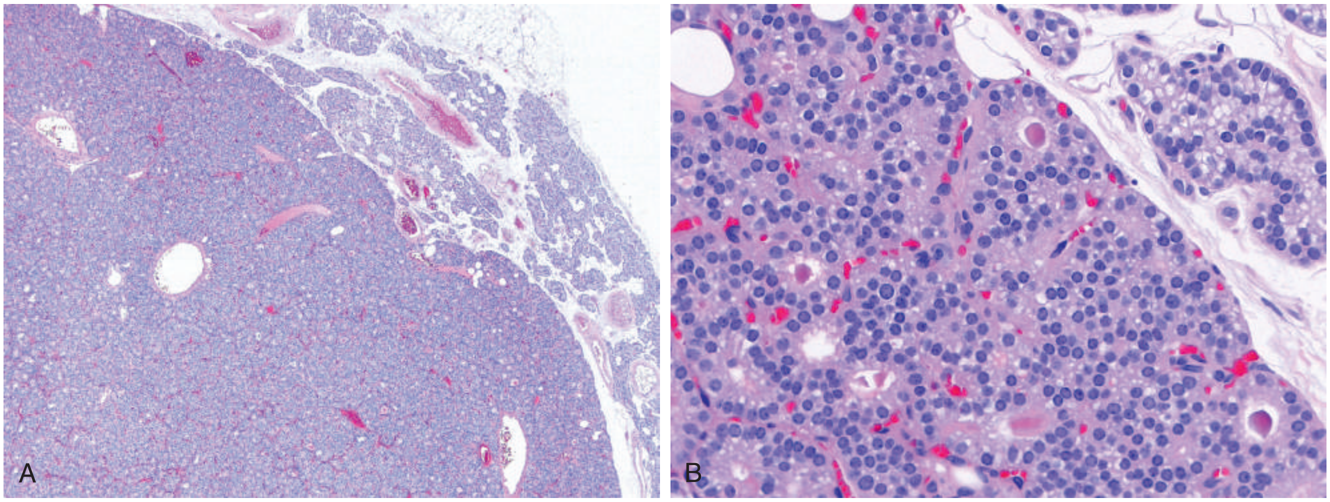

Fig. 20.20 Chief cell parathyroid adenoma. (A) In this low-power view, a solitary hypercellular adenoma is delineated from the residual normocellular gland on the upper right. (B) High-power detail shows minimal variation in nuclear size and occasional follicle formation. *(Courtesy of Dr. Nicole Cipriani, Department of Pathology, University of Chicago, Chicago, Illinois.)*

inhibition by elevated serum calcium. Most parathyroid adenomas weigh between 0.5 and 5 g. On microscopic examination, parathyroid adenomas are composed predominantly of chief cells (Fig. 20.20). A rim of compressed, non-neoplastic parathyroid tissue, generally separated by a fibrous capsule, often is visible at the edge of the adenoma. The chief cells of the adenoma are larger and show greater nuclear size variability than normal chief cells. Cells with bizarre and pleomorphic nuclei are often seen within adenomas (so-called "**endocrine atypia**") and must not be taken as a sign of malignancy. Mitotic figures are rare. In contrast with the normal parathyroid parenchyma, adipose tissue is inconspicuous within adenomas.

Parathyroid hyperplasia is typically a multiglandular process. In some cases, however, enlargement may be grossly apparent in only one or two glands, complicating the distinction between hyperplasia and adenoma. Microscopically, the most common pattern seen is that of chief cell hyperplasia, which may involve the glands in a diffuse or multinodular pattern. Less commonly, the constituent cells contain abundant clear cytoplasm as a consequence of the accumulation of glycogen—a condition designated water-clear cell hyperplasia. As in the case of adenomas, stromal fat is inconspicuous within foci of hyperplasia.

Parathyroid carcinomas may be circumscribed lesions that are difficult to distinguish from adenomas, or they may be clearly invasive neoplasms. These tumors enlarge one parathyroid gland and consist of gray-white, irregular masses that sometimes exceed 10 g in weight. The cells usually are uniform and resemble normal parathyroid cells. They are arrayed in nodular or trabecular patterns. The tumor mass is usually enclosed by a dense, fibrous capsule. There is general agreement that a **diagnosis of carcinoma based on cytologic detail is unreliable; invasion of surrounding tissues and metastasis are the only definitive criteria.** Local recurrence occurs in one-third of cases, and more distant dissemination occurs in another one-third.

Morphologic changes in other organs:

- **Skeletal changes** include increased osteoclastic activity, which results in erosion of bone matrix and mobilization of calcium salts, particularly in the metaphyses of long tubular bones. Bone resorption is accompanied by increased osteoblastic activity and the formation of new bone trabeculae. In more severe cases, the cortex is grossly thinned and the bone marrow contains increased amounts of fibrous tissue accompanied by foci of hemorrhage and cysts **(osteitis fibrosa cystica)** (Chapter 21). Aggregates of osteoclasts, reactive giant cells, and hemorrhagic debris occasionally form masses that may be mistaken for neoplasms (**brown tumors** of hyperparathyroidism).
- **Renal changes.** PTH-induced hypercalcemia favors the formation of urinary tract stones **(nephrolithiasis)** as well as calcification of the renal interstitium and tubules **(nephrocalcinosis).**
- **Metastatic calcification** secondary to hypercalcemia also may be seen in other sites, including the stomach, lungs, myocardium, and blood vessels.

Clinical Features

Primary hyperparathyroidism usually is a disease of adults and is much more common in women than in men (gender ratio of nearly 4:1). *The most common manifestation of primary hyperparathyroidism is an increase in serum ionized calcium.* In fact, primary hyperparathyroidism is the most common cause of *clinically silent hypercalcemia.* Other conditions also may produce hypercalcemia (Table 20.4). The most common cause of clinically apparent hypercalcemia

Table 20.4 Causes of Hypercalcemia

Increased PTH	Decreased PTH
Hyperparathyroidism	Hypercalcemia of malignancy
Primary (adenoma > hyperplasia)*	Osteolytic metastases
	PTH-rP–mediated
Secondary†	Vitamin D toxicity
Tertiary†	Immobilization
Familial hypocalciuric hypercalcemia	Drugs (thiazide diuretics)
	Granulomatous diseases (sarcoidosis)

PTH, Parathyroid hormone; *PTH-rP,* PTH-related protein.
*Primary hyperparathyroidism is the most common cause of hypercalcemia overall.
†Secondary and tertiary hyperparathyroidism are most commonly associated with progressive renal failure.

in adults is cancer, which can cause hypercalcemia through a variety of mechanisms, including secretion of PTH-like polypeptides and osteolytic bone metastases (Chapter 6). The prognosis for patients with malignancy-associated hypercalcemia is poor, because it often occurs in those with advanced cancers. In individuals with hypercalcemia caused by parathyroid hyperfunction, serum PTH is inappropriately elevated, whereas serum PTH is low to undetectable in those with hypercalcemia caused by nonparathyroid diseases, including malignancy. Other laboratory alterations referable to PTH excess include hypophosphatemia and increased urinary excretion of both calcium and phosphate.

Primary hyperparathyroidism traditionally has been associated with a constellation of symptoms that include *painful bones, renal stones, abdominal groans, and psychic moans*. Pain, secondary to fractures of bones weakened by osteoporosis or osteitis fibrosa cystica and resulting from renal stones, with obstructive uropathy, was at one time a prominent manifestation of primary hyperparathyroidism. Because serum calcium is now routinely assessed in most patients who need blood tests for unrelated conditions, hyperparathyroidism is usually detected early in its course. Hence, many of the classic clinical manifestations, particularly those referable to bone and renal disease, are seen much less frequently. Additional signs and symptoms that may be encountered in some cases include the following:

- *Gastrointestinal disturbances,* including constipation, nausea, peptic ulcers, pancreatitis, and gallstones
- *Central nervous system alterations,* including depression, lethargy, and seizures
- *Neuromuscular abnormalities,* including weakness and hypotonia
- *Polyuria* and secondary polydipsia

Although some of these alterations (e.g., polyuria and muscle weakness) are clearly related to hypercalcemia, the pathophysiology of many of the other manifestations of the disorder remains poorly understood.

Secondary Hyperparathyroidism

Secondary hyperparathyroidism is caused by chronic depression of serum calcium levels, most often as a result of renal failure, leading to compensatory overactivity of the parathyroids. The mechanisms by which chronic renal failure induces secondary hyperparathyroidism are complex and not fully understood. Chronic renal insufficiency is associated with decreased phosphate excretion, which in turn results in hyperphosphatemia. The elevated serum phosphate levels directly depress serum calcium levels. In addition, loss of renal α_1-hydroxylase activity, which is required for the synthesis of the active form of vitamin D, reduces the intestinal absorption of calcium (Chapter 8). These alterations cause chronic hypocalcemia, which stimulates the activity of the parathyroid glands.

MORPHOLOGY

The parathyroid glands in secondary hyperparathyroidism are hyperplastic. As in primary hyperplasia, the degree of glandular enlargement is not necessarily symmetric. On microscopic examination, the hyperplastic glands contain an increased number of chief cells, or cells with more abundant, clear cytoplasm **(water-clear cells),** in a diffuse or multinodular distribution. Fat cells are decreased in number. **Bone changes** similar to those seen in primary hyperparathyroidism also may be present. **Metastatic calcification** may be seen in many tissues.

Clinical Features

The clinical manifestations of secondary hyperparathyroidism usually are dominated by those related to chronic renal failure. Bone abnormalities *(renal osteodystrophy)* and other changes associated with PTH excess are, in general, less severe than those seen in primary hyperparathyroidism. Serum calcium remains near normal because the compensatory increase in PTH levels sustains serum calcium. The metastatic calcification of blood vessels (secondary to hyperphosphatemia) occasionally may result in significant ischemic damage to skin and other organs—a process referred to as *calciphylaxis.* In a minority of patients, parathyroid activity may become autonomous and excessive, with resultant hypercalcemia—a process sometimes termed *tertiary hyperparathyroidism.* Parathyroidectomy may be necessary to control the hyperparathyroidism in such patients.

SUMMARY
HYPERPARATHYROIDISM

- Primary hyperparathyroidism is the most common cause of asymptomatic hypercalcemia.
- In a majority of cases, primary hyperparathyroidism is caused by a sporadic parathyroid adenoma and, less commonly, by parathyroid hyperplasia.
- Parathyroid adenomas are solitary, while hyperplasia typically is a multiglandular process.
- Skeletal manifestations of hyperparathyroidism include bone resorption, *osteitis fibrosa cystica*, and *brown tumors*. Renal changes include nephrolithiasis (stones) and nephrocalcinosis.
- Most cases of hyperparathyroidism are clinically silent because of early detection of hypercalcemia during routine blood testing.
- Secondary hyperparathyroidism is caused by hypercalcemia most often secondary to renal failure, and the parathyroid glands are hyperplastic.
- Malignancies are the most important cause of symptomatic hypercalcemia, which results from osteolytic metastases or release of PTH-related protein from nonparathyroid tumors.

HYPOPARATHYROIDISM

Hypoparathyroidism is far less common than hyperparathyroidism. The major causes of hypoparathyroidism include the following:

- *Surgical ablation*: The most common cause is inadvertent removal of parathyroids during thyroidectomy or other surgical neck dissections.

- *Congenital absence:* This occurs in conjunction with thymic aplasia (Di George syndrome) and cardiac defects, secondary to deletions on chromosome 22q11.2 (Chapter 7).
- *Autoimmune hypoparathyroidism:* This is a hereditary polyglandular deficiency syndrome arising from autoantibodies to multiple endocrine organs (parathyroid, thyroid, adrenals, and pancreas). This condition is caused by mutations in the *autoimmune regulator (AIRE)* gene and is discussed more extensively later, in the context of autoimmune adrenalitis.

The major clinical manifestations of hypoparathyroidism are secondary to hypocalcemia. Acute cases (as may occur after surgical ablation) manifest as *increased neuromuscular irritability* (tingling, muscle spasms, facial grimacing, and sustained carpopedal spasm or tetany), *cardiac arrhythmias*, and, on occasion, *increased intracranial pressure* and *seizures.* Manifestations of chronic hypoparathyroidism include cataracts, calcification of the cerebral basal ganglia, and dental abnormalities.

Endocrine Pancreas

The endocrine pancreas consists of the islets of Langerhans, which contain four major cell types—beta, alpha, delta, and PP (pancreatic polypeptide) cells. *The beta cell produces insulin,* which regulates glucose utilization in tissues and reduces blood glucose levels, as will be detailed in the discussion of diabetes; *the alpha cell secretes glucagon,* which raises glucose levels through its glycogenolytic activity in the liver; *delta cells secrete somatostatin,* which suppresses both insulin and glucagon release; and *PP cells secrete pancreatic polypeptide*, which exerts several gastrointestinal effects, such as stimulation of secretion of gastric and intestinal enzymes and inhibition of intestinal motility. The most important disease of the endocrine pancreas is diabetes mellitus, caused by deficient production or action of insulin.

DIABETES MELLITUS

Diabetes mellitus is a group of metabolic disorders characterized by hyperglycemia. Hyperglycemia in diabetes (in common parlance, the suffix “mellitus” is often not used) results from defects in insulin secretion, insulin action, or, most commonly, both. The chronic hyperglycemia and attendant metabolic abnormalities of diabetes are often associated with secondary damage in multiple organ systems, especially the kidneys, eyes, nerves, and blood vessels. **In the United States, diabetes is the leading cause of end-stage renal disease, adult-onset blindness, and nontraumatic lower-extremity amputations resulting from atherosclerosis of arteries.**

According to the American Diabetes Association, diabetes affects over 29 million children and adults, or 9.3% of the population, in the United States, nearly one-third of whom are currently unaware that they have hyperglycemia. Approximately 1.4 million new cases of diabetes are diagnosed each year in the United States, and there is a wide variability in prevalence between different ethnic groups. For example, the prevalence of diabetes in American Indian/Alaskan Natives is almost twice that of Caucasians. Increasingly sedentary lifestyles and poor eating habits have contributed to the increases in diabetes and obesity, which some have termed the *diabesity epidemic.* A staggering 86 million adults in the United States have *prediabetes,* which is defined as *elevated blood sugar that does not reach the criterion accepted for an outright diagnosis of diabetes* (discussed next); individuals with prediabetes have an elevated risk for development of frank diabetes.

Diagnosis

Blood glucose is normally maintained in a very narrow range, usually 70 to 120 mg/dL. According to the American Diabetes Association (ADA) and the World Health Organization (WHO), **diagnostic criteria for diabetes include the following:**

1. A fasting plasma glucose greater than or equal to 126 mg/dL, and/or
2. A random plasma glucose greater than or equal to 200 mg/dL (in a patient with classic hyperglycemic signs, discussed later), and/or
3. A 2-hour plasma glucose greater than or equal to 200 mg/dL during an oral glucose tolerance test with a loading dose of 75 gm, and/or
4. A glycated hemoglobin (HbA1C) level greater than or equal to 6.5% (glycated hemoglobin is further discussed under chronic complications of diabetes)

All tests, except the random blood glucose test in a patient with classic hyperglycemic signs, need to be repeated and confirmed on a separate day. Of note, many acute conditions associated with stress, such as severe infections, burns, or trauma, can lead to transient hyperglycemia due to secretion of hormones such as catecholamines and cortisol that oppose the effects of insulin. The diagnosis of diabetes requires persistence of hyperglycemia following resolution of the acute illness.

Impaired glucose tolerance (prediabetes) is defined as:

1. A fasting plasma glucose between 100 and 125 mg/dL (“impaired fasting glucose”), and/or
2. A 2-hour plasma glucose between 140 and 199 mg/dL during an oral glucose tolerance test, and/or
3. HbA1C level between 5.7% and 6.4%

As many as one-fourth of individuals with impaired glucose tolerance will develop overt diabetes in the next 5 years, with additional risk factors such as obesity and family history compounding such risk. In addition, individuals with prediabetes have an elevated risk of cardiovascular disease.

Classification

Although all forms of diabetes share hyperglycemia as a common feature, the underlying causes of hyperglycemia vary widely. Previous classification schemes of diabetes were based on age at onset of the disease

Table 20.5 Simplified Classification of Diabetes

1. *Type 1 Diabetes*
Beta cell destruction, usually leading to absolute insulin deficiency
2. *Type 2 Diabetes*
Combination of insulin resistance and beta cell dysfunction
3. *Genetic Defects of Beta Cell Function*
Maturity-onset diabetes of the young (MODY) (see text)
Insulin gene mutations
4. *Genetic Defects in Insulin Action*
Insulin receptor mutations
5. *Exocrine Pancreatic Defects*
Chronic pancreatitis
Pancreatectomy
Cystic fibrosis
Hemochromatosis
6. *Endocrinopathies*
Growth hormone excess (acromegaly)
Cushing syndrome
Hyperthyroidism
Pheochromocytoma
7. *Infections*
Cytomegalovirus infection
Coxsackievirus B infection
Congenital rubella
8. *Drugs*
Glucocorticoids
Thyroid hormone
β-Adrenergic agonists
9. *Gestational Diabetes*
Diabetes associated with pregnancy

Modified from Diagnosis and classification of diabetes mellitus (American Diabetes Association). *Diabetes Care* 37:S81-S90; 2014.

or on the mode of therapy; in contrast, the current etiologic classification reflects a greater understanding of the pathogenesis of each variant (Table 20.5). *The vast majority of cases of diabetes fall into one of two broad classes:*

- *Type 1 diabetes is an autoimmune disease characterized by pancreatic β-cell destruction and an absolute deficiency of insulin*. It accounts for approximately 5% to 10% of all cases, and is the most common subtype diagnosed in patients younger than 20 years of age.
- *Type 2 diabetes is caused by a combination of peripheral resistance to insulin action and an inadequate secretory response by the pancreatic β cells ("relative insulin deficiency")*. Approximately 90% to 95% of diabetic patients have type 2 diabetes, and many of them are overweight. Although classically considered "adult-onset," the prevalence of type 2 diabetes in children and adolescents is increasing at an alarming pace due to the increasing rates of obesity in these age groups.

A variety of monogenic and secondary causes are responsible for the remaining cases (discussed later). Of note, when combined, monogenic and secondary forms of diabetes account for >10% of diabetes (which together makes them more common than type 1 diabetes). An important point is that although the major types of diabetes arise by different pathogenic mechanisms, *the long-term complications in kidneys, eyes, nerves, and blood vessels are the same and are the principal causes of morbidity and death.*

Normal Insulin Physiology and Glucose Homeostasis

Before discussing the pathogenesis of the two major types of diabetes, we briefly review normal insulin physiology and glucose metabolism.

Normal glucose homeostasis is tightly regulated by three interrelated processes: (1) glucose production in the liver; (2) glucose uptake and utilization by peripheral tissues, chiefly skeletal muscle; and (3) the actions of insulin and counterregulatory hormones (especially glucagon).

The principal function of insulin is to increase the rate of glucose transport into certain cells in the body (Fig. 20.21). These are the striated muscle cells (including myocardial cells) and, to a lesser extent, adipocytes, representing collectively about two thirds of total body weight. Glucose uptake in other peripheral tissues, most notably the brain, is insulin-independent. In muscle cells, glucose is then either stored as glycogen or oxidized to generate adenosine triphosphate (ATP) and metabolic intermediates needed for cell growth. In adipose tissue, glucose is metabolized to lipids, which are stored as fat. Besides promoting lipid synthesis (lipogenesis), insulin also inhibits lipid degradation (lipolysis) in adipocytes. Similarly, insulin promotes amino acid uptake and protein synthesis while inhibiting protein degradation. Thus, the metabolic effects of insulin can be summarized as anabolic, with increased synthesis and reduced degradation of glycogen, lipid, and protein. In addition to these metabolic effects, insulin has several mitogenic functions, including initiation of DNA synthesis in certain cells and stimulation of their growth and differentiation.

Insulin reduces the production of glucose from the liver. Insulin and glucagon have opposing regulatory effects on glucose homeostasis. During *fasting* states, low

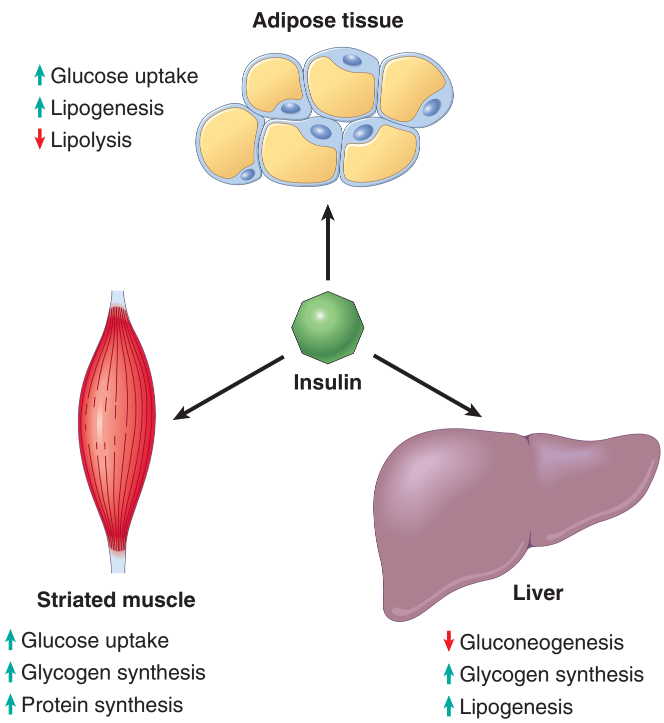

Fig. 20.21 Metabolic actions of insulin in striated muscle, adipose tissue, and liver.

insulin and high glucagon levels facilitate hepatic gluconeogenesis and glycogenolysis (glycogen breakdown) while decreasing glycogen synthesis, thereby preventing hypoglycemia. Thus, *fasting* plasma glucose levels are determined primarily by hepatic glucose output. After a meal, insulin levels rise and glucagon levels fall in response to the large glucose load.

The most important stimulus that triggers insulin release from pancreatic beta cells is glucose itself. Oral intake of food leads to secretion of multiple hormones, notably the incretins produced by cells in the intestines. These hormones stimulate insulin secretion from beta cells, and also reduce glucagon secretion and delay gastric emptying, which promotes satiety. The incretin effect is significantly blunted in patients with type 2 diabetes, and restoring incretin function can lead to improved glycemic control and loss of weight (through restoration of satiety). These observations have resulted in the development of new classes of drugs for patients with type 2 diabetes that mimic incretins or enhance the levels of endogenous incretins through delaying their degradation.

In peripheral tissues (skeletal muscle and adipose tissue), secreted insulin binds to the *insulin receptor*, triggering a number of intracellular responses that promote glucose uptake and postprandial glucose utilization, thereby maintaining glucose homeostasis. Abnormalities at various points along this complex signaling cascade, from synthesis and release of insulin by beta cells to insulin receptor interactions in peripheral tissues, can result in the diabetic phenotype.

Pathogenesis of Type 1 Diabetes

Type 1 diabetes is an autoimmune disease in which islet destruction is caused primarily by immune effector cells reacting against endogenous beta cell antigens. Although type 1 diabetes is the most common form of diabetes in childhood, it is important to remember that it can present at any age. Most patients with type 1 diabetes depend on exogenous insulin for survival; without insulin they develop serious metabolic complications such as ketoacidosis and coma. Although the clinical onset of type 1 diabetes is abrupt, it results from a chronic autoimmune attack on beta cells that usually starts years before the disease becomes evident (Fig. 20.22). The classic manifestations of the disease (such as ketoacidosis) occur late in its course, after more than 90% of the beta cells have been destroyed.

As with most autoimmune diseases, the pathogenesis of type 1 diabetes involves genetic susceptibility and environmental factors. Genome-wide association studies have identified over 20 susceptibility loci for type 1 diabetes. Of these, the strongest association is with class II MHC (HLA-DR) genes. Between 90% and 95% of white patients with type 1 diabetes have HLA-DR3, or DR4, or both, in contrast with about 40% of normal subjects, and 40% to 50% of patients are DR3/DR4 heterozygotes, in contrast with 5% of normal subjects. Of note, however, most individuals who inherit these HLA alleles do not develop diabetes, indicating that these genes contribute to the disease but do not, by themselves, cause it. Several non-HLA genes also increase susceptibility to type 1 diabetes, including polymorphisms within the gene encoding

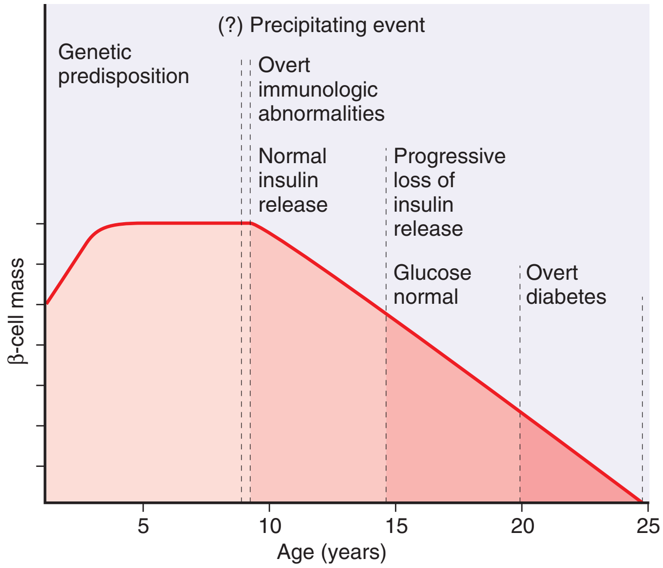

Fig. 20.22 Stages in the development of type 1 diabetes mellitus. The stages are listed from left to right, and hypothetical β cell mass is plotted against age. *(From Eisenbarth GE: Type 1 diabetes—a chronic autoimmune disease.* N Engl J Med *314:1360, 1986.)*

insulin itself, as well as *CTLA4* and *PTPN22*. As discussed in Chapter 5, CTLA-4 is an inhibitory receptor of T cells, and PTPN-22 is a protein tyrosine phosphatase; both are thought to inhibit T-cell responses, so polymorphisms that interfere with their functional activity are expected to set the stage for excessive T-cell activation. Polymorphisms in the *insulin* gene may reduce its expression in the thymus, thus reducing the elimination of T cells reactive with this self protein (Chapter 5).

Additional evidence suggests that environmental factors, especially infections, are involved in type 1 diabetes. It has been proposed that certain viruses (mumps, rubella, and coxsackie B viruses, in particular) may be initiating triggers, perhaps because some viral antigens mimic beta cell antigens, leading to bystander damage to the islets, but this idea is not conclusively established. More recent advances in elucidating environmental contributions to the pathogenesis of type 1 diabetes have come from studies of the human microbiome. Studies in diabetic children have shown evidence for "intestinal dysbiosis" (change in composition of usual commensal flora), with reduction in diversity of the microbiome, and reduced abundance of certain bacterial species during progression of subclinical to clinical stages of the disease. Whether this is a cause or consequence of hyperglycemia remains unclear.

The fundamental immune abnormality in type 1 diabetes is a failure of self-tolerance in T cells specific for beta cell antigens. This failure of tolerance may result from some combination of defective clonal deletion of self-reactive T cells in the thymus and abnormalities of regulatory T cells (Tregs) that normally dampen effector T-cell responses (Chapter 5). One consequence of loss of self tolerance is the production of **autoantibodies** against a variety of beta cell antigens, including insulin and the beta cell enzyme glutamic acid decarboxylase, which are detected in the blood of 70% to 80% of patients. In the rare cases in which the pancreatic lesions have been examined

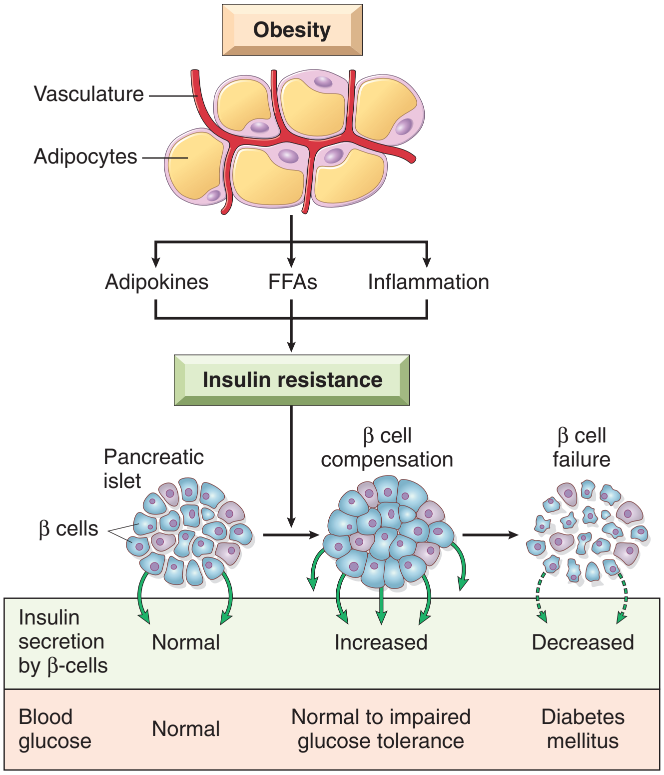

Fig. 20.23 Development of type 2 diabetes. Insulin resistance associated with obesity is induced by adipokines, free fatty acids, and chronic inflammation in adipose tissue. Pancreatic β cells compensate for insulin resistance by hypersecretion of insulin. However, at some point, β cell compensation is followed by β cell failure, and diabetes ensues. *(Reproduced with permission from Kasuga M: Insulin resistance and pancreatic β-cell failure.* J Clin Invest *116:1756, 2006.)*

early in the disease process, the islets show necrosis of beta cells and lymphocytic infiltration (so-called "insulitis", described later).

Pathogenesis of Type 2 Diabetes

Type 2 diabetes is a heterogeneous and multifactorial complex disease that involves interactions of genetics, environmental risk factors, and inflammation. Unlike type 1 diabetes, however, there is no evidence of an autoimmune basis. **The two defects that characterize type 2 diabetes are: (1) a decreased ability of peripheral tissues to respond to insulin (insulin resistance) and (2) beta cell dysfunction that is manifested as inadequate insulin secretion in the face of insulin resistance and hyperglycemia** (Fig. 20.23). Insulin resistance predates the development of hyperglycemia and usually is accompanied by compensatory beta cell hyperfunction and hyperinsulinemia in the early stages of the evolution of diabetes.

Environmental factors, such as a sedentary lifestyle and dietary habits, unequivocally play a role, as described in the subsequent discussion of the association with obesity. Genetic factors also are involved, as evidenced by a concordance rate of 80% to 90% in monozygotic twins, which is even greater than that for type 1 diabetes (approximately 50% concordance rates in twins), suggesting perhaps an even larger genetic component in type 2 diabetes. Additional evidence for a genetic basis has emerged from recent large-scale genome-wide association studies, which have identified dozens of susceptibility loci called *diabetogenic genes*. Unlike type 1 diabetes, however, the disease is not linked to genes involved in immune tolerance and regulation (e.g., *HLA, CTLA4*).

Insulin Resistance

***Insulin resistance* is defined as the failure of target tissues to respond normally to insulin.** The liver, skeletal muscle, and adipose tissue are the major tissues where insulin resistance manifests as follows:

- Failure to inhibit endogenous glucose production (gluconeogenesis) in the liver, which contributes to high fasting blood glucose levels
- Abnormally low glucose uptake and glycogen synthesis in skeletal muscle following a meal, which contributes to a high postprandial blood glucose level
- Failure to inhibit hormone-sensitive lipase in adipose tissue, leading to excess circulating free fatty acids (FFAs), which, as will be discussed, exacerbates the state of insulin resistance

Obesity and Insulin Resistance

Few factors play as important a role in the development of insulin resistance as obesity. The association of obesity with type 2 diabetes has been recognized for decades, with visceral obesity being common in a majority of affected patients. Insulin resistance is present even with simple obesity unaccompanied by hyperglycemia, indicating a fundamental abnormality of insulin signaling in states of fat excess. The term *metabolic syndrome* has been applied to a constellation of findings dominated by visceral obesity, accompanied by insulin resistance, glucose intolerance, and cardiovascular risk factors such as hypertension and abnormal lipid profiles. Individuals with metabolic syndrome are at high risk for the development of type 2 diabetes.

It is not only the absolute amount but also the distribution of body fat that has an effect on insulin sensitivity: central obesity (abdominal fat) is more likely to be associated with insulin resistance than is peripheral (gluteal/subcutaneous) obesity. *Obesity can adversely impact insulin sensitivity in numerous ways* (see Fig. 20.23):

- *Excess FFAs.* Cross-sectional studies have demonstrated an inverse correlation between fasting plasma FFAs and insulin sensitivity. The level of intracellular triglycerides often is markedly increased in muscle and liver in obese individuals, presumably because excess circulating FFAs are taken up into these organs. Central adipose tissue is more "lipolytic" than peripheral adipose tissue, which might explain the particularly deleterious consequences of the central pattern of fat distribution. Intracellular triglycerides and products of fatty acid metabolism are potent inhibitors of insulin signaling and result in an acquired insulin resistance state.
- *Adipokines.* Adipose tissue is not merely a passive storage depot for fat; it also is an endocrine organ that releases hormones in response to changes in metabolic status. A variety of proteins secreted into the systemic circulation by adipose tissue have been identified that are known collectively as *adipokines* (or *adipose cytokines*). Some of these promote hyperglycemia, and others (such as leptin and adiponectin) decrease blood glucose, in

part by increasing the insulin sensitivity of peripheral tissues. Adiponectin levels are decreased in obesity, thus contributing to insulin resistance.

- *Inflammation*. Over the past several years, inflammation has emerged as an important contributor to the pathogenesis of type 2 diabetes. It is now known that a permissive inflammatory milieu (mediated by proinflammatory cytokines that are secreted in response to excess nutrients such as FFAs) results in both peripheral insulin resistance and beta cell dysfunction (discussed later). Excess FFAs within macrophages and beta cells can activate the *inflammasome,* a multiprotein cytoplasmic complex that leads to secretion of the cytokine interleukin (IL-1β; Chapter 5). IL-1β stimulates the secretion of additional proinflammatory cytokines from macrophages, islets, and other cells, and IL-1 as well as other cytokines promote insulin resistance in peripheral tissues. Thus, excess FFAs can impede insulin signaling directly, as well as indirectly through the release of cytokines.

Beta Cell Dysfunction

While insulin resistance by itself can lead to impaired glucose tolerance, **beta cell dysfunction is an essential component in the development of overt diabetes.** Beta cell function actually increases early in the disease process in most patients with type 2 diabetes, mainly as a compensatory measure to counter insulin resistance and maintain euglycemia. Eventually, however, beta cells are unable to adapt to the long-term demands of peripheral insulin resistance, and the hyperinsulinemic state gives way to a state of relative insulin deficiency.

Several mechanisms have been implicated in causing beta cell dysfunction in type 2 diabetes, including the following:

- Excess free fatty acids that compromise beta cell function and attenuate insulin release *(lipotoxicity)*
- Chronic hyperglycemia *(glucotoxicity)*
- Abnormal *incretin effect,* leading to reduced secretion of hormones that promote insulin release (discussed earlier)
- Amyloid replacement of islets, present in more than 90% of diabetic islets (see Morphology). It is unclear whether the amyloid is a cause or effect of beta cell "burnout."
- Polymorphisms associated with an increased lifetime risk for type 2 diabetes in genes that control insulin secretion.

Monogenic Forms of Diabetes

Type 1 and type 2 diabetes are genetically complex, and despite the associations with multiple susceptibility loci, no single-gene defect (mutation) can account for predisposition to these diseases. By contrast, monogenic forms of diabetes (see Table 20.5) are uncommon examples of the diabetes occurring as a result of loss-of-function mutations within a single gene. *Monogenic causes of diabetes* include primary defects in beta cell function and insulin receptor signaling. Monogenic diabetes can be classified based on age of onset into *congenital early onset diabetes* (manifesting in the neonatal period) and *maturity onset diabetes of the young* (MODY), which develops beyond the neonatal period but usually before 25 years of age. Some of the underlying causes of congenital diabetes include mutations of the insulin gene itself, and mutations in mitochondrial DNA that lead to a syndrome of maternally inherited diabetes and bilateral deafness (the maternal pattern of inheritance being a *sine qua non* of mitochondrial DNA mutations). Rare instances of insulin receptor mutations that affect receptor synthesis, insulin binding, or downstream signal transduction can cause severe insulin resistance, accompanied by hyperinsulinemia (due to lack of feedback inhibition) and congenital diabetes. In contrast, MODY is caused by mutations in genes encoding factors driving beta cell function (see Table 20.5), and at least superficially, tends to resemble usual type 2 diabetes in many of its clinical features. Thus, it is not surprising that the diagnosis of MODY is often missed in individuals who harbor an underlying pathogenic mutation.

Other Subtypes of Diabetes

In addition to Types 1 and 2 and monogenic forms of diabetes, the other broad subtypes include secondary diabetes and pregnancy-induced ("gestational") diabetes. Secondary diabetes arising as a result of endocrinopathies (for example, Cushing syndrome or growth hormone excess) have been described in relevant portions of this chapter. Here, we will briefly discuss a form of secondary diabetes arising as a result of a variety of chronic exocrine pancreatic diseases ("pancreatogenic" diabetes), and the important subtype known as gestational diabetes.

- *Gestational diabetes*. Approximately 5% of pregnancies occurring in the United States are complicated by hyperglycemia. Pregnancy is a "diabetogenic" state in which the prevailing hormonal milieu favors a state of insulin resistance. In some euglycemic pregnant women this can give rise to gestational diabetes. Women with pregestational diabetes (where hyperglycemia is already present in the periconception period) have an increased risk for stillbirth and congenital malformations in the fetus (Chapter 7). Therefore, tight glycemic control is needed early in pregnancy to prevent congenital defects, and through the later trimesters of pregnancy to prevent fetal overgrowth (macrosomia). The latter occurs because maternal hyperglycemia can induce compensatory secretion of insulin-like growth factors in the fetus. Most pregnant women who develop gestational diabetes require insulin for glycemic control. Gestational diabetes typically resolves following delivery; however, there is an elevated risk for developing outright diabetes within the next ten years (highest in the first five years after pregnancy), after which the risk of diabetes reverts to that of women without antecedent gestational diabetes.
- *Pancreatogenic diabetes* is defined as hyperglycemia occurring as a result of a disorder of the exocrine pancreas (see Table 20.5). Pancreatogenic diabetes is heterogeneous, with underlying causes ranging from cystic fibrosis, to chronic pancreatitis, to pancreatic adenocarcinoma. In fact, evidence suggests that approximately 1% of new-onset diabetes in older adults is actually a manifestation of an occult pancreatic adenocarcinoma.

Acute Metabolic Complications of Diabetes

It is difficult to discuss with brevity the diverse clinical presentations of diabetes mellitus. We will discuss the most common initial presentation or mode of diagnosis for each of the two major subtypes, followed by a discussion of acute and chronic complications of diabetes.

Initial Presentation

In the initial 1 or 2 years after manifestation of overt type 1 diabetes (referred to as the *honeymoon period*), exogenous insulin requirements may be minimal because of residual insulin secretion, but eventually the beta cell reserve is exhausted and exogenous insulin becomes essential to control hyperglycemia. Although beta cell destruction is a gradual process, the transition from impaired glucose tolerance to overt diabetes may be abrupt, heralded by an event associated with increased insulin requirements such as infection. The onset of diabetes is marked by *polyuria, polydipsia, polyphagia* (known as the *classic triad of diabetes*), and in severe cases, *ketoacidosis*, all resulting from metabolic derangements (Fig. 20.24).

Since insulin is a major anabolic hormone, its deficiency has widespread effects. The assimilation of glucose into

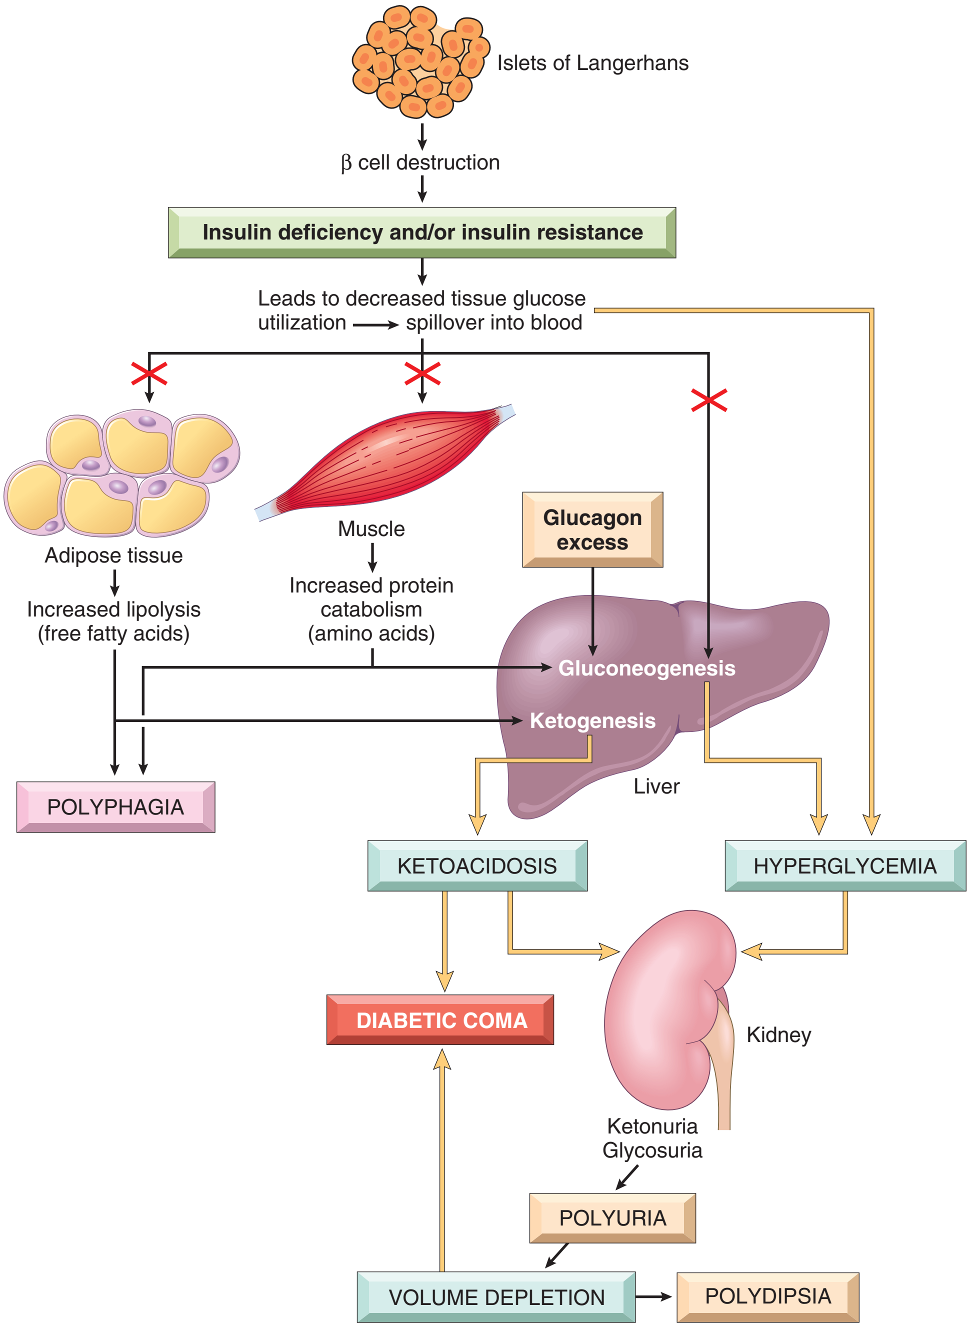

Fig. 20.24 Sequence of metabolic derangements leading to diabetic coma in type 1 diabetes mellitus. An absolute insulin deficiency leads to a catabolic state, eventuating in ketoacidosis and severe volume depletion. These derangements bring about sufficient central nervous system compromise to cause coma and, eventually, death if left untreated.

muscle and adipose tissue is sharply diminished or abolished. Storage of glycogen in liver and muscle ceases, and reserves are depleted by glycogenolysis. The resultant hyperglycemia exceeds the renal threshold for reabsorption, and glycosuria ensues. The glycosuria induces osmotic diuresis and polyuria, causing the loss of water and electrolytes. The renal water loss combined with hyperosmolarity due to increased levels of glucose in the blood depletes intracellular water, triggering osmoreceptors in the brain. This sequence of events generates intense thirst (polydipsia). The deficiency of insulin leads to the catabolism of proteins and fats. Gluconeogenic amino acids produced by proteolysis are taken up and by the liver and used as building blocks for glucose. The catabolism of proteins and fats induces a negative energy balance, which in turn leads to increasing appetite (polyphagia), thus completing the classic triad. Despite the increased appetite, catabolic effects dominate, resulting in weight loss and muscle weakness. *The combination of polyphagia and weight loss is paradoxical and should always point to the possibility of diabetes*.

Diabetic Ketoacidosis and Hyperosmolar Non-ketotic Coma

In patients with type 1 diabetes, significant deviations from normal dietary intake, unusual physical activity, infection, or any other forms of stress may worsen the metabolic imbalance, leading to *diabetic ketoacidosis*. *The plasma glucose usually is in the range of 500 to 700 mg/dL* as a result of absolute insulin deficiency and unopposed effects of counter-regulatory hormones (epinephrine, glucagon). The marked hyperglycemia causes an osmotic diuresis and dehydration characteristic of the ketoacidotic state. The second major effect is activation of the ketogenic machinery. Insulin deficiency leads to activation of hormone-sensitive lipase, with resultant excessive breakdown of adipose stores, giving rise to increased FFAs, which are oxidized by the liver to produce ketones. Ketogenesis is an adaptive phenomenon in times of starvation, generating ketones as a source of energy for consumption by vital organs (e.g., the brain). The rate at which ketones are formed may exceed the rate at which they can be used by peripheral tissues, leading to ketonemia and ketonuria. If the urinary excretion of ketones is compromised by dehydration, the accumulating ketones decrease blood pH, resulting in metabolic acidosis.

Type 2 diabetes also may manifest with polyuria and polydipsia. In some cases, medical attention is sought because of unexplained weakness or weight loss. *Most frequently, however, the diagnosis is made after routine blood or urine testing in asymptomatic individuals*. In the decompensated state, patients with type 2 diabetes may develop *hyperosmolar nonketotic coma*. This syndrome is engendered by severe dehydration resulting from sustained osmotic diuresis and urinary fluid loss due to chronic hyperglycemia. Typically, the affected individual is an older adult diabetic who is disabled by a stroke or an infection and is unable to maintain adequate water intake. The absence of ketoacidosis and its symptoms (nausea, vomiting, respiratory difficulties) delays recognition of the seriousness of the situation until the onset of severe dehydration and coma.

Chronic Complications of Diabetes

The morbidity associated with long-standing diabetes of any type results from the chronic complications of hyperglycemia, and the resulting damage induced in both large- and medium-sized muscular arteries (diabetic macrovascular disease) and small-vessels (diabetic microvascular disease). Macrovascular disease causes accelerated atherosclerosis among diabetics, resulting in increased myocardial infarction, stroke, and lower-extremity ischemia. The effects of microvascular disease are most profound in the retina, kidneys, and peripheral nerves, resulting in diabetic retinopathy, nephropathy, and neuropathy, respectively (Fig. 20.25). The pathologic findings in these tissues and their clinical consequences are described next. There is extreme variability among patients in the time of onset of these complications, their severity, and the particular organ or organs involved. In individuals with tight control of their diabetes, the onset may be delayed (hence the need for tight control of hyperglycemia).

Pathogenesis of Chronic Complications of Diabetes

The pathogenesis of the long-term complications of diabetes is multifactorial, although persistent hyperglycemia (glucotoxicity) seems to be a key mediator. At least three distinct metabolic pathways seem to be involved in the pathogenesis of long-term complications; it is likely that all of them play a role in a tissue-specific manner.

1. *Formation of advanced glycation end products (AGEs).* AGEs are formed as a result of nonenzymatic reactions between intracellular glucose-derived precursors (glyoxal, methylglyoxal, and 3-deoxyglucosone) and the amino groups of proteins. The rate of AGE formation is greatly accelerated by hyperglycemia. AGEs bind to a specific receptor (RAGE), which is expressed on inflammatory cells (macrophages and T cells), endothelium and vascular smooth muscle. The detrimental effects of AGE-RAGE signaling within the vascular compartment include the following:
   - Release of cytokines and growth factors, including transforming growth factor β (TGFβ), which leads to deposition of excess basement membrane material, and vascular endothelial growth factor (VEGF), implicated in diabetic retinopathy (discussed later)
   - Generation of *reactive oxygen species (ROS)* in endothelial cells
   - Increased *procoagulant activity* on endothelial cells and macrophages
   - Enhanced *proliferation of vascular smooth muscle cells and synthesis of extracellular matrix*

   In addition to receptor-mediated effects, *AGEs can directly cross-link extracellular matrix proteins*. These cross-linked proteins can trap other plasma or interstitial proteins; for example, low-density lipoprotein (LDL) gets trapped within AGE-modified large-vessel walls, accelerating atherosclerosis (Chapter 10), while albumin can be trapped within capillary walls, accounting in part for the basement membrane thickening that is characteristic of diabetic microangiopathy (discussed later).
2. *Activation of protein kinase C.* Activation of intracellular protein kinase C (PKC) by calcium ions and the second messenger diacylglycerol (DAG) is an important

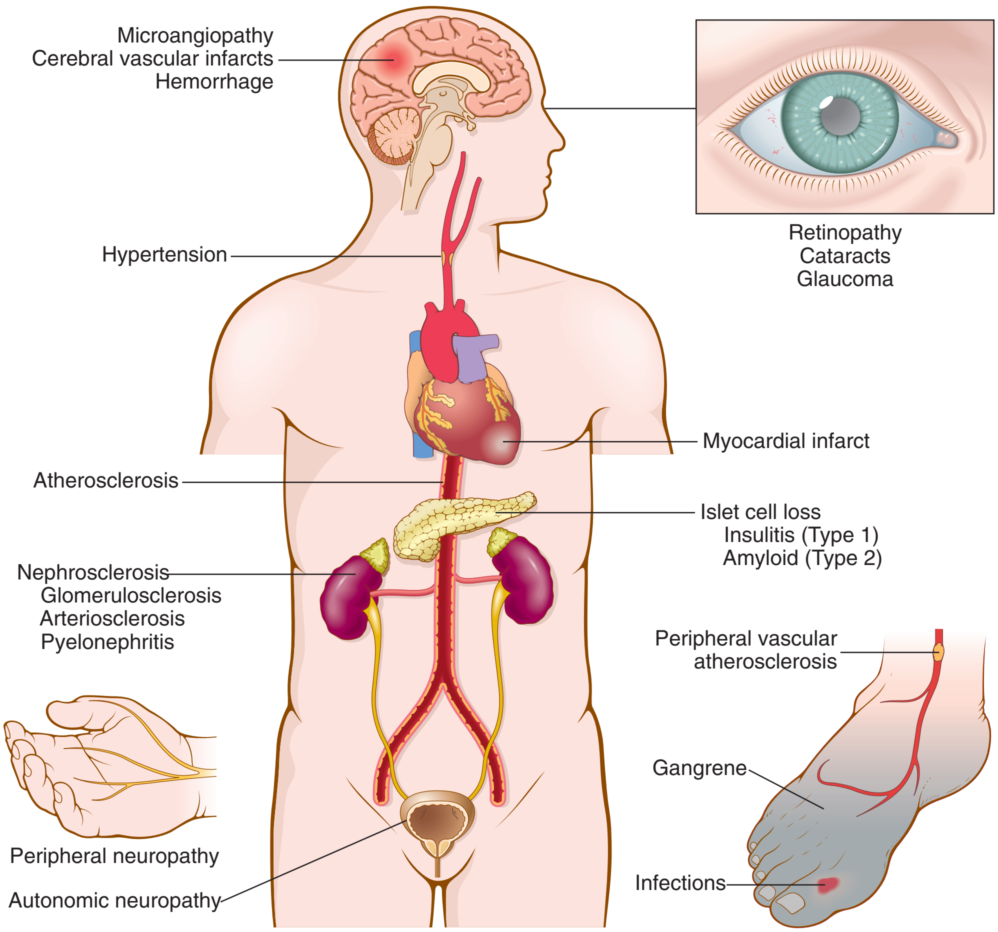

Fig. 20.25 Long-term complications of diabetes.

signal transduction pathway in many cellular systems. Intracellular hyperglycemia can stimulate the de novo synthesis of DAG from glycolytic intermediates and hence cause activation of PKC. The downstream effects of PKC activation are numerous and include production of *proangiogenic molecules* such as vascular endothelial growth factor (VEGF), implicated in the neovascularization seen in diabetic retinopathy, and profibrogenic molecules such as transforming growth factor β, leading to increased deposition of extracellular matrix and basement membrane material.

3. *Disturbances in polyol pathways.* In some tissues that do not require insulin for glucose transport (e.g., nerves, lens, kidneys, blood vessels), hyperglycemia leads to an increase in intracellular glucose that is then metabolized by the enzyme aldose reductase to sorbitol, a polyol, and eventually to fructose, in a reaction that uses NADPH (the reduced form of nicotinamide dinucleotide phosphate) as a cofactor. NADPH also is required by the enzyme glutathione reductase in a reaction that regenerates reduced glutathione (GSH). As described in Chapter 2, GSH is one of the important anti-oxidant mechanisms in the cell, and reductions in GSH increase cellular susceptibility to *oxidative stress.* In neurons, persistent hyperglycemia appears to be the major underlying cause of diabetic neuropathy *(glucose neurotoxicity).*

MORPHOLOGY

The most important morphologic changes are related to the many late systemic complications of diabetes. These changes are seen in both type 1 and type 2 diabetes (see Fig. 20.25).

Pancreas. Lesions in the pancreas are inconstant. One or more of the following alterations may be present:

- **Reduction in the number and size of islets.** This change most often is seen in type 1 diabetes, particularly with rapidly advancing disease. Most of the islets are small, inconspicuous, and not easily detected.
- **Leukocytic infiltrates in the islets** (insulitis) are principally composed of T lymphocytes (Fig. 20.26A). They are most often seen type 1 diabetes at the time of clinical presentation.
- **Amyloid deposition within islets in type 2 diabetes** begins in and around capillaries and between cells. At advanced stages, the islets may be virtually obliterated (see Fig. 20.26B); fibrosis also may be observed. Similar lesions may be found in older nondiabetics, apparently as part of normal aging.
- **An increase in the number and size of islets, especially characteristic of nondiabetic newborns of diabetic mothers.** Presumably, fetal islets undergo hyperplasia in response to the maternal hyperglycemia.

Diabetic macrovascular disease. The hallmark of diabetic macrovascular disease is **accelerated atherosclerosis**

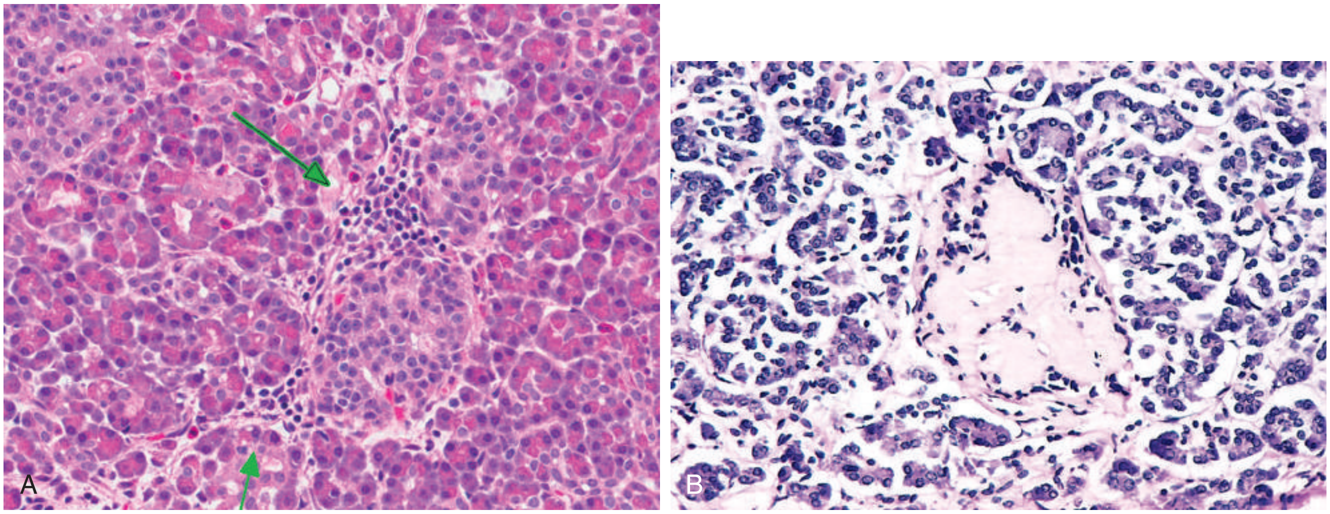

Fig. 20.26 (A) Autoimmune insulitis in a human pancreatic explant. Arrows point to inflammation surrounding islet of Langerhans, while the surrounding acinar structures are essentially normal. *(Photograph provided by Dr. Martha Campbell-Thompson, JDRF Network for Pancreatic Organ Donors, University of Florida., Gainesville, Florida.)* (B) Amyloidosis of a pancreatic islet in type 2 diabetes. Amyloidosis typically is observed late in the natural history of this form of diabetes, with islet inflammation noted at earlier observations.

affecting the aorta and large- and medium-sized arteries. Except for its greater severity and earlier age at onset, atherosclerosis in diabetics is indistinguishable from that in nondiabetics (Chapter 10). **Myocardial infarction, caused by atherosclerosis of the coronary arteries, is the most common cause of death in diabetics**. Significantly, it is almost as common in diabetic women as in diabetic men. By contrast, myocardial infarction is uncommon in nondiabetic women of reproductive age. **Gangrene of the lower extremities**, as a result of advanced vascular disease, is about 100 times more common in individuals with diabetes than in the general population. The larger renal arteries also are subject to severe atherosclerosis, but the most damaging effect of diabetes on the kidneys is exerted at the level of the glomeruli and the microcirculation, as discussed later.

Hyaline arteriolosclerosis, the vascular lesion associated with hypertension (Chapters 10 and 14), is both more prevalent and more severe in diabetics than in nondiabetics, but it is not specific for diabetes and may be seen in older adults who do not suffer from either diabetes or hypertension. It takes the form of an amorphous, hyaline thickening of the wall of the arterioles, which causes narrowing of the lumen (Fig. 20.27). Not surprisingly, in diabetic patients, its severity is related not only to the duration of the disease but also to the presence or absence of hypertension.

Diabetic microangiopathy. One of the most consistent morphologic features of diabetes is **diffuse thickening of basement membranes.** The thickening is most evident in the capillaries of the skin, skeletal muscle, retina, renal glomeruli, and renal medulla. However, it also may be seen in nonvascular structures such as renal tubules, the Bowman capsule, peripheral nerves, and placenta. By both light and electron microscopy, the basal lamina separating parenchymal or endothelial cells from the surrounding tissue is markedly thickened by concentric layers of hyaline material composed predominantly of type IV collagen (Fig. 20.28). Of note, despite the increase in the thickness of basement membranes, diabetic capillaries are leaky, leading to extravasation of plasma proteins. **The microangiopathy underlies the development of diabetic nephropathy, retinopathy, and some forms of neuropathy.** An indistinguishable microangiopathy can be found in aged nondiabetic patients, but rarely to the extent seen in individuals with long-standing diabetes.

Diabetic nephropathy. The kidneys are prime targets of diabetes (see also Chapter 14). Renal failure is second only to myocardial infarction as a cause of death from this disease. The lesions include mainly: (1) glomerular lesions; (2) renal vascular lesions, principally arteriolosclerosis; and (3) pyelonephritis, including necrotizing papillitis.

The most important **glomerular lesions** are capillary basement membrane thickening, diffuse mesangial sclerosis, and nodular glomerulosclerosis. The glomerular capillary basement membranes are thickened along their entire length. This change can be detected by electron microscopy within a few years of

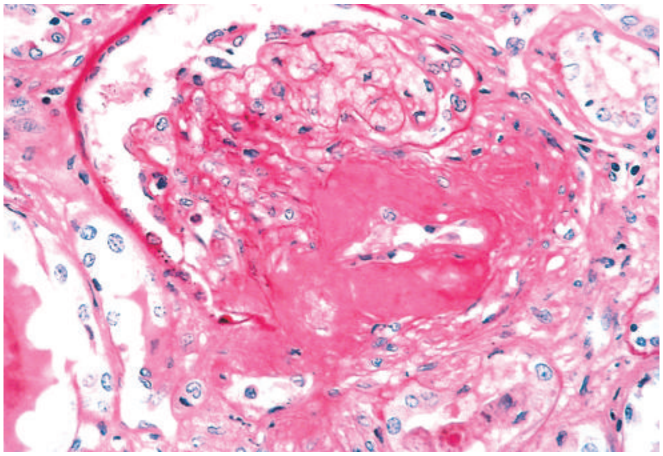

Fig. 20.27 Severe renal hyaline arteriolosclerosis in a periodic acid–Schiff stained specimen. Note the markedly thickened, tortuous afferent arteriole. The amorphous nature of the thickened vascular wall is evident. *(Courtesy of Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Science Center, San Antonio, Texas.)*

the onset of diabetes, sometimes without any associated change in renal function (Fig. 20.29).

Diffuse mesangial sclerosis refers to an increase in mesangial matrix associated with mesangial cell proliferation and basement membrane thickening. It is found in most individuals with disease of more than 10 years' duration. When glomerulosclerosis is severe, patients develop the nephrotic syndrome, characterized by proteinuria, hypoalbuminemia, and edema (Chapter 14).

Nodular glomerulosclerosis (Kimmelstiel-Wilson lesion) is a distinctive glomerular lesion characterized by ball-like deposits of a laminated matrix in the periphery of the glomerulus (Fig. 20.30). These nodules are PAS-positive and usually contain trapped mesangial cells. Nodular glomerulosclerosis is encountered in approximately 15% to 30% of individuals with long-term diabetes and is a major contributor to renal dysfunction. Diffuse mesangial sclerosis also may be seen in association with old age and hypertension; by contrast, the nodular form of glomerulosclerosis is virtually pathognomonic of diabetes. Both the diffuse and the nodular forms of glomerulosclerosis induce sufficient ischemia to cause scarring of the kidneys, manifested by a finely granular–appearing cortical surface (Fig. 20.31).

Renal atherosclerosis and arteriolosclerosis constitute part of the macrovascular disease seen in diabetics. The kidney is one of the most frequently and severely affected organs; the changes in the arteries and arterioles are similar to those found throughout the body. Hyaline arteriolosclerosis affects not only the afferent but also the efferent arterioles. Such efferent arteriolosclerosis is rarely if ever encountered in individuals who do not have diabetes.

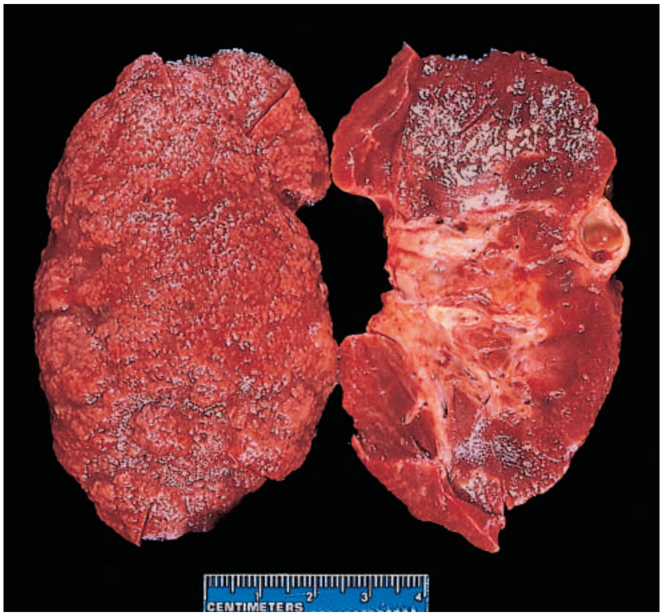

Fig. 20.31 Nephrosclerosis in a patient with long-standing diabetes. The bisected kidney demonstrates diffuse granular transformation of the surface *(left)* and marked thinning of the cortex *(right)*. Additional features include some irregular depressions, the result of pyelonephritis, and an incidental cortical cyst *(far right)*.

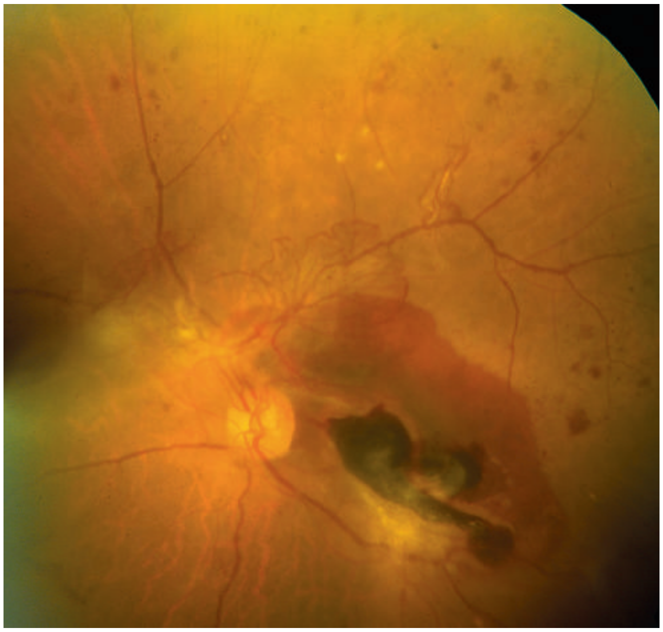

Fig. 20.32 Characteristic morphologic changes of diabetic retinopathy. Features include advanced proliferative retinopathy with retinal hemorrhages, exudates, neovascularization, and tractional retinal detachment *(lower-right corner). (Courtesy of Dr. Rajendra Apte, Washington University School of Medicine, St. Louis, Missouri.)*

Pyelonephritis is an acute or chronic inflammation of the kidneys that usually begins in the interstitial tissue and then spreads to involve the tubules. Both the acute and chronic forms of this disease occur in nondiabetics as well as in diabetics are more common in individuals with diabetes, and once affected, diabetics also tend to have more severe involvement. One special pattern of acute pyelonephritis, **necrotizing papillitis** (or papillary necrosis), is much more prevalent in diabetics than in nondiabetics.

Ocular complications of diabetes. Visual impairment, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes. **The ocular involvement may take the form of retinopathy, cataract formation, or glaucoma.** Retinopathy, the most common pattern, consists of a constellation of changes that together are considered by many ophthalmologists to be virtually diagnostic of the disease. The lesion in the retina takes two forms: nonproliferative retinopathy and proliferative retinopathy.

Nonproliferative retinopathy includes intraretinal or preretinal hemorrhages, retinal exudates, microaneurysms, venous dilations, edema, and, most importantly, thickening of the retinal capillaries (microangiopathy). The retinal exudates can be "soft" (microinfarcts) or "hard" (deposits of plasma proteins and lipids) (Fig. 20.32). The microaneurysms are discrete saccular dilations of retinal choroidal capillaries that appear through the ophthalmoscope as small red dots. Dilations tend to occur at focal points of weakening, resulting from loss of pericytes. Retinal edema presumably results from excessive capillary permeability. Underlying all of these changes is the microangiopathy, which is thought to lead to loss of capillary pericytes and hence to focal weakening of capillary structure.

The so-called **proliferative retinopathy** is a process of neovascularization and fibrosis. This lesion leads to serious consequences, including blindness, especially if it involves the macula. Vitreous hemorrhages may result from the rupture of newly formed capillaries; the subsequent organization of the hemorrhage can pull the retina off its substratum (retinal detachment).

Diabetic neuropathy. The central and peripheral nervous systems are not spared by diabetes. The most frequent pattern of involvement is that of a peripheral, symmetric neuropathy of the lower extremities affecting both motor and sensory function, particularly the latter. Other forms include autonomic neuropathy, which produces disturbances in bowel and bladder function and sometimes sexual impotence, and diabetic mononeuropathy, which may manifest as sudden footdrop or wristdrop or isolated cranial nerve palsies. The neurologic changes may be the result of microangiopathy and increased permeability of the capillaries that supply the nerves, as well as direct axonal damage.

Clinical Features of Chronic Diabetes

As the previous discussion has emphasized, type 1 and type 2 diabetes are distinct pathophysiologic entities with the common manifestation of hyperglycemia. Table 20.6 summarizes some of the clinical, genetic and histopathologic features that distinguish the two diseases. Nonetheless, as previously stated, the long-term sequela of both types 1 and 2 diabetes, arising as a result of uncontrolled

Table 20.6 Type 1 Versus Type 2 Diabetes Mellitus

Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Clinical	
Onset usually in childhood and adolescence	Onset usually in adulthood; increasing incidence in childhood and adolescence
Normal weight or weight loss preceding diagnosis	Vast majority of patients are obese (80%)
Progressive decrease in insulin levels	Increased blood insulin (early); normal or moderate decrease in insulin (late)
Circulating islet autoantibodies	No islet autoantibodies
Diabetic ketoacidosis in absence of insulin therapy	Nonketotic hyperosmolar coma
Genetics	
Major linkage to MHC class I and II genes; also linked to polymorphisms in *CTLA4* and *PTPN22*	No HLA linkage; linkage to candidate diabetogenic and obesity-related genes
Pathogenesis	
Breakdown in self-tolerance to islet autoantigens	Insulin resistance in peripheral tissues, failure of compensation by beta cells Multiple obesity-associated factors (circulating nonesterified fatty acids, inflammatory mediators, adipocytokines) linked to pathogenesis of insulin resistance
Pathology	
Autoimmune "insulitis"	Amyloid deposition in islets (late)
Beta cell depletion, islet atrophy	Mild beta cell depletion

HLA, Human leukocyte antigen; *MHC*, major histocompatibility complex.

or poorly controlled hyperglycemia, are similar, and are responsible for much of the morbidity and mortality in diabetics. In most instances these complications appear approximately 15 to 20 years after the onset of hyperglycemia. The major chronic complications of the disease are described next.

- *Macrovascular complications, such as myocardial infarction, renal vascular insufficiency, and cerebrovascular accidents, are the most common causes of mortality in long-standing diabetes.* Diabetics have a two to four times greater incidence of coronary artery disease, and a fourfold higher risk of death from cardiovascular complications, than nondiabetics. Diabetes is often accompanied by underlying conditions that favor the development of adverse cardiovascular events, including hypertension and dyslipidemia (see earlier discussion on metabolic syndrome). The hallmark of cardiovascular disease is accelerated atherosclerosis of the large- and medium-sized arteries (i.e., macrovascular disease). The importance of obesity in the pathogenesis of insulin resistance has already been discussed, but it also is an independent risk factor for development of atherosclerosis.
- *Diabetic nephropathy is a leading cause of end-stage renal disease in the United States*. The earliest manifestation of diabetic nephropathy is the appearance of small amounts of albumin in the urine (>30 but <300 mg/day). Without specific interventions, approximately 80% of patients with type 1 diabetes and 20% to 40% of those with type 2 diabetes will develop overt nephropathy with macroalbuminuria (excretion of >300 mg/day) over the ensuing 10 to 15 years, usually accompanied by the appearance of hypertension. The progression from overt nephropathy to end-stage renal disease is highly variable and is evidenced by a progressive drop in glomerular filtration rate. By 20 years after diagnosis, more than 75% of individuals with type 1 diabetes and about 20% of those with type 2 diabetes with overt nephropathy will develop end-stage renal disease, necessitating dialysis or renal transplantation.
- *Visual impairment, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes*. Diabetes is the fourth leading cause of acquired blindness in the United States. Approximately 60% to 80% of patients develop some form of diabetic retinopathy approximately 15 to 20 years after diagnosis. The fundamental lesion of retinopathy—neovascularization—is attributable to hypoxia-induced overexpression of VEGF in the retina. Current treatment for this condition includes intravitreous injection of anti-angiogenic agents. In addition to retinopathy, diabetic patients also have an increased propensity for glaucoma and cataract formation, both of which contribute to visual impairment in diabetes.
- *Diabetic neuropathy* can produce a variety of clinical syndromes, afflicting the central nervous system, peripheral sensorimotor nerves, and autonomic nervous system. The most frequent pattern of nerve involvement is a distal symmetric polyneuropathy of the lower extremities that affects both motor and sensory function, particularly the latter (Chapter 22). Over time, the upper extremities may be involved as well, thus approximating a "glove and stocking" pattern of polyneuropathy. Other forms include autonomic neuropathy, which produces disturbances in bowel and bladder function and sometimes sexual impotence, and diabetic mononeuropathy, which may manifest as sudden footdrop, wristdrop, or isolated cranial nerve palsies.
- Diabetic patients are plagued by an *increased susceptibility to infections of the skin, tuberculosis, pneumonia, and pyelonephritis*. Infections cause about 5% of diabetes-related deaths. In an individual with diabetic neuropathy, a trivial infection in a toe may be the first event in a long succession of complications (gangrene, bacteremia, pneumonia) that may ultimately lead to death.

Several large-scale prospective studies have convincingly demonstrated that the microvascular complications, and the associated morbidity and mortality, from diabetes are attenuated by strict glycemic control. For patients with type 1 diabetes, insulin replacement therapy is the mainstay of treatment, while nonpharmacologic approaches such as dietary restrictions and exercise (which improves insulin sensitivity) are often the "first line of defense" for type 2 diabetes. Most patients with type 2 diabetes eventually require therapeutic intervention to reduce hyperglycemia. Glycemic control is assessed clinically by measuring the percentage of glycosylated hemoglobin, also known as *HbA1C,* which is formed by nonenzymatic addition of glucose moieties to hemoglobin in red cells. Unlike blood glucose levels, HbA1C is a measure of glycemic control over long periods of time (2–3 months) and is relatively unaffected by day-to-day variations. The ADA recommends maintenance of HbA1C levels at less than 7% to reduce the risk for long-term complications. In addition, diabetics need to maintain LDL and HDL cholesterol and triglycerides at optimal levels to reduce the risk for macrovascular complications. The adoption of a healthy and active lifestyle remains one of the best defenses against this modern day scourge.

SUMMARY

DIABETES MELLITUS: PATHOGENESIS AND LONG-TERM COMPLICATIONS

- Type 1 diabetes is an autoimmune disease characterized by progressive destruction of islet beta cells, leading to absolute insulin deficiency. Both autoreactive T cells and autoantibodies are involved.
- Type 2 diabetes is caused by insulin resistance and beta cell dysfunction, resulting in relative insulin deficiency. Autoimmunity is not involved.
- Obesity has an important relationship with insulin resistance (and hence type 2 diabetes), mediated by various factors, including excess free fatty acids, aberrant levels of adipokines, and an altered inflammatory milieu within adipose tissue.
- Monogenic forms of diabetes are uncommon and are caused by single-gene defects that result in primary beta cell dysfunction or lead to abnormalities of insulin–insulin receptor signaling.
- The long-term complications of diabetes are similar in all types and affect mainly blood vessels, and the kidneys, nerves, and eyes. The development of these complications is attributed to three underlying mechanisms: formation of AGEs, activation of PKC, and disturbances in polyol pathways leading to oxidative stress.

PANCREATIC NEUROENDOCRINE TUMORS

Pancreatic neuroendocrine tumors (PanNETs), also known as *islet cell tumors,* are rare in comparison with tumors of the exocrine pancreas, accounting for only 2% of all pancreatic neoplasms. PanNETs are most common in adults and may be single or multifocal; when they are malignant, the liver is the most common site of metastases. These tumors have a propensity to elaborate pancreatic hormones, but some are nonfunctional. The latter typically are larger at the time of diagnosis, since they come to clinical attention later in their natural history than functional PanNETs, which often present with symptoms related to excessive hormone production. All PanNETs, with the exception of insulinomas (see later), are regarded as having malignant potential, and in fact, 60% to 90% of PanNETs manifest with overtly malignant features of biologic aggressiveness, such as invasion into local tissues or distant metastases. The tumors frequently have mutations in tumor suppressor genes *MEN1* and *PTEN*, or inactivating mutations in genes (e.g. *ATRX*) whose products maintain telomere length.

Insulinomas

Beta cell tumors (insulinomas) are the most common type of PanNET and elaborate sufficient insulin to induce attacks of hypoglycemia when blood glucose levels fall below 50 mg/dL. These attacks manifest as confusion, stupor, and loss of consciousness. They are precipitated by fasting or exercise and are promptly relieved by feeding or parenteral administration of glucose. Most insulinomas are cured by surgical resection.

MORPHOLOGY

The majority of insulinomas are identified while they are small (<2 cm in diameter) and localized to the pancreas. Most are solitary lesions, although multifocal tumors or tumors ectopic to the pancreas may be encountered. Malignancy in insulinomas occurs in less than 10% of cases, and is diagnosed on the basis of local invasion or metastases. On histologic examination, the benign tumors look remarkably like giant islets, with preservation of the regular cords of monotonous cells and their orientation to the vasculature. Malignant lesions also tend to be well-differentiated and may be deceptively encapsulated. **Deposition of amyloid** is a characteristic feature of many insulinomas (Fig. 20.33). Under the electron microscope, neoplastic beta cells, like their normal counterparts, display distinctive round granules.

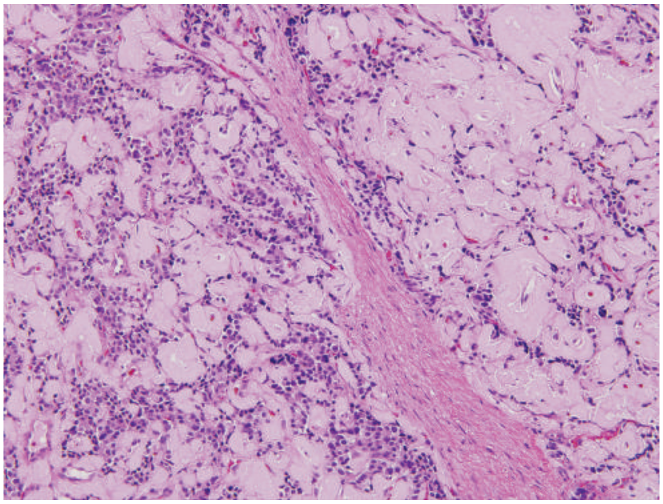

Fig. 20.33 Pancreatic neuroendocrine tumor (PanNET), also called *islet cell tumor.* The neoplastic cells are monotonous in appearance and demonstrate minimal pleomorphism or mitotic activity. There is abundant amyloid deposition, characteristic of an insulinoma.

Gastrinomas

Marked hypersecretion of gastrin usually has its origin in gastrin-producing tumors *(gastrinomas),* which are just as likely to arise in the duodenum and peripancreatic soft tissues as in the pancreas (the so-called "gastrinoma triangle"). *The Zollinger-Ellison syndrome refers to the association of pancreatic islet cell lesions with hypersecretion of gastric acid and severe peptic ulceration,* present in 90% to 95% of patients with gastrinomas. Hypergastrinemia from a pancreatic or duodenal tumor stimulates extreme gastric acid secretion, which, in turn, causes *peptic ulceration.* The duodenal and gastric ulcers often are multiple; although they are identical to those found in the general population, they often are unresponsive to usual therapy. In addition, ulcers may occur in unusual locations such as the jejunum; when intractable jejunal ulcers are found, Zollinger-Ellison syndrome should be considered. More than one-half of affected patients have diarrhea; in 30%, it is the presenting manifestation.

MORPHOLOGY

Gastrinomas may arise in the pancreas, the peripancreatic region, or the wall of the duodenum. **Over one-half of gastrin-producing tumors are locally invasive or have already metastasized at the time of diagnosis.** In approximately 25% of patients, gastrinomas arise in conjunction with other endocrine tumors, thus conforming to the MEN-1 syndrome (discussed later); MEN-1–associated gastrinomas frequently are multifocal, while sporadic gastrinomas usually are single. As with insulin-secreting tumors of the pancreas, gastrin-producing tumors are histologically bland and rarely exhibit marked anaplasia.

Adrenal Cortex

The adrenal glands are paired endocrine organs consisting of two regions, the cortex and medulla, which differ in their development, structure, and function. The *cortex* consists of three layers of distinct cell types. Beneath the capsule of the adrenal gland is the narrow layer of zona glomerulosa. An equally narrow zona reticularis abuts the

medulla. Intervening is the broad zona fasciculata, which makes up about 75% of the total cortex.

The adrenal cortex synthesizes three different types of steroids:

- *Glucocorticoids* (principally cortisol), synthesized primarily in the zona fasciculata, with a small contribution from the zona reticularis
- *Mineralocorticoids,* the most important being aldosterone, generated in the zona glomerulosa
- *Sex steroids* (estrogens and androgens), produced largely in the zona reticularis

The *adrenal medulla* is composed of chromaffin cells, which synthesize and secrete *catecholamines,* mainly epinephrine. This section deals first with disorders of the adrenal cortex and then of the medulla. Diseases of the adrenal cortex can be conveniently divided into those associated with cortical hyperfunction or hypofunction.

ADRENOCORTICAL HYPERFUNCTION: HYPERADRENALISM

There are three distinctive hyperadrenal clinical syndromes, each caused by abnormal production of one or more of the hormones produced by the three layers of the cortex:

- *Cushing syndrome,* characterized by an excess of cortisol
- *Hyperaldosteronism,* caused by an excess of mineralocorticoid
- *Adrenogenital* or *virilizing syndromes,* caused by an excess of androgens

The clinical features of some of these syndromes show some similarities because of the shared functions of adrenal steroids.

Hypercortisolism: Cushing Syndrome

Hypercortisolism (Cushing syndrome) is caused by elevated glucocorticoid levels. In clinical practice, the vast majority of cases of Cushing syndrome are the result of administration of exogenous glucocorticoids (iatrogenic). The remaining cases are endogenous, and the three most common disorders are as follows (Fig. 20.34):

- Primary hypothalamic-pituitary diseases associated with hypersecretion of ACTH
- Secretion of ectopic ACTH by nonpituitary neoplasms
- Primary adrenocortical neoplasms (adenoma or carcinoma) and, rarely, primary cortical hyperplasia

Primary hypothalamic-pituitary disease associated with hypersecretion of ACTH, also known as *Cushing disease,*

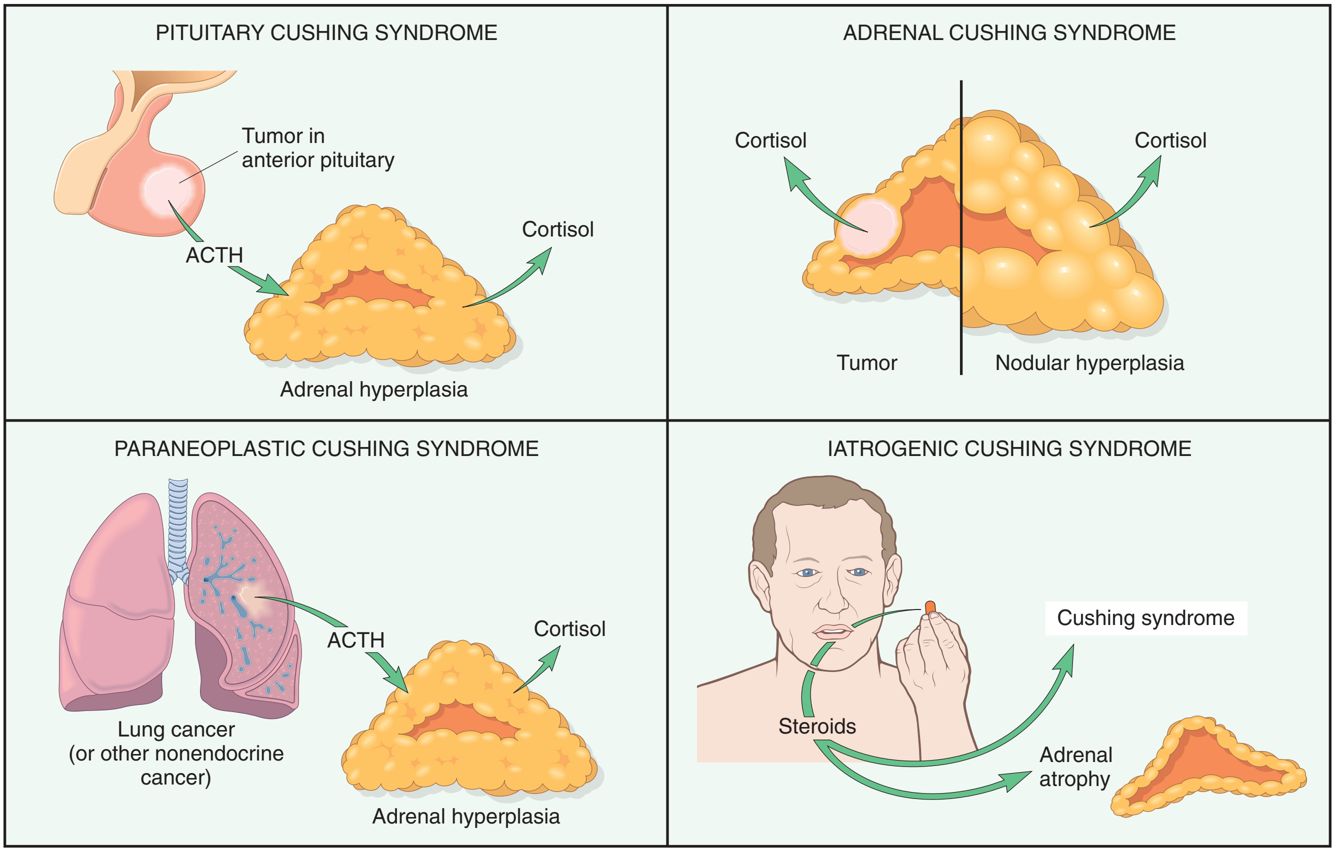

Fig. 20.34 Schematic representation of the various forms of Cushing syndrome: The three endogenous forms, as well as the more common exogenous (iatrogenic) form. *ACTH,* Adrenocorticotropic hormone.

accounts for approximately 70% of cases of spontaneous, endogenous Cushing syndrome. The prevalence of this disorder is about four times higher among women than among men, and it occurs most frequently during young adulthood (the twenties and thirties). In the vast majority of cases, the *pituitary gland contains an ACTH-producing microadenoma* that does not produce mass effects in the brain. In some cases there is a microadenoma and rarely, the anterior pituitary contains areas of *corticotroph cell hyperplasia* without a discrete adenoma. Corticotroph cell hyperplasia may be primary or, much less commonly, secondary to excessive ACTH release by a hypothalamic corticotropin-releasing hormone (CRH)–producing tumor. The adrenal glands in patients with Cushing disease show variable degrees of bilateral nodular cortical hyperplasia (discussed later), secondary to the elevated levels of ACTH ("ACTH-dependent" Cushing syndrome). The cortical hyperplasia is, in turn, responsible for the hypercortisolism.

Secretion of ectopic ACTH by nonpituitary tumors accounts for about 10% of cases of Cushing syndrome. In many instances the responsible tumor is a *small-cell carcinoma of the lung,* although other neoplasms, including carcinoids, medullary carcinomas of the thyroid, and PanNETs, have been associated with the syndrome. In addition to tumors that elaborate ectopic ACTH, occasional neuroendocrine neoplasms produce ectopic CRH, which, in turn, causes ACTH secretion and hypercortisolism. As in the pituitary variant, the adrenal glands undergo bilateral cortical hyperplasia secondary to elevated ACTH, but the rapid downhill course of patients with these cancers often cuts short the adrenal enlargement.

Primary adrenal neoplasms, such as adrenal adenoma and carcinoma, and rarely, *primary cortical hyperplasia,* are responsible for about 15% to 20% of cases of endogenous Cushing syndrome, also designated *ACTH-independent Cushing syndrome,* because the adrenals function autonomously. The biochemical hallmark of adrenal Cushing syndrome is elevated levels of cortisol and low serum levels of ACTH. In most cases, adrenal Cushing syndrome is caused by a unilateral adrenocortical neoplasm, which may be benign (adenoma) or malignant (carcinoma). Primary cortical hyperplasia of the adrenal cortices is a rare cause of Cushing syndrome. There are two variants of this entity; the first presents as macronodules of varying sizes (typically less than 3 cm in diameter) and the second as micronodules (1–3 mm).

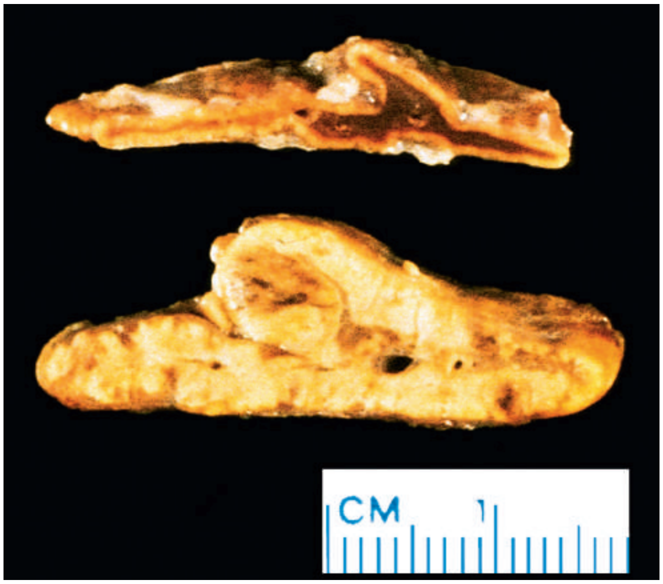

Fig. 20.35 Diffuse hyperplasia of the adrenal gland *(bottom)* contrasted with a normal adrenal gland *(top)*. In a cross-section, the adrenal cortex is yellow and thickened, and a subtle nodularity is evident. The abnormal gland was from a patient with ACTH-dependent Cushing syndrome, in whom both adrenal glands were diffusely hyperplastic. *ACTH*, Adrenocorticotropic hormone.

MORPHOLOGY

The main lesions of Cushing syndrome are found in the pituitary and adrenal glands. The **pituitary** in Cushing syndrome shows changes that vary with different causes. The most common alteration, resulting from high levels of endogenous or exogenous glucocorticoids, is termed Crooke hyaline change. In this condition, the normal granular, basophilic cytoplasm of the ACTH-producing cells in the anterior pituitary is replaced by homogeneous, lightly basophilic material. This alteration is the result of the accumulation of intermediate keratin filaments in the cytoplasm. In pituitary Cushing syndrome, there is an adenoma (described under diseases of the pituitary).

Morphologic changes in the adrenal glands also depend on the cause of the hypercortisolism and include: (1) cortical atrophy, (2) diffuse hyperplasia, (3) macronodular or micronodular hyperplasia, or (4) an adenoma or carcinoma.

In patients in whom the syndrome results from exogenous glucocorticoids, suppression of endogenous ACTH results in bilateral **cortical atrophy,** due to a lack of stimulation of the zona fasciculata and zona reticularis by ACTH. The zona glomerulosa is of normal thickness in such cases, because this portion of the cortex functions independently of ACTH. In cases of endogenous hypercortisolism, by contrast, the adrenals either are hyperplastic or contain a cortical neoplasm.

Diffuse hyperplasia is found in patients with ACTH-dependent Cushing syndrome (Fig. 20.35). Both glands are enlarged, either subtly or markedly, each weighing up to 30 g. The adrenal cortex is diffusely thickened and variably nodular, although the latter is not as pronounced as in cases of ACTH-independent nodular hyperplasia. The yellow color of diffusely hyperplastic glands derives from the presence of **lipid-rich** cells, which appear vacuolated under the microscope.

In **primary cortical hyperplasia,** the cortex is replaced almost entirely by **macronodules** or 1- to 3-mm darkly pigmented **micronodules** (Fig. 20.36). The pigment is believed to be lipofuscin, a wear-and-tear pigment (Chapter 2).

Functional adenomas or carcinomas of the adrenal cortex are not morphologically distinct from nonfunctioning adrenal neoplasms (discussed later). Both the benign and malignant lesions are more common in women in their thirties to fifties. Adrenocortical **adenomas** are yellow tumors surrounded by thin or well-developed capsules, and most weigh less than 30 g (Fig. 20.37A). On microscopic examination, they are composed of cells similar to those encountered in the normal zona fasciculata (see Fig. 20.37B). The **carcinomas** associated with Cushing syndrome, by contrast, tend to be larger than the adenomas.

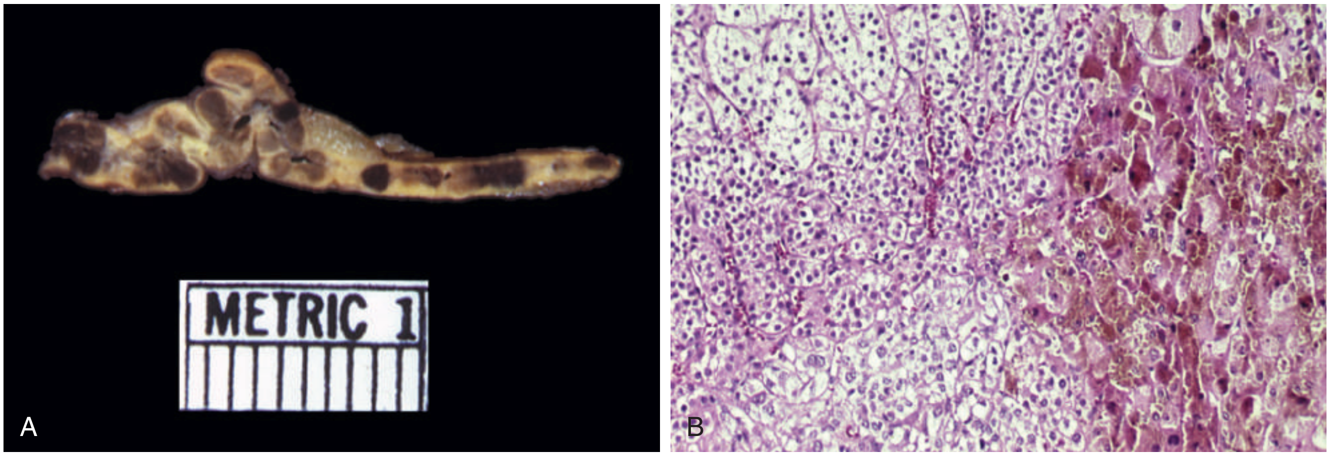

Fig. 20.36 (A) Primary pigmented nodular adrenocortical hyperplasia showing prominent pigmented nodules in the adrenal gland. (B) On histologic examination, the nodules are composed of cells containing lipofuscin pigment, seen in the right part of the field. *(Photographs courtesy of Dr. Aidan Carney, Department of Medicine, Mayo Clinic, Rochester, Minnesota.)*

These tumors are nonencapsulated masses frequently exceeding 200 to 300 g in weight, having all of the anaplastic characteristics of cancer, as detailed later. With functioning tumors, both benign and malignant, the adjacent adrenal cortex and that of the contralateral adrenal gland are atrophic, as a result of suppression of endogenous ACTH by high cortisol levels.

Clinical Features

The signs and symptoms of Cushing syndrome represent an exaggeration of the known actions of glucocorticoids. Cushing syndrome usually develops gradually and, like many other endocrine abnormalities, may be quite subtle in its early stages. A major exception to this insidious onset is Cushing syndrome associated with small-cell carcinomas of the lung, when the rapid course of the underlying disease precludes development of many of the characteristic features. Early manifestations of Cushing syndrome include *hypertension* and *weight gain.* With time, the more characteristic centripetal redistribution of adipose tissue becomes apparent, with resultant truncal obesity, "moon facies," and accumulation of fat in the posterior neck and back ("buffalo hump"). Hypercortisolism causes selective atrophy of fast-twitch (type II) myofibers, with resultant decreased muscle mass and proximal limb weakness. Glucocorticoids induce gluconeogenesis and inhibit the uptake of glucose by cells, resulting in secondary diabetes with its attendant *hyperglycemia*, *glucosuria*, and *polydipsia*. The catabolic effects of insulin resistance on proteins cause loss of collagen. Thus, the skin is thin, fragile, and easily bruised; *cutaneous striae* are particularly common in the abdominal area (Fig. 20.38). Cortisol also has diverse effects on calcium metabolism that lead to resorption of bone, which results in the development of *osteoporosis,* with consequent increased susceptibility to fractures. Because

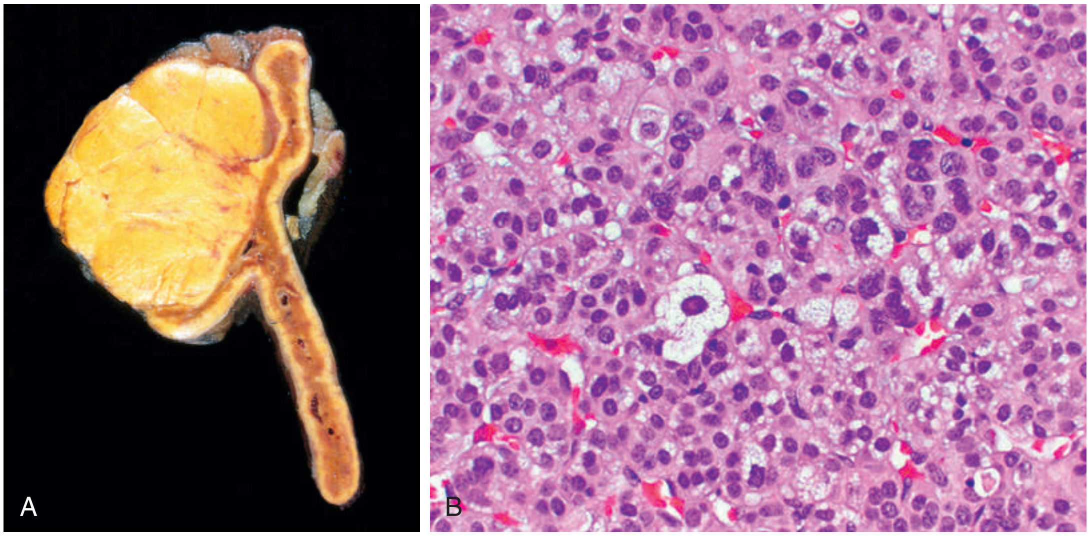

Fig. 20.37 Adrenocortical adenoma. (A) The adenoma is distinguished from nodular hyperplasia by its solitary, circumscribed nature. The functional status of an adrenocortical adenoma cannot be predicted from its gross or microscopic appearance. (B) Histologic features of an adrenal cortical adenoma. The neoplastic cells are vacuolated because of the presence of intracytoplasmic lipid. There is mild nuclear pleomorphism. Mitotic activity and necrosis are not seen.

Fig. 20.38 A patient with Cushing syndrome. Characteristic features include central obesity, "moon facies," and abdominal striae. *(Reproduced with permission from Lloyd RV, et al:* Atlas of nontumor pathology: endocrine diseases. *Washington, DC, American Registry of Pathology, 2002.)*

glucocorticoids suppress the immune response, patients with Cushing syndrome also are at increased risk for a variety of infections. Additional manifestations include *hirsutism* and *menstrual abnormalities,* as well as a number of *psychiatric symptoms* including mood swings, depression, and frank psychosis. Extraadrenal Cushing syndrome caused by pituitary or ectopic ACTH secretion usually is associated with increased skin pigmentation secondary to melanocyte-stimulating activity in the ACTH precursor molecule.

In pituitary and ectopic Cushing syndrome, ACTH levels are elevated and the urine is characterized by high levels of excreted corticosteroids. In contrast, ACTH levels are low in Cushing syndrome secondary to adrenal tumors.

SUMMARY

HYPERCORTISOLISM (CUSHING SYNDROME)

- The most common cause of hypercortisolism is exogenous administration of steroids.
- Endogenous hypercortisolism most often is secondary to an ACTH-producing pituitary microadenoma *(Cushing disease),* followed by primary adrenal neoplasms (*ACTH-independent* hypercortisolism) and paraneoplastic ACTH production by tumors (e.g., small-cell lung cancer).
- The morphologic features in the adrenal include bilateral cortical atrophy (in exogenous steroid-induced disease), bilateral diffuse or nodular hyperplasia (most common finding in endogenous Cushing syndrome), or an adrenocortical neoplasm.

Hyperaldosteronism

Hyperaldosteronism is the generic term for a group of closely related conditions characterized by chronic excess aldosterone secretion. Hyperaldosteronism may be primary, or it may be secondary to an extraadrenal cause.

Primary hyperaldosteronism refers to autonomous overproduction of aldosterone with resultant suppression of the renin-angiotensin system and decreased plasma renin activity. The causes of primary hyperaldosteronism are as follows (Fig. 20.39):

- *Bilateral idiopathic hyperaldosteronism,* characterized by bilateral nodular hyperplasia of the adrenal glands. This is the most common underlying cause of primary hyperaldosteronism, accounting for about 60% of cases. The pathogenesis of idiopathic hyperaldosteronism is unclear, although a subset harbors germ line mutations in the *KCNJ5* gene, which encodes a potassium channel protein that is expressed in the adrenal gland.
- *Adrenocortical neoplasm,* either an aldosterone-producing adenoma (the most common cause) or, rarely, an adrenocortical carcinoma. In approximately 35% of cases, primary hyperaldosteronism is caused by a solitary aldosterone-secreting adenoma, a condition referred to as *Conn syndrome.* Somatic mutations of *KCNJ5* (see earlier) are also present in a subset of aldosterone-secreting adenomas.
- Rarely, familial hyperaldosteronism may result from a genetic defect that leads to overactivity of the *aldosterone synthase gene, CYP11B2.*

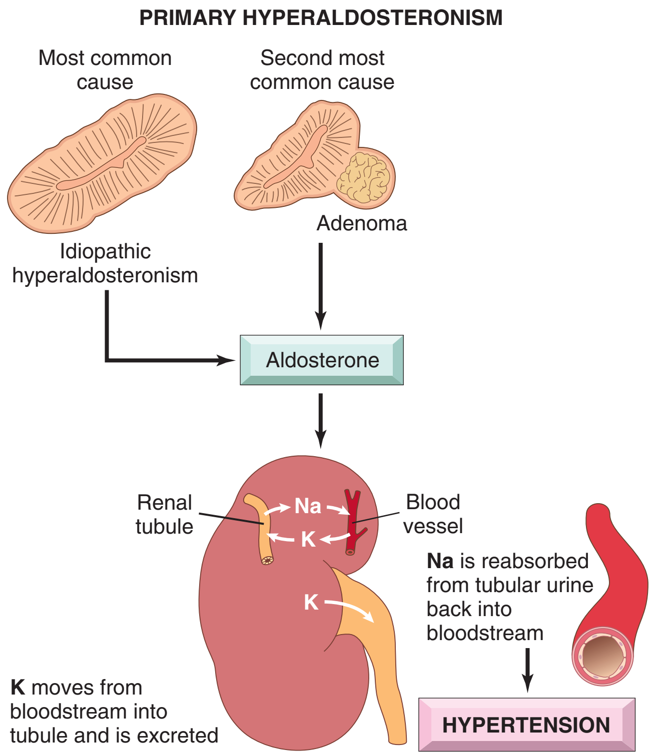

Fig. 20.39 The major causes of primary hyperaldosteronism and its principal effects on the kidney.

In *secondary hyperaldosteronism,* aldosterone release occurs in response to activation of the renin-angiotensin system. This condition is characterized by *increased levels of plasma renin* and is encountered in association with the following:

- Decreased renal perfusion (arteriolar nephrosclerosis, renal artery stenosis)
- Arterial hypovolemia and edema (congestive heart failure, cirrhosis, nephrotic syndrome)
- Pregnancy (caused by estrogen-induced increases in plasma renin substrate)

MORPHOLOGY

Aldosterone-producing adenomas are almost always solitary, small (<2 cm in diameter), well-circumscribed lesions. They are bright yellow on cut section and, surprisingly, are composed of lipid-laden cortical cells more closely resembling fasciculata cells than glomerulosa cells (the normal source of aldosterone). In general, the cells tend to be uniform in size and shape; occasionally there is some nuclear and cellular pleomorphism. A characteristic feature of aldosterone-producing adenomas is the presence of eosinophilic, laminated cytoplasmic inclusions, known as ***spironolactone bodies.*** These typically are found after treatment with the anti-hypertensive agent spironolactone, which is the drug of choice in primary hyperaldosteronism. In contrast with cortical adenomas associated with Cushing syndrome, those associated with hyperaldosteronism do not usually suppress ACTH secretion. Therefore, the adjacent adrenal cortex and that of the contralateral gland are not atrophic. **Bilateral idiopathic hyperplasia** is marked by diffuse or focal hyperplasia of cells resembling those of the normal zona glomerulosa.

Clinical Features

The most important clinical consequence of hyperaldosteronism is hypertension. With an estimated prevalence rate of 5% to 10% among unselected hypertensive patients, primary hyperaldosteronism may be the most common cause of secondary hypertension (i.e., hypertension secondary to an identifiable cause). The long-term effects of hyperaldosteronism-induced hypertension are cardiovascular compromise (e.g., left ventricular hypertrophy and reduced diastolic volumes) and an increase in the prevalence of adverse events such as stroke and myocardial infarction. *Hypokalemia* results from renal potassium wasting and, when present, can cause a variety of neuromuscular manifestations, including weakness, paresthesias, visual disturbances, and occasionally frank tetany. Hypokalemia was considered a mandatory feature of primary hyperaldosteronism, but almost 50% of normokalemic patients are now being diagnosed largely due to early detection.

In primary hyperaldosteronism, the therapy varies according to cause. Adenomas are amenable to surgical excision. By contrast, surgical intervention is not very beneficial in patients with primary hyperaldosteronism due to bilateral hyperplasia, which often occurs in children and young adults. These patients are best managed medically with an *aldosterone antagonist* such as spironolactone. The treatment of secondary hyperaldosteronism rests on correcting the underlying cause of the renin-angiotensin system hyperstimulation.

Adrenogenital Syndromes

Adrenogenital syndromes refer to a group of disorders caused by androgen excess, which may stem from a number of etiologies, including primary gonadal disorders and several primary adrenal disorders. The adrenal cortex secretes two compounds—dehydroepiandrosterone and androstenedione—which require conversion to testosterone in peripheral tissues for their androgenic effects. Unlike gonadal androgens, adrenal androgen formation is regulated by ACTH; thus, excessive secretion can present as an isolated syndrome or in combination with features of Cushing disease. The adrenal causes of androgen excess include *adrenocortical neoplasms* and an uncommon group of disorders collectively designated *congenital adrenal hyperplasia (CAH).* Adrenocortical neoplasms associated with symptoms of androgen excess *(virilization)* are more likely to be carcinomas than adenomas. They are morphologically identical to other functional or nonfunctional cortical neoplasms.

CAH represents a group of autosomal recessive disorders, each characterized by a hereditary defect in an enzyme involved in adrenal steroid biosynthesis, particularly cortisol. In these conditions, decreased cortisol production results in a compensatory increase in ACTH secretion due to absence of feedback inhibition. The resultant adrenal hyperplasia causes increased production of cortisol precursor steroids, which are then channeled into synthesis of androgens with virilizing activity. Certain enzyme defects also may impair aldosterone secretion, adding salt loss to the virilizing syndrome. *The most common enzymatic defect in CAH is 21-hydroxylase deficiency,* which accounts for more than 90% of cases. 21-hydroxylase deficiency may range in degree from a total lack to a mild loss, depending on the nature of the underlying mutation. In the adrenal glands cortisol, aldosterone and sex steroids are synthesized from cholesterol through various intermediates. 21-hydroxylase is required for synthesis of cortisol and aldosterone but not sex steroids. Thus, a deficiency of this enzyme reduces cortisol and aldosterone synthesis and shunts the common precursors into the sex steroid pathway.

MORPHOLOGY

In all cases of CAH, the adrenals are **hyperplastic bilaterally,** sometimes expanding to 10 to 15 times their normal weights. The adrenal cortex is thickened and nodular, and on cut section, the widened cortex appears brown as a result of depletion of lipid. The proliferating cells mostly are compact, eosinophilic cells intermixed with lipid-laden clear cells. Hyperplasia of corticotroph (ACTH-producing) cells is present in the anterior pituitary in most patients.

Clinical Features

The clinical manifestations of CAH are determined by the specific enzyme deficiency and include abnormalities

related to androgen excess, with or without aldosterone and glucocorticoid deficiency. Depending on the nature and severity of the enzymatic defect, the onset of clinical symptoms may occur in the perinatal period, later childhood, or (less commonly) adulthood.

In 21-hydroxylase deficiency, excessive androgenic activity causes signs of masculinization in females, ranging from clitoral hypertrophy and pseudohermaphroditism in infants to oligomenorrhea, hirsutism, and acne in postpubertal girls. In males, androgen excess is associated with enlargement of the external genitalia and other evidence of precocious puberty in young patients. Most men with CAH are fertile but some have failure of Leydig cell development and oligospermia. In approximately one-third of individuals with 21-hydroxylase deficiency, the enzymatic defect is severe enough to produce aldosterone deficiency, with resultant salt (sodium) wasting. Concomitant cortisol deficiency places individuals with CAH at risk for acute adrenal insufficiency (discussed later).

CAH should be suspected in any neonate with ambiguous genitalia. Severe enzyme deficiency in infancy can be a life-threatening condition, with vomiting, dehydration, and salt wasting. In the milder variants, women may present with delayed menarche, oligomenorrhea, or hirsutism. In all cases, an androgen-producing ovarian neoplasm must be excluded. Treatment of CAH is with exogenous glucocorticoids, which, in addition to providing adequate levels of glucocorticoids, also suppress ACTH levels, thereby decreasing the excessive synthesis of the steroid hormones responsible for many of the clinical abnormalities. Mineralocorticoid supplementation is required in the salt-wasting variants of CAH.

SUMMARY
ADRENOGENITAL SYNDROMES

- The adrenal cortex can secrete excess androgens in either of two settings: adrenocortical neoplasms (usually *virilizing* carcinomas) or congenital adrenal hyperplasia (CAH).
- CAH consists of a group of autosomal recessive disorders characterized by defects in steroid biosynthesis, usually cortisol; the most common subtype is caused by deficiency of the enzyme 21-hydroxylase.
- Reduction in cortisol production causes a compensatory increase in ACTH secretion, which in turn stimulates androgen production. Androgens have virilizing effects, including masculinization in females (ambiguous genitalia, oligomenorrhea, hirsutism), precocious puberty in males, and, in some instances, salt (sodium) wasting and hypotension.
- Bilateral hyperplasia of the adrenal cortex is characteristic.

ADRENAL INSUFFICIENCY

Adrenocortical insufficiency, or hypofunction, may be caused by either primary adrenal disease (primary hypoadrenalism) or decreased stimulation of the adrenals resulting from ACTH deficiency (secondary hypoadrenalism). Primary adrenocortical insufficiency may be *acute* (called *adrenal crisis*), or *chronic (Addison disease)*.

Table 20.7 Causes of Adrenal Insufficiency

Acute
Waterhouse-Friderichsen syndrome
Sudden withdrawal of long-term corticosteroid therapy
Stress in patients with underlying chronic adrenal insufficiency
Chronic
Autoimmune adrenalitis (60%–70% of cases in developed countries)—includes APS1 (*AIRE* mutations) and APS2 (polygenic)
Infections Tuberculosis Acquired immunodeficiency syndrome Fungal infections
Hemochromatosis
Sarcoidosis
Systemic amyloidosis
Metastatic disease

APS1, APS2, Autoimmune polyendocrine syndrome types 1 and 2; *AIRE,* autoimmune regulator gene.

Acute Adrenocortical Insufficiency

Acute adrenocortical insufficiency occurs most commonly in the clinical settings listed in Table 20.7. Individuals with chronic adrenocortical insufficiency may develop an acute crisis after any stress that taxes their limited physiologic reserves. In patients maintained on exogenous corticosteroids, rapid withdrawal of steroids or failure to increase steroid doses in response to an acute stress may precipitate a similar adrenal crisis, because of the inability of the atrophic adrenals to produce glucocorticoid hormones. *Massive adrenal hemorrhage* may destroy enough of the adrenal cortex to cause acute adrenocortical insufficiency. This condition may occur in patients maintained on anti-coagulant therapy, in postoperative patients who develop disseminated intravascular coagulation, during pregnancy, and in patients suffering from overwhelming sepsis; in the latter setting, it is known as the *Waterhouse-Friderichsen syndrome* (Fig. 20.40). This catastrophic syndrome is classically associated with *Neisseria meningitidis* septicemia but can also be caused by other organisms. Waterhouse-Friderichsen syndrome can occur at any age but is somewhat more common in children. The basis for the adrenal hemorrhage is uncertain but may be attributable to direct bacterial seeding of small vessels in the adrenal, the development of disseminated intravascular coagulation (Chapter 4), endotoxin-induced vasculitis, or some form of hypersensitivity vasculitis.

Chronic Adrenocortical Insufficiency: Addison Disease

Addison disease, or chronic adrenocortical insufficiency, is an uncommon disorder resulting from progressive destruction of the adrenal cortex. More than 90% of all cases are attributable to one of four disorders: *autoimmune adrenalitis, tuberculosis,* the *acquired immune deficiency syndrome* (AIDS), or *metastatic cancer* (see Table 20.7).

- *Autoimmune adrenalitis* accounts for 60% to 70% of cases and is by far the most common cause of primary adrenal insufficiency in countries where infectious causes are

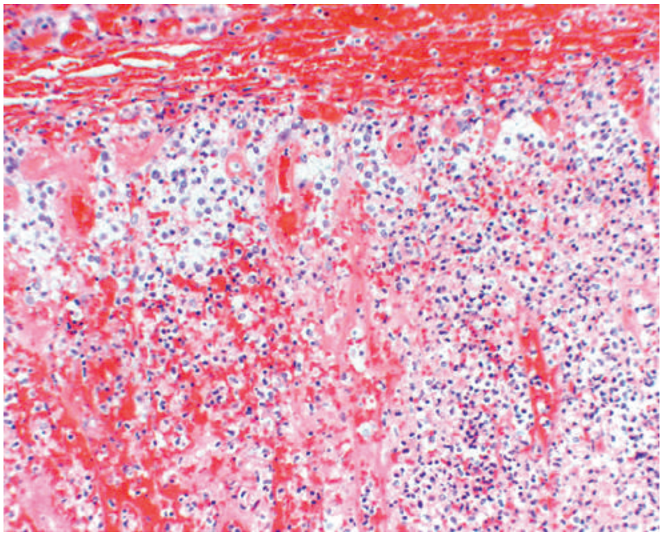

Fig. 20.40 Waterhouse-Friderichsen syndrome. Bilateral adrenal hemorrhage in an infant with overwhelming sepsis, resulting in acute adrenal insufficiency. At autopsy, the adrenal glands were grossly hemorrhagic and shrunken; in this photomicrograph, little residual cortical architecture is discernible.

uncommon. As the name implies, there is autoimmune destruction of steroid-producing cells, and autoantibodies to several key steroidogenic enzymes have been detected in affected patients. Autoimmune adrenalitis may occur in association with several distinct *a*utoimmune *p*olyendocrine *s*yndromes (APS). The best characterized of these is APS1, which is caused by mutations in the *autoimmune regulator (AIRE)* gene on chromosome 21. It is characterized by mucocutaneous candidiasis and abnormalities of skin, dental enamel, and nails (ectodermal dystrophy) occurring in association with a combination of organ-specific autoimmune disorders that result in destruction of target organs. The AIRE protein is involved in the expression of tissue antigens in the thymus and the elimination of T cells specific for these antigens (Chapter 5). Individuals with APS1 develop autoantibodies against IL-17 and IL-22, which are the principal effector cytokines secreted by T_H17 T cells (Chapter 5). Because these two T_H17-derived cytokines are crucial for defense against fungal infections, affected patients develop chronic mucocutaneous candidiasis.

- *Infections,* particularly tuberculosis and those produced by fungi, also may cause primary chronic adrenocortical insufficiency. Tuberculous adrenalitis, which once accounted for as many as 90% of cases of Addison disease, has become less common with improved anti-tuberculosis therapy. With the resurgence of tuberculosis mainly because of HIV infection and immunodeficiency, this cause of adrenal deficiency must be borne in mind. When present, tuberculous adrenalitis usually is associated with active infection in other sites, particularly the lungs and genitourinary tract. Among fungi, disseminated infections caused by *Histoplasma capsulatum* and *Coccidioides immitis* also may result in chronic adrenocortical insufficiency. Patients with AIDS are at risk for the development of adrenal insufficiency from several other infectious (cytomegalovirus, *Mycobacterium avium-intracellulare*) and noninfectious (Kaposi sarcoma) complications of their disease.
- *Metastatic neoplasms* involving the adrenals are another potential cause of adrenal insufficiency. The adrenals are a fairly common site for metastases in patients with disseminated carcinomas, which sometimes destroy sufficient adrenal cortex to produce a degree of adrenal insufficiency. Carcinomas of the lung and breast are the source of a majority of metastases in the adrenals.

Secondary Adrenocortical Insufficiency

Any disorder of the hypothalamus and pituitary that reduces the output of ACTH, such as metastatic cancer, infection, infarction, or irradiation, leads to a syndrome of hypoadrenalism having many similarities to Addison disease. ACTH deficiency may occur alone, but in some instances, it is only one part of panhypopituitarism, associated with multiple pituitary hormone deficiencies. In patients with primary disease, the destruction of the adrenal cortex prevents a response to exogenously administered ACTH in the form of increased plasma levels of cortisol. By contrast, secondary adrenocortical insufficiency is characterized by low serum ACTH and a prompt rise in plasma cortisol levels in response to ACTH administration.

MORPHOLOGY

The appearance of the adrenal glands varies with the cause of the adrenocortical insufficiency. In **secondary hypoadrenalism,** the adrenals are reduced to small, flattened structures that usually retain their yellow color because of a small amount of residual lipid. A uniform, thin rim of atrophic yellow cortex surrounds a central, intact medulla. Histologic evaluation reveals atrophy of cortical cells with loss of cytoplasmic lipid, particularly in the zona fasciculata and zona reticularis. **Primary autoimmune adrenalitis** is characterized by irregularly shrunken glands, which may be exceedingly difficult to identify within the suprarenal adipose tissue. On histologic examination, the cortex contains only scattered residual cortical cells in a collapsed network of connective tissue. A variable lymphoid infiltrate is present in the cortex and may extend into the subjacent medulla (Fig. 20.41). The medulla is otherwise preserved. In **tuberculosis or fungal diseases,** the adrenal architecture may be effaced by a granulomatous inflammatory reaction identical to that encountered in other sites of infection. When hypoadrenalism is caused by **metastatic carcinoma,** the adrenals are enlarged, and their normal architecture is obscured by the infiltrating neoplasm.

Clinical Features

In general, clinical manifestations of adrenocortical insufficiency do not appear until at least 90% of the adrenal cortex has been compromised. The initial manifestations often include progressive weakness and easy fatigability, which may be dismissed as nonspecific complaints. *Gastrointestinal disturbances* are common and include anorexia, nausea, vomiting, weight loss, and diarrhea. In patients

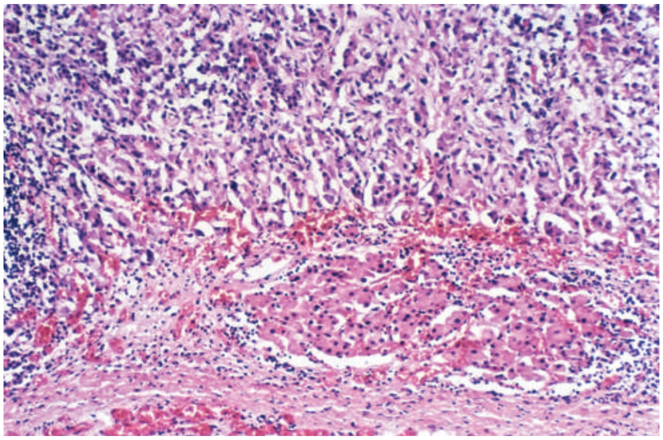

Fig. 20.41 Autoimmune adrenalitis. In addition to loss of all but a subcapsular rim of cortical cells, there is an extensive mononuclear cell infiltrate.

with primary adrenal disease, increased levels of ACTH precursor hormone stimulate melanocytes, with resultant *hyperpigmentation* of the skin and mucosal surfaces. The face, axillae, nipples, areolae, and perineum are particularly common sites of hyperpigmentation. By contrast, hyperpigmentation is not seen in patients with secondary adrenocortical insufficiency because melanotropic hormone levels are not increased. Decreased mineralocorticoid (aldosterone) activity in patients with primary adrenal insufficiency results in potassium retention and sodium loss, with consequent *hyperkalemia, hyponatremia, volume depletion,* and *hypotension*, whereas secondary hypoadrenalism is characterized by deficient cortisol and androgen output but normal or near-normal aldosterone synthesis. Hypoglycemia occasionally may occur as a result of glucocorticoid deficiency and impaired gluconeogenesis. It is more common in infants and children than adults. Stresses such as infections, trauma, or surgical procedures in affected patients may precipitate an acute adrenal crisis, manifested by intractable vomiting, abdominal pain, hypotension, coma, and vascular collapse. Death follows rapidly unless corticosteroids are replaced immediately.

SUMMARY

ADRENOCORTICAL INSUFFICIENCY (HYPOADRENALISM)

- Primary adrenocortical insufficiency can be acute (Waterhouse-Friderichsen syndrome) or chronic (Addison disease).
- Chronic adrenal insufficiency in the Western world most often is secondary to autoimmune adrenalitis, which occurs in the context of autoimmune polyendocrine syndromes.
- Tuberculosis and infections due to opportunistic pathogens associated with the human immunodeficiency virus and tumors metastatic to the adrenals are the other important causes of chronic hypoadrenalism.
- Patients typically present with fatigue, weakness, and gastrointestinal disturbances. Primary adrenocortical insufficiency also is characterized by high ACTH levels with associated skin pigmentation.

ADRENOCORTICAL NEOPLASMS

It should be evident from the discussion of adrenocortical hyperfunction that functional adrenal neoplasms may be responsible for any of the various forms of hyperadrenalism. **While functional adenomas are most commonly associated with hyperaldosteronism and with Cushing syndrome, a virilizing neoplasm is more likely to be a carcinoma**. Not all adrenocortical neoplasms, however, elaborate steroid hormones. Determination of whether a cortical neoplasm is functional or not is based on clinical evaluation and measurement of the hormone or its metabolites in the laboratory.

MORPHOLOGY

Adrenocortical adenomas were described earlier in the discussions of Cushing syndrome and hyperaldosteronism. Most cortical adenomas do not cause hyperfunction and usually are encountered as incidental findings at the time of autopsy or during abdominal imaging for an unrelated cause. In fact, the half-facetious appellation of **"adrenal incidentaloma"** has crept into the medical lexicon to describe these incidentally discovered tumors. On cut surface, adenomas usually are yellow to yellow-brown, owing to the presence of lipid within the neoplastic cells (see Fig. 20.37). As a general rule they are small, averaging 1 to 2 cm in diameter. On microscopic examination, adenomas are composed of cells similar to those populating the normal adrenal cortex. As with other endocrine tumors, pleomorphism may be encountered in benign tumors and is not a reliable marker of malignancy.

Adrenocortical carcinomas are rare neoplasms that may occur at any age, including in childhood. Two rare inherited causes of adrenal cortical carcinomas are Li-Fraumeni syndrome (Chapter 6) and Beckwith-Wiedemann syndrome (Chapter 7). In most cases, adrenocortical carcinomas are large, invasive lesions that efface the native adrenal gland. On cut surface, adrenocortical carcinomas typically are variegated, poorly demarcated lesions containing areas of necrosis, hemorrhage, and cystic change (Fig. 20.42). Microscopic examination typically shows these tumors

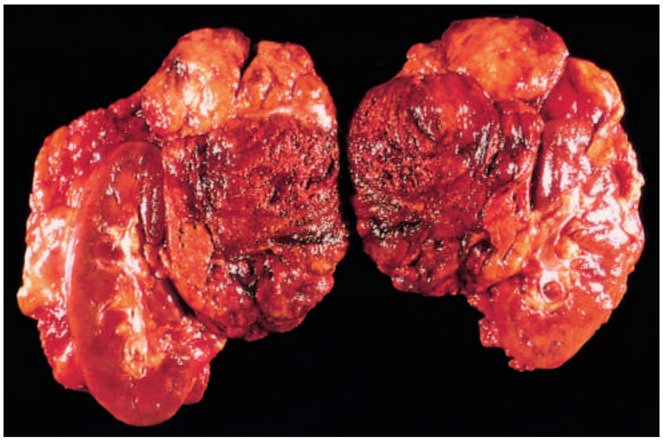

Fig. 20.42 Adrenal carcinoma. The tumor dwarfs the kidney and compresses the upper pole. It is largely hemorrhagic and necrotic.

to be composed of well-differentiated cells resembling those seen in cortical adenomas or bizarre, pleomorphic cells, which may be difficult to distinguish from those of an undifferentiated carcinoma metastatic to the adrenal gland (Fig. 20.43). Adrenal cancers have a strong tendency to invade the adrenal vein, vena cava, and lymphatics. Metastases to regional and periaortic nodes are common, as is distant hematogenous spread to the lungs and other viscera. Bone metastases are unusual. The median patient survival is about 2 years. Of note, **carcinomas metastatic to the adrenal cortex are significantly more frequent than a primary adrenocortical carcinoma.**

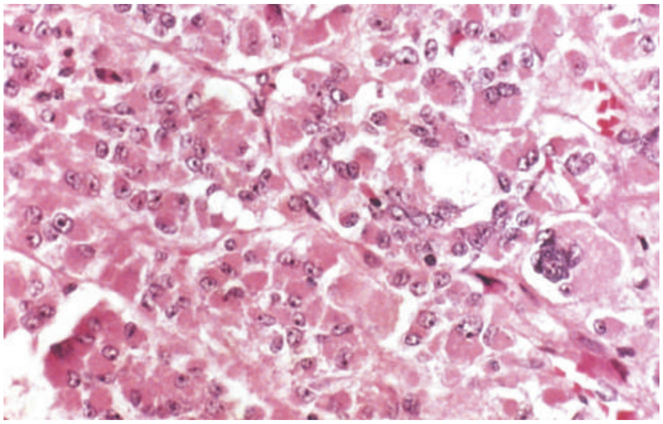

Fig. 20.43 Adrenal carcinoma with marked anaplasia.

Adrenal Medulla

The adrenal medulla is embryologically, functionally, and structurally distinct from the adrenal cortex. It is populated by cells derived from the neural crest (chromaffin cells) and their supporting (sustentacular) cells. The *chromaffin cells* are so named because of their brown-black color after exposure to potassium dichromate. They synthesize and secrete catecholamines in response to signals from preganglionic nerve fibers in the sympathetic nervous system. Similar collections of cells are distributed throughout the body in the extraadrenal paraganglion system. The most important diseases of the adrenal medulla are neoplasms, which include both neuronal neoplasms (including neuroblastomas and more mature ganglion cell tumors) and neoplasms composed of chromaffin cells (pheochromocytomas).

TUMORS OF THE ADRENAL MEDULLA

Pheochromocytoma

Pheochromocytomas are neoplasms composed of chromaffin cells, which, like their nonneoplastic counterparts, synthesize and release catecholamines and, in some cases, other peptide hormones. These tumors are of special importance because, although uncommon, they (like aldosterone-secreting adenomas) give rise to a surgically correctable form of hypertension.

Pheochromocytomas usually subscribe to a convenient "rule of 10s":

- *10% of pheochromocytomas are extraadrenal,* occurring in sites such as the organ of Zuckerkandl and the carotid body, where they usually are called *paragangliomas,* rather than pheochromocytomas.
- *10% of adrenal pheochromocytomas are bilateral;* this proportion may rise to 50% in cases that are associated with familial syndromes.
- *10% of adrenal pheochromocytomas are malignant,* although the associated hypertension represents a serious and potentially lethal complication of even benign tumors. Frank malignancy is somewhat more common in tumors arising in extraadrenal sites.
- *10% of adrenal pheochromocytomas are not associated with hypertension.* Of the 90% that present with hypertension, approximately two-thirds have "paroxysmal" episodes associated with sudden rise in blood pressure and palpitations, which can, on occasion, be fatal.

One "traditional" 10% rule that has since been modified pertains to familial cases. It is now recognized that *as many as 25% of individuals with pheochromocytomas and paragangliomas harbor a germ line mutation* in one of at least six known genes, including *RET,* which causes type 2 MEN syndromes (described later); NF1, which causes type 1 neurofibromatosis (Chapter 22); VHL, which causes von Hippel-Lindau disease (Chapters 14 and 23); and three genes encoding subunits within the succinate dehydrogenase complex (*SDHB, SDHC,* and *SDHD*), which is involved in mitochondrial electron transport and oxygen sensing. It is postulated that loss of function in one or more of these subunits leads to stabilization of the transcription factor hypoxia-inducible factor 1α (HIF-1α), promoting tumorigenesis.

MORPHOLOGY

Pheochromocytomas range in size from small, circumscribed lesions confined to the adrenal to large, hemorrhagic masses weighing several kilograms. On cut surface, smaller pheochromocytomas are yellow-tan, well-defined lesions that compress the adjacent adrenal gland (Fig. 20.44). Larger lesions tend to be hemorrhagic, necrotic, and cystic and typically efface the adrenal gland. Incubation of the fresh tissue with potassium dichromate solutions turns the tumor dark brown, as noted earlier.

On microscopic examination, pheochromocytomas are composed of polygonal to spindle-shaped chromaffin cells and their supporting cells, compartmentalized into small nests, by a rich vascular network (Fig. 20.45). The cytoplasm of the neoplastic cells often has a finely granular appearance, highlighted by a

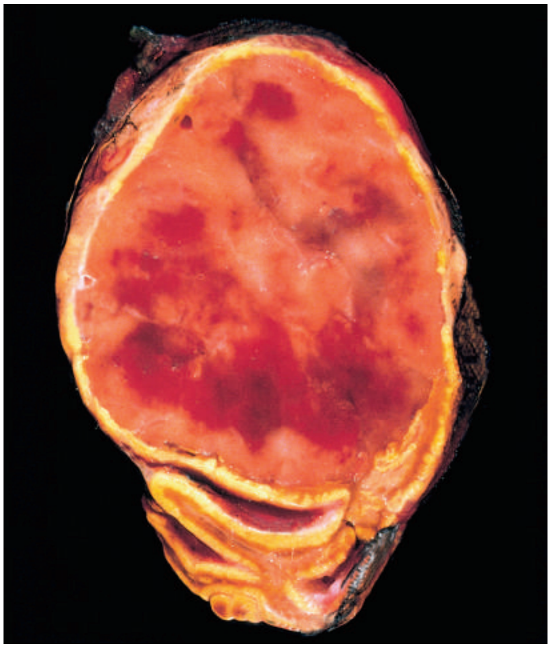

Fig. 20.44 Pheochromocytoma. The tumor is enclosed within an attenuated cortex and demonstrates areas of hemorrhage. The comma-shaped residual adrenal gland is seen *(lower portion).*

variety of silver stains, because of the presence of granules containing catecholamines. Electron microscopy reveals variable numbers of membrane-bound, electron-dense granules, representing catecholamines and sometimes other peptides. The nuclei of the neoplastic cells are often quite pleomorphic. Both capsular and vascular invasion, as well as cellular pleomorphism, may be encountered in some benign lesions. **Therefore, the definitive diagnosis of malignancy in pheochromocytomas is based on the presence of metastases.** These may involve regional lymph nodes as well as more distant sites, including liver, lung, and bone.

Clinical Features

The dominant clinical manifestation of pheochromocytoma is hypertension, observed in 90% of patients. Approximately two-thirds of patients with hypertension demonstrate paroxysmal episodes, which are described as an abrupt, precipitous elevation in blood pressure, associated with tachycardia, palpitations, headache, sweating, tremor, and a sense of apprehension. These episodes may also be associated with pain in the abdomen or chest, nausea, and vomiting. Isolated paroxysmal episodes of hypertension occur in fewer than half of patients; more commonly, patients demonstrate a chronic, sustained elevation in blood pressure punctuated by the aforementioned paroxysms. The elevations of blood pressure are induced by the sudden release of catecholamines that may acutely precipitate congestive heart failure, pulmonary edema, myocardial infarction, ventricular fibrillation, and cerebrovascular accidents. The cardiac complications have been attributed to what has been called *catecholamine cardiomyopathy,* or *catecholamine-induced myocardial instability and ventricular arrhythmias.* In some cases, pheochromocytomas secrete other hormones such as ACTH and somatostatin and may therefore be associated with clinical features related to the effects of these and other peptide hormones. The laboratory diagnosis is based on demonstration of increased urinary excretion of free catecholamines and their metabolites, such as vanillylmandelic acid and metanephrines. Isolated benign pheochromocytomas are treated with surgical excision. With multifocal lesions, long-term medical treatment for hypertension may be required.

Neuroblastoma and Other Neuronal Neoplasms

Neuroblastoma is the most common extracranial solid tumor of childhood. These neoplasms occur most commonly during the first 5 years of life and may arise during infancy. Neuroblastomas may occur anywhere in the sympathetic nervous system and occasionally within the brain, but they are most common in the abdomen; a majority of these tumors arise in either the adrenal medulla or the retroperitoneal sympathetic ganglia. Most neuroblastomas are sporadic, although familial cases also have been described. These tumors are discussed in Chapter 7, along with other pediatric neoplasms.

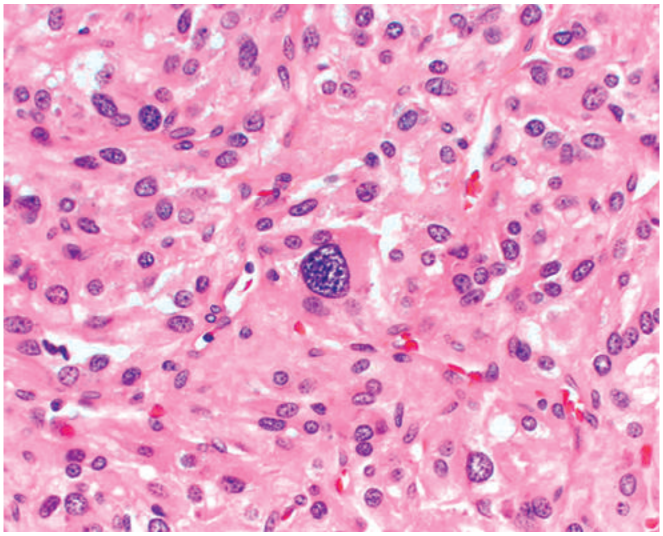

Fig. 20.45 Photomicrograph of pheochromocytoma, demonstrating characteristic nests of cells with abundant cytoplasm. Granules containing catecholamine are not visible in this preparation. It is not uncommon to find bizarre cells (such as the one in the center of this image), even in pheochromocytomas that are benign.

Multiple Endocrine Neoplasia (MEN) Syndromes

The MEN syndromes are a group of inherited diseases caused by proliferative lesions (hyperplasias, adenomas, and carcinomas) of multiple endocrine organs. Like other inherited cancer disorders (Chapter 6), endocrine tumors arising in the context of MEN syndromes have certain distinctive features that are not shared with their sporadic counterparts:

- These tumors occur at a younger age than that typical for sporadic cancers.
- They arise in multiple endocrine organs, either synchronously (at the same time) or metachronously (at different times).
- Even in one organ, the tumors often are multifocal.
- The tumors usually are preceded by an asymptomatic stage of endocrine hyperplasia involving the cell of origin of the tumor (e.g., patients with MEN-2 almost universally demonstrate C cell hyperplasia in the thyroid parenchyma adjacent to medullary thyroid carcinomas).
- These tumors are usually more aggressive and recur in a higher proportion of cases than similar endocrine tumors that occur sporadically.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

MEN-1 syndrome is caused by germ line mutations in the *MEN1* tumor suppressor gene, which encodes a protein called Menin. Menin is a component of several different transcription factor complexes, and loss of Menin function leads to deregulation of the corresponding binding partners, promoting endocrine neoplasia. Organs most commonly involved are the parathyroid, the pancreas, and the pituitary—the "3 Ps."

- *Parathyroid. Primary hyperparathyroidism* is the most common manifestation of MEN-1 (80%–95% of patients) and is the initial manifestation of the disorder in most patients, appearing in almost all by 40 to 50 years of age. Parathyroid abnormalities include hyperplasia and adenomas.
- *Pancreas.* Endocrine tumors of the pancreas are the leading cause of death in MEN-1. These tumors usually are aggressive and present with metastatic disease. Pancreatic endocrine tumors often are functional (i.e., secrete hormones). Zollinger-Ellison syndrome, associated with gastrinomas, and hypoglycemia, associated with insulinomas, are common endocrine manifestations.
- *Pituitary.* The most frequent pituitary tumor in patients with MEN-1 syndrome is a prolactin-secreting macroadenoma. In some cases, acromegaly develops in association with somatotropin-secreting tumors.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

MEN-2 syndrome actually comprises two distinct groups of disorders that are unified by the occurrence of activating (i.e., gain-of-function) mutations of the ***RET*** proto-oncogene at chromosomal locus 10q11.2. A strong genotype-phenotype correlation has been recognized for the MEN-2 syndromes, and differences in mutation patterns account for the variable features in the two subtypes. MEN-2 is inherited in an autosomal dominant pattern.

Multiple Endocrine Neoplasia Type 2A

Organs commonly involved in MEN-2A include the following:

- *Thyroid:* Medullary carcinoma of the thyroid develops in virtually all untreated cases, and the tumors usually occur in the first 2 decades of life. The tumors commonly are multifocal, and foci of C cell hyperplasia can be found in the adjacent thyroid. *Familial medullary thyroid cancer* is seen in a variant of MEN-2A, without the other characteristic manifestations listed here. In comparison with MEN-2, familial medullary carcinoma typically occurs at an older age and follows a more indolent course.
- *Adrenal medulla:* Adrenal pheochromocytomas develop in 50% of the patients; fortunately, no more than 10% of these tumors are malignant.
- *Parathyroid:* Approximately 10% to 20% of patients develop parathyroid gland hyperplasia with manifestations of primary hyperparathyroidism.

Multiple Endocrine Neoplasia Type 2B

A single amino acid change in RET, distinct from the mutations that are seen in MEN-2A, seems to be responsible for virtually all cases of MEN-2B. Patients develop medullary thyroid carcinomas, which are usually multifocal and more aggressive than in MEN-2A, and pheochromocytomas. MEN-2B has the following distinctive features:

- *Primary hyperparathyroidism does not develop* in patients with MEN-2B.
- *Extraendocrine manifestations* are characteristic in patients with MEN-2B. These include ganglioneuromas of mucosal sites (gastrointestinal tract, lips, tongue) and a *marfanoid habitus,* in which overly long bones of the axial skeleton give an appearance resembling that in Marfan syndrome (Chapter 7).

Before the advent of genetic testing, relatives of patients with the MEN-2 syndrome were screened with annual biochemical tests, which often lacked sensitivity. Now, routine genetic testing identifies *RET* mutation carriers earlier and more reliably in MEN-2 kindreds. All individuals carrying germ line RET mutations are advised to have prophylactic thyroidectomy to prevent the inevitable development of medullary carcinomas.

CHAPTER 21

Bones, Joints, and Soft Tissue Tumors

CHAPTER OUTLINE

Bone

BASIC STRUCTURE AND FUNCTION OF BONE

The functions of bone include mechanical support, transmission of forces generated by muscles, protection of viscera, mineral homeostasis, and providing a niche for the production of blood cells. The constituents of bone include an extracellular matrix and specialized cells responsible for production and maintenance of the matrix.

Matrix

Bone matrix is composed of an organic component known as osteoid (35%) and a mineral component (65%). Embedded within the bone matrix are a variety of bone cells including osteocytes that lay down bone and osteoclasts that reabsorb bone. These two cells types maintain bone homeostasis. Osteoid is made up predominantly of type I collagen with smaller amounts of glycosaminoglycans and other proteins. The unique feature of bone matrix, its hardness, is imparted by the inorganic moiety hydroxyapatite ($Ca_{10}[PO_4]_6[OH]_2$). The bone matrix is synthesized in one of two histologic forms, woven or lamellar (Fig. 21.1). Woven bone is produced rapidly, such as during fetal development or fracture repair, but the haphazard arrangement of collagen fibers imparts less structural integrity than the parallel collagen fibers in slowly produced lamellar bone. In an adult, the presence of woven bone is always abnormal, but it is not specific for any particular bone disease. A cross section of a typical long bone shows a dense outer cortex and a central medulla composed of bony trabeculae separated by marrow.

Cells

Bone contains three major cell types:

- *Osteoblasts*, located on the surface of the matrix, synthesize, transport and assemble bone matrix and regulate

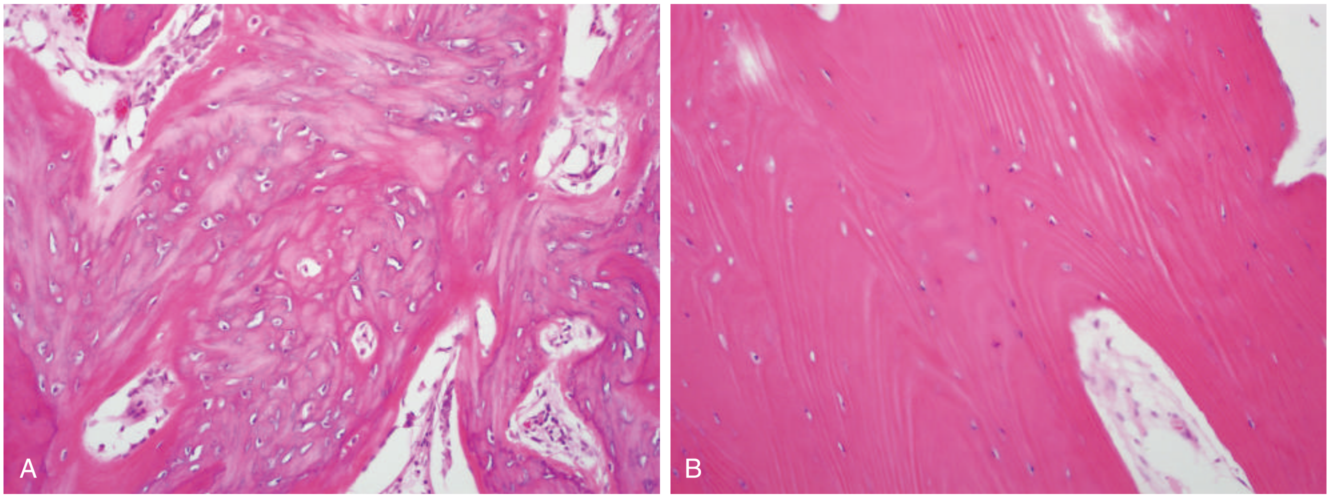

Fig. 21.1 Woven bone (A) is more cellular and disorganized than lamellar bone (B).

its mineralization (Fig. 21.2A). They are derived from mesenchymal stem cells that are located under the periosteum in the developing bone and additionally in the medullary space later in life.

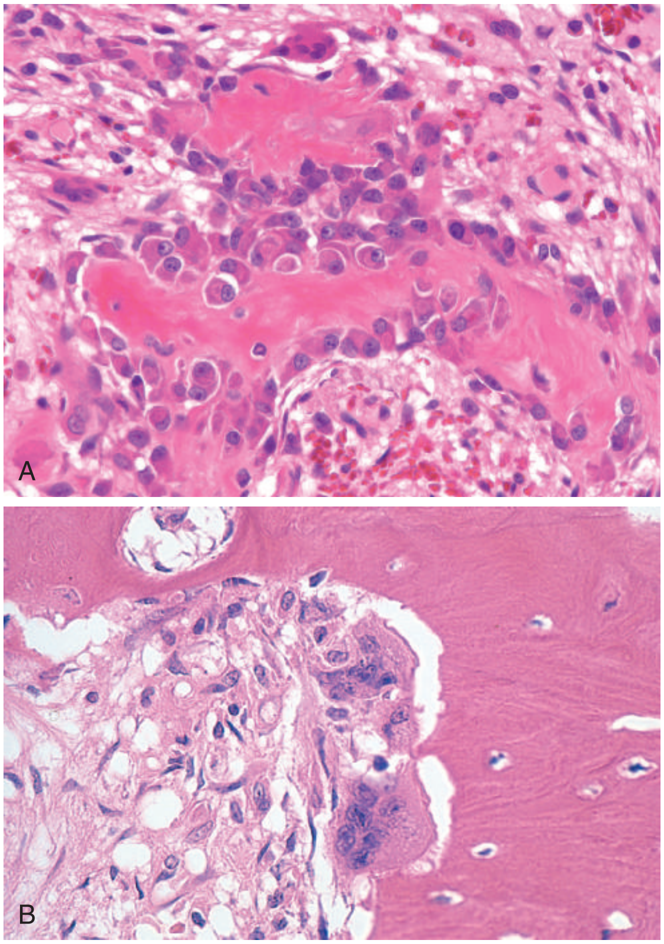

Fig. 21.2 (A) Active osteoblasts synthesizing bone matrix. The surrounding spindle cells represent osteoprogenitor cells. (B) Two osteoclasts resorbing bone.

- *Osteocytes*, located within the bone, are interconnected by an intricate network of cytoplasmic processes through tunnels known as canaliculi. Osteocytes help to control calcium and phosphate levels, detect mechanical forces, and translate them into biologic activity—a process called mechanotransduction.
- *Osteoclasts*, located on the surface of bone, are specialized multinucleated macrophages, derived from circulating monocytes, which are responsible for bone resorption (Fig. 21.2B). By means of cell surface integrins, osteoclasts attach to bone matrix and create a sealed extracellular trench (resorption pit). The cells secrete acid and neutral proteases (predominantly matrix metalloproteases [MMPs]) into the pit, and these enzymes resorb the bone.

Development

During embryogenesis, long bones develop from a cartilage mold by the process of endochondral ossification. A cartilage mold *(anlagen)* is synthesized by mesenchymal precursor cells. At approximately 8 weeks' gestation, the central portion of the anlagen is resorbed, creating the medullary canal. Simultaneously, at midshaft *(diaphysis)*, osteoblasts begin to deposit the cortex beneath the periosteum producing the *primary center of ossification* and growing the bone radially. At each longitudinal end *(epiphysis)*, endochondral ossification proceeds in a centrifugal fashion *(secondary center of ossification)*. Eventually, a plate of the cartilage becomes entrapped between the two expanding centers of ossification, forming the *physis* or *growth plate* (Fig. 21.3). The chondrocytes within the growth plate undergo sequential proliferation, hypertrophy, and apoptosis. In the region of apoptosis the matrix mineralizes and is invaded by capillaries, providing the nutrients for osteoblasts, which synthesize osteoid. This process produces longitudinal bone growth.

Intramembranous ossification, by contrast, is responsible for the development of flat bones. Bones of the cranium, for example, are formed by osteoblasts directly

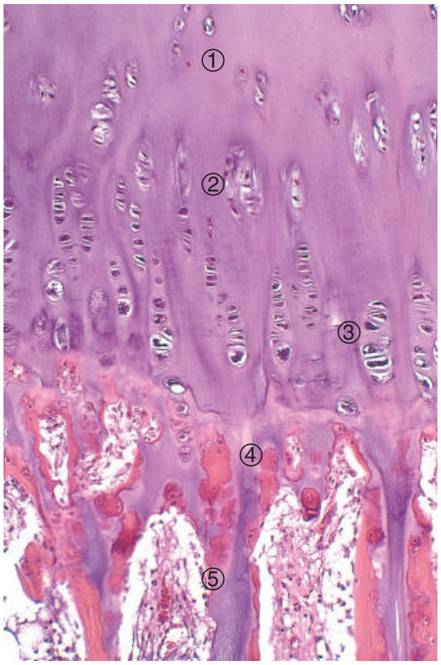

Fig. 21.3 Active growth plate with ongoing endochondral ossification. 1, Reserve zone. 2, Zone of proliferation. 3, Zone of hypertrophy. 4, Zone of mineralization. 5, Primary spongiosa.

from a fibrous layer of tissue, without cartilage anlagen. The enlargement of flat bones is achieved by deposition of new bone on a preexisting surface.

Homeostasis and Remodeling

The adult skeleton appears static but is actually constantly turning over in a tightly regulated process known as remodeling. Remodeling takes place at a microscopic locus known as the bone (or basic) multicellular unit (BMU), which consists of a unit of coupled osteoblast and osteoclast activity on the bone surface.

The events at the BMU are regulated by cell–cell interactions and cytokines (Fig. 21.4). An important signaling pathway that controls remodeling involves three factors: (1) the transmembrane receptor activator of NF-κB (RANK), which is expressed on osteoclast precursors; (2) RANK ligand (RANKL), which is expressed on osteoblasts and marrow stromal cells; and (3) osteoprotegerin (OPG), a secreted "decoy" receptor made by osteoblasts that can block RANK interaction with RANKL. RANK signaling activates the transcription factor NF-κB, which is essential for the generation and survival of osteoclasts. Other important pathways include monocyte-colony stimulating factor (M-CSF), produced by osteoblasts. WNT proteins produced by various cells bind to the LRP5 and LRP6 receptors on osteoblasts and trigger the production of OPG. The importance of these pathways is proven by rare but informative germline mutations in the *OPG, RANK, RANKL,* and *LRP5* genes, which cause severe disturbances of bone metabolism (described later).

Bone resorption or bone formation can be favored by tipping the RANK-to-OPG ratio. Systemic factors that affect this balance include hormones, vitamin D, inflammatory cytokines (e.g., IL-1), and growth factors (e.g., bone morphogenetic factors). The mechanisms are complex, but parathyroid hormone (PTH), IL-1, and glucocorticoids promote osteoclast differentiation and bone turnover. In contrast, BMPs and sex hormones (estrogen, testosterone) generally block osteoclast differentiation or activity by favoring OPG expression.

Peak bone mass is achieved in early adulthood after the cessation of skeletal growth. This set point is determined by many factors, including polymorphisms in the vitamin D and LRP5/6 receptors, nutrition, and physical activity. Beginning in the fourth decade, resorption exceeds formation, resulting in a decline in skeletal mass.

CONGENITAL DISORDERS OF BONE AND CARTILAGE

Congenital abnormalities of the skeleton frequently result from inherited mutations and first become manifest

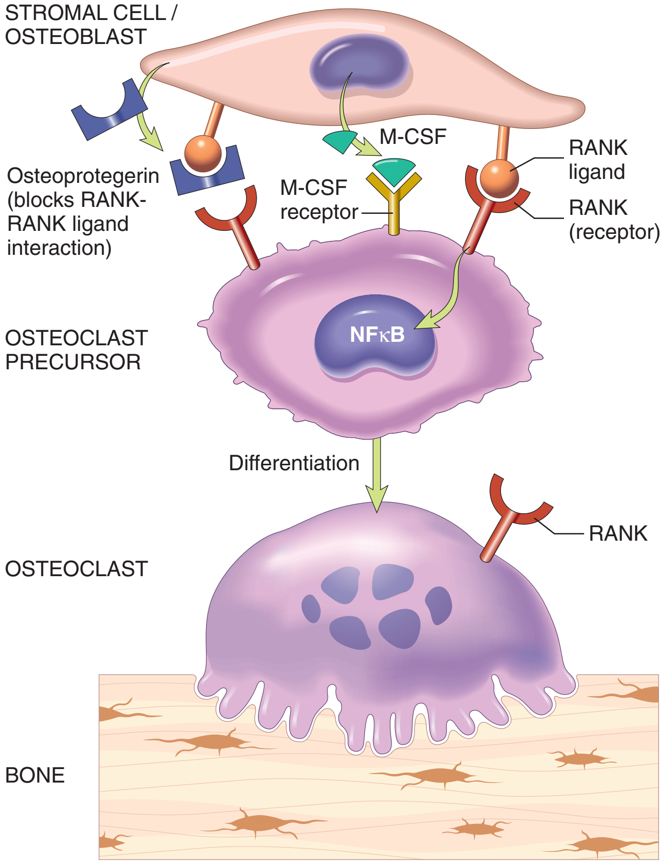

Fig. 21.4 Paracrine molecular mechanisms that regulate osteoclast formation and function. Osteoclasts are derived from the same mononuclear cells that differentiate into macrophages. Osteoblast/stromal cell membrane-associated RANKL binds to its receptor RANK located on the cell surface of osteoclast precursors. This interaction in the background of macrophage colony-stimulating factor (M-CSF) causes the precursor cells to produce functional osteoclasts. Stromal cells also secrete osteoprotegerin (OPG), which acts as a "decoy" receptor for RANKL, preventing it from binding the RANK receptor on osteoclast precursors. Consequently, OPG prevents bone resorption by inhibiting osteoclast differentiation.

during the early stages of bone formation. The spectrum of developmental disorders of bone is broad, and the classification system is not standardized. Here we will categorize the major diseases according to their perceived pathogenesis.

Congenital anomalies can result from localized abnormalities in the migration and condensation of mesenchyme (dysostosis) or global disorganization of bone and/or cartilage (dysplasia). Dysostoses result from defects in the formation of mesenchymal condensations and their differentiation into the cartilage anlage. The most common forms include the complete absence of a bone or a digit *(aplasia)*, extra bones or digits *(supernumerary digit)*, and abnormal fusion of bones (e.g., *syndactyly, craniosynostosis*). Genetic alterations that affect homeobox genes, cytokines, and cytokine receptors are especially common among the dysostoses. In contrast, dysplasias arise from mutations in genes that control development or remodeling of the entire skeleton. It is important to note that, as for developmental anomalies in other tissues, the term *dysplasia* implies abnormal growth rather than a premalignant lesion as used in the context of neoplasia (Chapter 6).

More than 350 skeletal dysostoses and dysplasias, most of them extremely rare, have been described. Examples of diseases with defined genetic abnormalities are discussed below. Note that various point mutations in a single gene (e.g., *COL2A1*) can result in different phenotypes, whereas mutations in diverse genes (e.g., *LRP5, RANKL*) can give rise to similar clinical phenotypes.

Achondroplasia

Achondroplasia, the most common skeletal dysplasia and a major cause of dwarfism, is an autosomal dominant disorder resulting from retarded cartilage growth. The disease is caused by gain-of-function mutations in fibroblast growth factor receptor 3 (FGFR3). Normally, FGF inhibits endochondral growth. FGFR3 mutation results in a constitutively active receptor, thereby exaggerating this effect and suppressing growth. Approximately 90% of cases stem from new mutations, almost all of which occur in the paternal allele. Affected individuals have shortened proximal extremities, a trunk of relatively normal length, and an enlarged head with bulging forehead and conspicuous depression of the root of the nose. The skeletal abnormalities are usually not associated with changes in longevity, intelligence, or reproductive status.

Thanatophoric Dysplasia

Thanatophoric dysplasia, the most common lethal form of dwarfism, results from diminished proliferation of chondrocytes and disorganization in the zone of proliferation. It also is caused by gain-of-function mutations in FGFR3, albeit ones that are distinct from those that cause achondroplasia. It occurs in about 1 of every 20,000 live births. Affected individuals have micromelic shortening of the limbs, frontal bossing, relative macrocephaly, a small chest cavity, and a bell-shaped abdomen. The underdeveloped thoracic cavity leads to respiratory insufficiency, and these individuals usually die at birth or soon thereafter.

Type I Collagen Diseases (Osteogenesis Imperfecta)

Osteogenesis imperfecta (OI), the most common inherited disorder of connective tissue, is a phenotypically diverse disorder caused by deficiencies in the synthesis of type I collagen. OI principally affects bone and other tissues rich in type I collagen (joints, eyes, ears, skin, and teeth). It usually results from autosomal dominant mutations in the genes that encode the α1 and α2 chains of type I collagen. These defects cause misfolding of the mutated collagen polypeptides, and they interfere with the proper assembly of wild-type collagen chains (a *dominant negative* loss of function).

The fundamental abnormality in OI is too little bone, resulting in extreme skeletal fragility. Other findings include blue sclerae caused by decreased collagen content, making the sclera translucent and allowing partial visualization of the underlying choroid; hearing loss related to a sensorineural deficit and impeded conduction due to abnormalities in the bones of the middle ear; and dental imperfections (small, misshapen, and blue-yellow teeth) secondary to a deficiency in dentin.

OI can be separated into multiple clinical subtypes that vary widely in severity. The type 2 variant is at one end of the spectrum and is uniformly fatal in utero or during the perinatal period. In contrast, individuals with the type 1 form have a normal life span despite a susceptibility to fractures, particularly during childhood.

Osteopetrosis

Osteopetrosis, also known as *marble bone disease*, refers to a group of rare genetic diseases that are characterized by reduced bone resorption and diffuse symmetric skeletal sclerosis resulting from impaired formation or function of osteoclasts. The term *osteopetrosis* reflects the stonelike quality of the bones. However, the bones are abnormally brittle and fracture easily, like a piece of chalk. Osteopetrosis is classified into variants based on both the mode of inheritance and the severity of clinical findings.

Most of the mutations underlying osteopetrosis interfere with the process of acidification of the osteoclast resorption pit, which is required for the dissolution of calcium hydroxyapatite within the matrix. These include autosomal recessive mutations in the enzyme carbonic anhydrase 2 (CA2), or mutations in the *TCIRG1* gene, which encodes a component of a vacuolar ATPase that helps to maintain acidic pH in osteoclasts, which is essential for breaking down bone. Bones involved by osteopetrosis lack a medullary canal, and the ends of long bones are bulbous (Erlenmeyer flask deformity) and misshapen. The neural foramina are small and compress exiting nerves. The primary spongiosa, which is normally removed during growth, persists and fills the medullary cavity, leaving no room for the hematopoietic marrow.

Severe infantile osteopetrosis is autosomal recessive and is often fatal because of leukopenia, despite extensive extramedullary hematopoiesis that can lead to prominent hepatosplenomegaly. The mild autosomal dominant form may not be detected until adolescence or adulthood, when it is discovered on radiographic studies for repeated

fractures. These individuals also may have mild cranial nerve deficits and anemia.

SUMMARY

CONGENITAL DISORDERS OF BONE AND CARTILAGE

Abnormalities in a single bone or a localized group of bones are called **dysostoses** and arise from defects in the migration and condensation of mesenchyme. They manifest as absent, supernumerary, or abnormally fused bones. Global disorganizations of bone and/or cartilage are called **dysplasias.** Developmental abnormalities can be categorized by the associated genetic defect.

- FGFR3 mutations are responsible for achondroplasia and thanatophoric dysplasia, both of which manifest as dwarfism.
- Mutations in the genes for type I collagen underlie most types of osteogenesis imperfecta (brittle bone disease), characterized by defective bone formation and skeletal fragility.
- Mutations in *CA2* and *TCIRG1* result in osteopetrosis (in which bones are hard but brittle) and renal tubular acidosis.

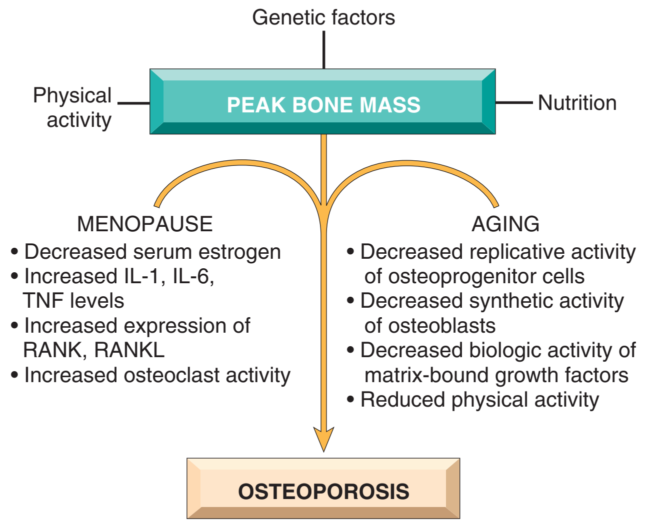

Fig. 21.5 Pathophysiology of postmenopausal and senile osteoporosis (see text).

METABOLIC DISORDERS OF BONE

Osteopenia and Osteoporosis

The term *osteopenia* refers to decreased bone mass, while *osteoporosis* is defined as osteopenia that is severe enough to significantly increase the risk of fracture. Radiographically, osteoporosis is considered bone mass at least 2.5 standard deviations below mean peak bone mass, whereas osteopenia is 1 to 2.5 standard deviations below the mean. The disorder may be localized or generalized (involving the entire skeleton). Although osteoporosis can be secondary to endocrine disorders (e.g., hyperthyroidism), gastrointestinal disorders (e.g., malnutrition), or drugs (e.g., corticosteroids), most osteoporosis is primary.

The most common forms of osteoporosis are the senile and postmenopausal types. The following discussion relates largely to these forms of osteoporosis.

Pathogenesis

Peak bone mass is achieved during young adulthood. Its magnitude is influenced by hereditary factors, especially polymorphisms in the genes that influence bone metabolism (discussed later). Physical activity, muscle strength, diet, and hormonal state also make important contributions. After maximal skeletal mass is attained, bone turnover continues with a net deficit in bone formation resulting in an average loss of 0.7% of bone mass per year. Although much remains unknown, discoveries in the molecular biology of bone formation and resorption have provided new insights into the pathogenesis of osteoporosis (Fig. 21.5):

- *Age-related changes.* Osteoblasts from older individuals have reduced proliferative and biosynthetic potential and reduced response to growth factors compared to osteoblasts in younger individuals. The net result is a diminished capacity to make bone. This form of osteoporosis, known as *senile osteoporosis,* is categorized as a *low-turnover* osteoporosis.
- *Reduced physical activity.* The decreased physical activity that is associated with normal aging contributes to senile osteoporosis. Mechanical forces stimulate normal bone remodeling as evidenced by bone loss in an immobilized or paralyzed extremity. The type of exercise is important, as load magnitude influences bone density more than the number of load cycles. Thus, resistance exercises such as weight training are more effective stimuli for increasing bone mass than repetitive endurance activities such as bicycling.
- *Genetic factors.* Single gene defects (e.g., *LRP5* mutations) account for only a small fraction of osteoporosis cases. Polymorphisms in other genes have been linked to osteoporosis by genome-wide association studies, in particular genes in the Wnt signaling pathway.
- *Calcium nutritional state.* Adolescents (particularly girls) tend to have low dietary calcium intake, a factor that restricts peak bone mass. Calcium deficiency, increased PTH concentrations, and reduced levels of vitamin D also may play a role in the development of senile osteoporosis.
- *Hormonal influences.* In the decade after menopause, yearly reductions in bone mass may be as much as 2% of cortical bone and 9% of medullary bone. *Estrogen deficiency* plays the major role in this phenomenon and close to 40% of postmenopausal women are affected by osteoporosis. Decreased estrogen levels after menopause increase both bone resorption and formation but the latter does not keep up with the former, leading to *high-turnover* osteoporosis. The decreased estrogen may increase secretion of inflammatory cytokines by monocytes. These cytokines stimulate osteoclast recruitment and activity by increasing the levels of RANKL, diminishing the expression of OPG, decreasing osteoclast proliferation, and preventing osteoclast apoptosis. Cytokines such as IL-6, TNF-α, and IL-1 also have been implicated in postmenopausal osteoporosis, either independently or as downstream mediators of estrogen signaling.

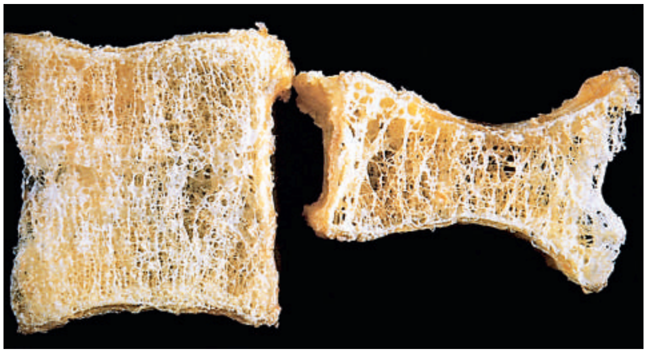

Fig. 21.6 Osteoporotic vertebral body *(right)* shortened by compression fractures compared with a normal vertebral body *(left)*. Note that the osteoporotic vertebra has a characteristic loss of horizontal trabeculae and thickened vertical trabeculae.

MORPHOLOGY

The hallmark of osteoporosis is histologically normal bone that is decreased in quantity. The entire skeleton is affected in postmenopausal and senile osteoporosis, but certain bones tend to be more severely impacted. In postmenopausal osteoporosis the increase in osteoclast activity affects mainly bones or portions of bones that have increased surface area, such as the cancellous compartment of vertebral bodies (Fig. 21.6). The trabecular plates become perforated, thinned, and lose their interconnections (Fig. 21.7), leading to progressive microfractures and eventual vertebral collapse.

Clinical Course

The clinical manifestations of osteoporosis depend on which bones are involved. Vertebral fractures that frequently occur in the thoracic and lumbar regions are painful, and, when multiple, can cause significant loss of height and various deformities, including lumbar *lordosis* and *kyphoscoliosis*. The immobility following fractures of the femoral neck, pelvis, or spine results in complications such as pulmonary embolism and pneumonia, accounting for 40,000 to 50,000 deaths per year.

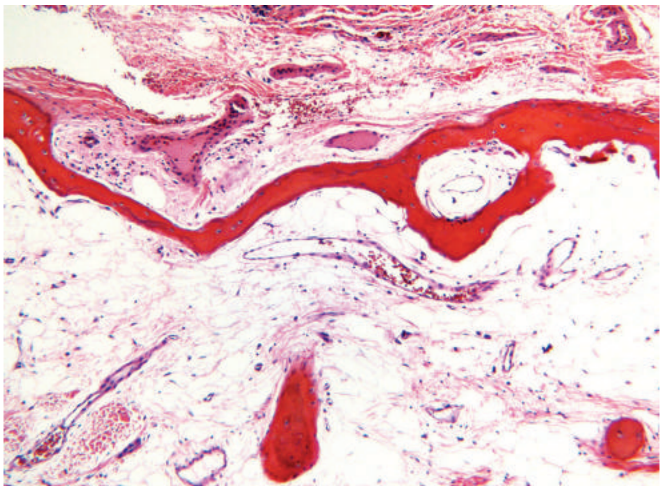

Fig. 21.7 In advanced osteoporosis, both the trabecular bone of the medulla *(bottom)* and the cortical bone *(top)* are markedly thinned.

Osteoporosis cannot be reliably detected in plain radiographs until 30% to 40% of the bone mass is lost, and measurement of blood levels of calcium, phosphorus, and alkaline phosphatase are not diagnostic. Osteoporosis is thus a difficult condition to screen for in asymptomatic people. The best estimates of bone loss, aside from biopsy (which is rarely performed), are specialized radiographic imaging techniques, such as dual-energy x-ray absorptiometry and quantitative computed tomography, both of which measure bone density.

The prevention and treatment of senile and postmenopausal osteoporosis includes exercise, appropriate calcium and vitamin D intake, and pharmacologic agents that decrease resorption (bisphosphonates). Bisphosphonates reduce osteoclast activity and induce osteoclast apoptosis. Denosumab, an anti-RANKL antibody that blocks osteoclast activation, has shown promise in treating some forms of postmenopausal osteoporosis. The major challenge in pharmacotherapy of osteoporosis has been the inability to uncouple bone formation and resorption. Novel agents are currently undergoing clinical trials in an attempt to overcome this limitation. Although menopausal hormone therapy has been used to prevent fracture, complications, particularly deep venous thrombosis and stroke, have prompted the search for more selective estrogen receptor modulators.

Rickets and Osteomalacia

Both rickets and osteomalacia are manifestations of vitamin D deficiency or its abnormal metabolism (detailed in Chapter 8). *Rickets* refers to the disorder in children, in whom it interferes with the deposition of bone in the growth plates. *Osteomalacia* is the adult counterpart, in which bone formed during remodeling is undermineralized, resulting in a predisposition to fractures. The fundamental defect is an impairment of mineralization and a resultant accumulation of unmineralized matrix.

Hyperparathyroidism

Excess production and activity of PTH result in increased osteoclast activity, bone resorption, and osteopenia. Although the entire skeleton is affected, the osteopenia in some bones (e.g., phalanges) is more conspicuous radiographically. Isolated hyperparathyroidism peaks in middle adulthood and slightly earlier if presenting as a component of multiple endocrine neoplasia (MEN, types I and IIA).

Pathogenesis

As discussed in Chapter 20, PTH plays a central role in calcium homeostasis through the following effects:

- Osteoclast activation, increasing bone resorption, and calcium mobilization. PTH mediates the effect indirectly by increased RANKL expression on osteoblasts.
- Increased resorption of calcium by the renal tubules.
- Increased urinary excretion of phosphates.
- Increased synthesis of active vitamin D, 1,25$(OH)_2$-D, by the kidneys, which in turn enhances calcium absorption

from the gut and mobilizes bone calcium by inducing RANKL on osteoblasts.

The net result of the actions of PTH is an elevation in serum calcium, which, under normal circumstances, inhibits further PTH production. However, excessive or inappropriate levels of PTH can result from autonomous parathyroid secretion *(primary hyperparathyroidism)* or can occur in the setting of underlying renal disease *(secondary hyperparathyroidism)* (see Chapter 20). PTH is directly responsible for the bone changes seen in primary hyperparathyroidism. Abnormalities stemming from chronic renal insufficiency that contribute to bone disease in secondary hyperparathyroidism include inadequate 1,25-$(OH)_2$-D synthesis, hyperphosphatemia, metabolic acidosis, and aluminum deposition in bone (in those undergoing renal dialsysis).

MORPHOLOGY

Symptomatic, untreated primary hyperparathyroidism manifests with three interrelated skeletal abnormalities: **osteoporosis, brown tumors,** and **osteitis fibrosa cystica.** Osteoporosis is generalized, but is most severe in the phalanges, vertebrae, and proximal femur. Osteoclasts may tunnel into and dissect centrally along the length of the trabeculae, creating the appearance of railroad tracks and producing what is known as *dissecting osteitis* (Fig. 21.8). The marrow spaces around the affected surfaces are replaced by fibrovascular tissue. The correlative radiographic finding is a decrease in bone density.

The bone loss predisposes to microfractures and secondary hemorrhages that elicit an influx of macrophages and an ingrowth of reparative fibrous tissue, creating a mass of reactive tissue, known as a **brown tumor** (Fig. 21.9). The brown color is the result of the vascularity, hemorrhage, and hemosiderin. These lesions often undergo cystic degeneration. The combination of increased bone cell activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica**.

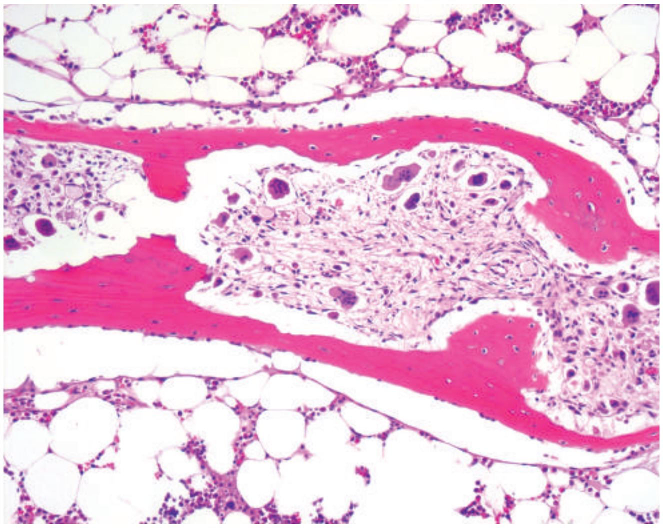

Fig. 21.8 Hyperparathyroidism with osteoclasts boring into the center of the trabecula resembling a train track (dissecting osteitis).

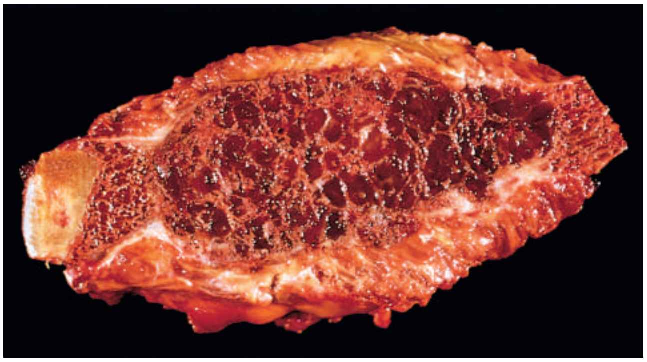

Fig. 21.9 Resected rib, harboring an expansile brown tumor adjacent to the costal cartilage.

Clinical Course

As bone mass decreases, affected patients are increasingly susceptible to fractures, bone deformation, and joint problems. Osteitis fibrosa cystica is now rarely encountered because hyperparathyroidism is usually diagnosed on routine blood tests and treated at an early stage. Restoration of PTH levels to normal can completely reverse the bone changes. Secondary hyperparathyroidism is usually not as severe or as prolonged as primary hyperparathyroidism, hence the skeletal abnormalities tend to be milder.

SUMMARY

METABOLIC DISORDERS OF BONE

- **Osteopenia** and **osteoporosis** represent histologically normal bone that is decreased in quantity. In osteoporosis the bone loss is sufficiently severe to significantly increase the risk of fracture. The disease is very common, with marked morbidity and mortality from fractures. Multiple factors including peak bone mass, age, activity, genetics, nutrition, and hormonal influences contribute to its pathogenesis.
- **Osteomalacia** is characterized by bone that is insufficiently mineralized. In the developing skeleton, the manifestations are characterized by a condition known as **rickets.**
- **Hyperparathyroidism** arises from either autonomous or compensatory hypersecretion of PTH and can lead to **osteoporosis**, **brown tumors,** and **osteitis fibrosa cystica**. However, in developed countries, where early diagnosis is the norm, these manifestations are rarely seen.

PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget disease is a condition of increased, but disordered and structurally unsound, bone. This unique skeletal disease can be divided into three sequential phases: (1) an initial osteolytic stage, (2) a mixed osteoclastic–osteoblastic stage, which ends with a predominance of osteoblastic activity and evolves into (3) a final burned-out quiescent osteosclerotic stage (Fig. 21.10).

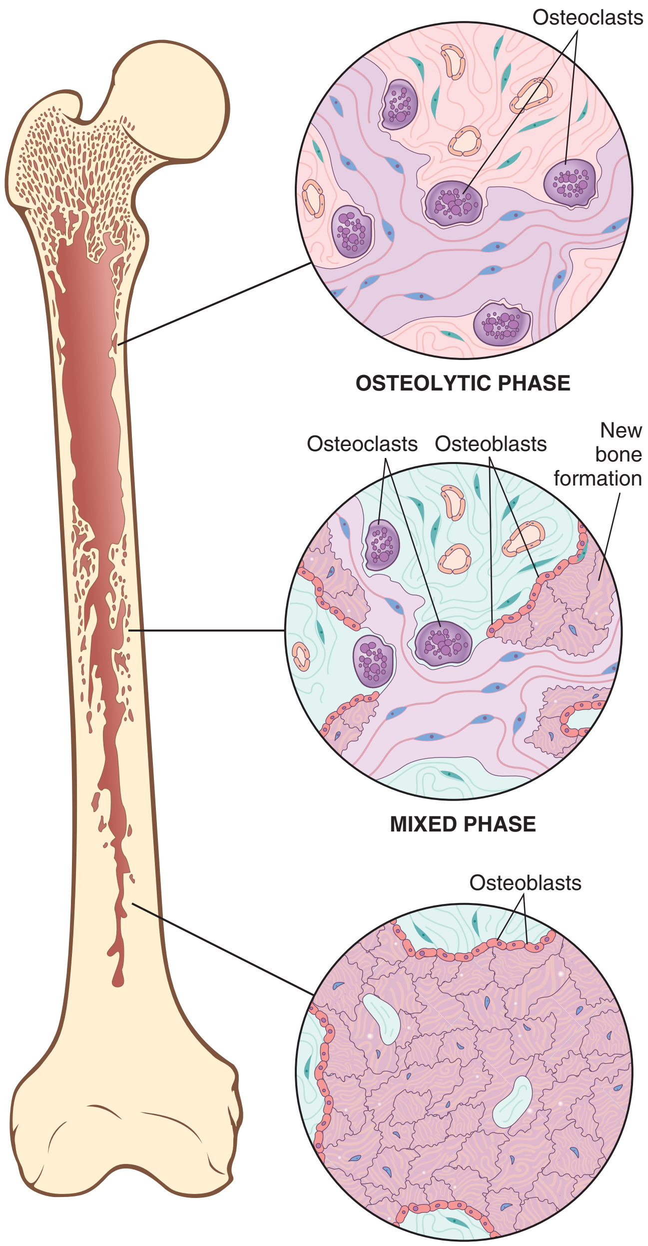

Fig. 21.10 Diagrammatic representation of Paget disease of bone demonstrating the three phases in the evolution of the disease.

Paget disease usually begins in late adulthood. An estimated 1% of the U.S. population older than age 40 is affected. An intriguing aspect is the striking geographic variation in the prevalence. Paget disease is relatively common in whites in England, France, Austria, regions of Germany, Australia, New Zealand, and the United States. In contrast, the disease is rare in the native populations of Scandinavia, China, Japan, and Africa.

Pathogenesis

Current evidence suggests both genetic and environmental causes of Paget disease. Approximately 50% of familial Paget disease and 10% of sporadic cases harbor mutations in the *SQSTM1* gene. The mutations increase the activity of NF-κB, which, in turn increases osteoclast activity. Activating mutations in *RANK* and inactivating mutations in *OPG* account for some cases of juvenile Paget disease. The geographic distribution is suggestive of some environmental influence. Of note in this regard, cell culture studies have shown that infection of osteoclast precursors with viruses such as measles or other RNA viruses alters vitamin D sensitivity and IL-6 secretion, both of which can lead to increased bone resorption.

MORPHOLOGY

Paget disease shows remarkable histologic variation throughout time and from site to site. **The hallmark, seen in the sclerotic phase, is a mosaic pattern of lamellar bone** (Fig. 21.11). The jigsaw puzzle–like appearance is produced by unusually **prominent cement lines**, which join haphazardly oriented units of lamellar bone. In the sclerotic phase, the bone is thickened but lacks structural stability making it vulnerable to deformation and fracture. The findings during the other phases are less specific. The initial lytic phase is characterized by numerous large osteoclasts and resorption pits. The osteoclasts may have 100 or more nuclei. Osteoclasts persist in the mixed phase, but many of the bone surfaces are also lined by prominent osteoblasts.

Clinical Course

Paget disease is *monostotic* in about 15% of cases and *polyostotic* in the remainder. The axial skeleton or proximal femur is involved in up to 80% of cases. Most cases are asymptomatic and are discovered as an incidental radiographic finding. Pain localized to the affected bone is a common symptom. Pain is caused by microfractures or by bone overgrowth that compresses spinal and cranial nerve roots. Enlargement of the craniofacial skeleton may produce *leontiasis ossea* (lion face) and a cranium so heavy that is difficult for the person to hold the head erect. The weakened Pagetic bone may lead to invagination of the skull base *(platybasia)* and compression of the posterior fossa. Weight bearing causes anterior bowing of the femurs and tibiae

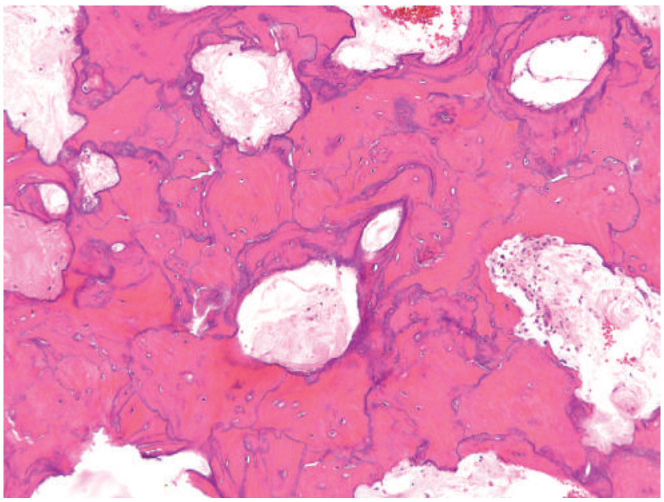

Fig. 21.11 Mosaic pattern of lamellar bone pathognomonic of Paget disease.

and distorts the femoral heads, resulting in the development of severe *secondary osteoarthritis*. *Chalk stick–type fractures* are another frequent complication and usually occur in the long bones of the lower extremities. Compression fractures of the spine result in spinal cord injury and the development of kyphosis. The diagnosis can frequently be made from the radiographic findings. Many affected individuals have elevated serum alkaline phosphatase levels but normal serum calcium and phosphorus.

A variety of tumor and tumorlike conditions develop in Pagetic bone. Secondary osteosarcoma occurs in less than 1% of all individuals with Paget disease, but appears in 5% to 10% of those with severe polyostotic disease. In the absence of malignant transformation, Paget disease is usually not a serious or life-threatening disease. Most affected individuals have mild symptoms that are readily suppressed by treatment with calcitonin and bisphosphonates.

FRACTURES

A fracture is defined as loss of bone integrity resulting from mechanical injury and/or diminished bone strength. Fractures are the most common pathologic conditions affecting bone. The following qualifiers describe fracture types and affect treatment:

- Simple: the overlying skin is intact
- Compound: the bone communicates with the skin surface
- Comminuted: the bone is fragmented
- Displaced: the ends of the bone at the fracture site are not aligned
- Stress: a slowly developing fracture that follows a period of increased physical activity in which the bone is subjected to repetitive loads
- Greenstick: extending only partially through the bone, common in infants when bones are soft
- Pathologic: involving bone weakened by an underlying disease process, such as a tumor

Healing of Fractures

Fracture repair involves regulated expression of a multitude of genes and can be separated into overlapping stages with particular molecular, biochemical, histologic, and biomechanical features.

Immediately after fracture, rupture of blood vessels results in a hematoma, which fills the fracture gap and surrounds the area of bone injury (Fig. 21.12). The clotted blood provides a fibrin mesh, sealing off the fracture site and creating a scaffold for the influx of inflammatory cells and the ingrowth of fibroblasts and new capillaries. Simultaneously, degranulated platelets and migrating inflammatory cells release PDGF, TGF-β, FGF, and other factors that activate osteoprogenitor cells in the periosteum, medullary cavity, and surrounding soft tissues and stimulate osteoclastic and osteoblastic activity. By the end of the first week, a mass of predominantly uncalcified tissue—called *soft callus* or *procallus*—provides anchorage between the ends of the fractured bones. After approximately 2 weeks, the soft callus is transformed into a *bony callus*. The

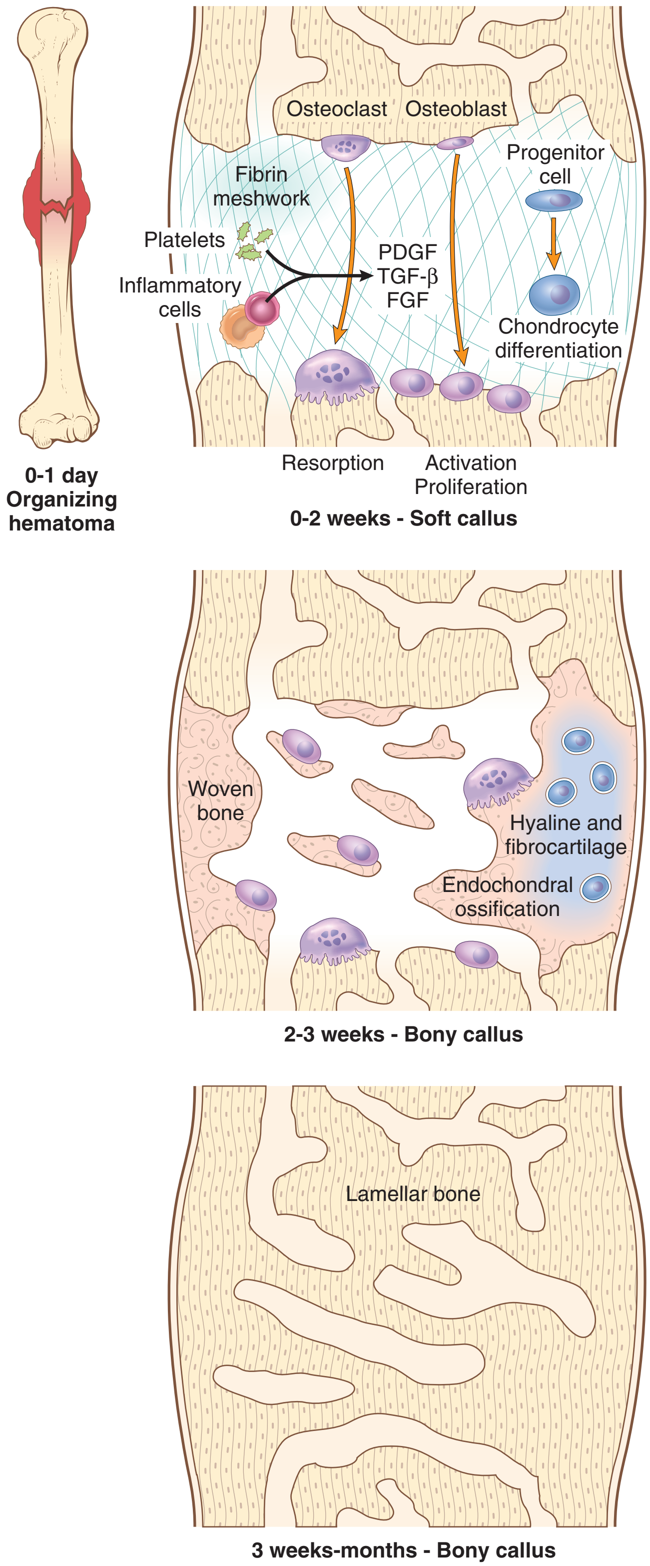

Fig. 21.12 The reaction to a fracture begins with an organizing hematoma. Within two weeks, the two ends of the bone are bridged by a fibrin meshwork in which osteoclasts, osteoblasts, and chondrocytes differentiate from precursors. These cells produce cartilage and bone matrix, which, with adequate immobilization, remodels into normal lamellar bone.

activated osteoprogenitor cells deposit *woven bone.* In some cases, the activated mesenchymal cells in the soft tissues and bone surrounding the fracture line also differentiate into chondrocytes that make fibrocartilage and hyaline cartilage. The newly formed cartilage along the fracture line undergoes endochondral ossification, forming a contiguous network of bone with newly deposited bone trabeculae in the medulla and beneath the periosteum. In this fashion, the fractured ends are bridged (Fig. 21.12).

As the callus matures and is subjected to weight-bearing forces, portions that are not physically stressed are resorbed. This remodeling reduces the size of the callus until the shape and outline of the fractured bone are reestablished as *lamellar bone*. The healing process is complete with restoration of the medullary cavity.

The sequence of events in the healing of a fracture can be easily impeded or blocked. Displaced and comminuted fractures frequently result in some deformity. Inadequate immobilization permits movement of the callus and prevents its normal maturation, resulting in *delayed union* or *nonunion*. If a nonunion persists, the malformed callus undergoes cystic degeneration, and the luminal surface may become lined by synovial-like cells, creating a false joint or *pseudoarthrosis*. Infection of the fracture site, especially common in open fractures, is a serious obstacle to healing. Malnutrition and skeletal dysplasia also hinder fracture healing.

OSTEONECROSIS (AVASCULAR NECROSIS)

Osteonecrosis refers to infarction (ischemic necrosis) of bone and marrow cells. A diverse set of conditions predisposes to bone ischemia, including vascular injury (e.g., trauma, vasculitis), drugs (e.g., corticosteroids), systemic disease (sickle cell crisis), and radiation. In about 25% of cases, the cause is unknown. The three suspected mechanisms causing osteonecrosis are mechanical disruption of vessels, thrombotic occlusion, and extravascular compression. Osteonecrosis has a wide age range but peaks in the 30s to 50s and accounts for about 10% of hip replacements in the United States.

MORPHOLOGY

Regardless of etiology, medullary infarcts are geographic and involve the trabecular bone and marrow. The cortex is usually not affected because of its collateral blood flow. In subchondral infarcts, a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base undergoes necrosis. The overlying articular cartilage remains viable, as it can access nutrients that are present in synovial fluid. Microscopically, dead bone is recognized by empty lacunae surrounded by necrotic adipocytes that frequently rupture. In the healing response, osteoclasts resorb the necrotic trabeculae. Trabeculae that remain act as scaffolding for the deposition of new bone in a process known as creeping substitution. In subchondral infarcts, the pace of this substitution is too slow to be effective, so there is collapse of the necrotic bone and distortion, fracture, and even sloughing of the articular cartilage (Fig. 21.13).

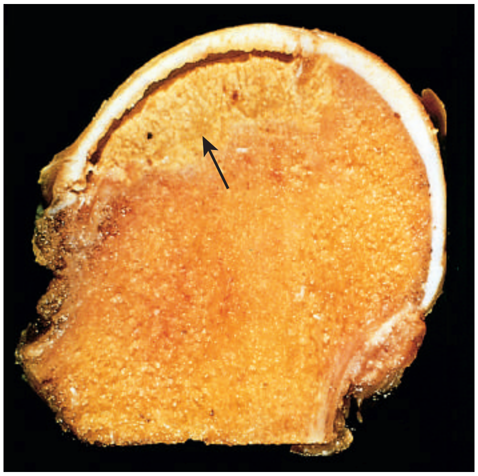

Fig. 21.13 Femoral head with a subchondral, wedge-shaped pale yellow area of osteonecrosis *(arrow)*. The space between the overlying articular cartilage and bone is caused by trabecular compression fractures without repair.

Clinical Course

The symptoms depend on the location and extent of infarct. Typically, subchondral infarcts cause pain that is initially associated only with activity but then becomes constant. Subchondral infarcts often collapse and may lead to severe, secondary osteoarthritis. Treatment ranges from conservative measures (limited weight bearing, immobilization) to surgery.

OSTEOMYELITIS

Osteomyelitis denotes inflammation of bone and marrow, virtually always secondary to infection. Osteomyelitis may be a complication of any systemic infection but frequently manifests as a primary solitary focus of disease. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but infections caused by certain pyogenic bacteria and mycobacteria are the most common.

Pyogenic Osteomyelitis

Pyogenic osteomyelitis is almost always caused by bacteria and rarely by fungi. Organisms may reach the bone by (1) hematogenous spread, (2) extension from a contiguous site, and (3) direct implantation after compound fractures or orthopedic procedures. In otherwise healthy children, most osteomyelitis is hematogenous in origin and develops in the long bones. In adults, however, osteomyelitis more often occurs as a complication of open fractures, surgical procedures, and infections of the feet in diabetics.

Staphylococcus aureus is responsible for 80% to 90% of the cases of culture-positive pyogenic osteomyelitis. These organisms express cell wall proteins that bind to bone matrix components such as collagen and facilitate adherence to bone. *Escherichia coli*, *Pseudomonas*, and *Klebsiella* are more frequently isolated from individuals with genitourinary tract infections or who are intravenous drug abusers. Mixed bacterial infections are seen in the setting of direct

spread, inoculation of organisms during surgery, or into open fractures. In the neonatal period, *Haemophilus influenzae* and group B streptococci are frequent pathogens, and individuals with sickle cell disease are predisposed to *Salmonella* infection. In almost 50% of suspected cases, no organisms can be isolated.

The osseous vascular circulation, which varies with age, determines the location of infection in most long bones. In infants and adults, vascular communication allows the spread of infection between the metaphysis and the epiphysis. By contrast, the avascular growth plate in the child interrupts infection spread between the metaphysis and epiphysis.

MORPHOLOGY

Changes associated with osteomyelitis depend on the stage (acute, subacute, or chronic) and location of the infection. In the acute phase, bacteria proliferate and induce a neutrophilic inflammatory reaction. Necrosis of bone cells and marrow ensues within the first 48 hours. The bacteria and inflammation spread longitudinally and radially throughout the Haversian systems to reach the periosteum. In children, the periosteum is loosely attached to the cortex. Thus, sizable subperiosteal abscess may form that dissect for long distances along the bone surface. Lifting of the periosteum further impairs the blood supply to the affected region, contributing to the necrosis. The dead bone is known as a ***sequestrum.*** Rupture of the periosteum leads to a soft tissue abscess, which can channel to the skin, creating a draining sinus. Sometimes the sequestrum crumbles, releasing fragments that pass through the sinus tract.

In infants (and uncommonly in adults), epiphyseal infection may spread through the articular surface or along capsular and tendoligamentous insertions into a joint, producing septic or suppurative arthritis, which can cause destruction of the articular cartilage and permanent disability.

After the first week, chronic inflammatory cells release cytokines that stimulate osteoclastic bone resorption, ingrowth of fibrous tissue, and the deposition of reactive bone at the periphery. The newly deposited bone can form a shell of living tissue, known as an **involucrum,** around the segment of devitalized infected bone (Fig. 21.14). The histologic findings of chronic osteomyelitis are more protean but typically involve marrow fibrosis, sequestrum, and an inflammatory infiltrate of lymphocytes and plasma cells.

Clinical Course

Hematogenous osteomyelitis sometimes manifests as an acute systemic illness with malaise, fever, chills, leukocytosis, and marked throbbing pain over the affected region. In other instances the presentation is subtle, with only unexplained fever (most often in infants) or localized pain (most often in adults). The diagnosis is strongly suggested by the characteristic radiographic findings of a lytic focus of bone destruction surrounded by a zone of sclerosis. Biopsy and bone cultures are required to identify the pathogen in most instances. The combination of antibiotics and surgical drainage is usually curative.

In 5% to 25% of cases, acute osteomyelitis fails to resolve and persists as chronic infection. Chronic infections may develop when there is delay in diagnosis, extensive bone necrosis, inadequate antibiotic therapy or surgical debridement, or weakened host defenses. The course of chronic infections may be punctuated by acute flare-ups; these are usually spontaneous and may occur after years of dormancy. Other complications of chronic osteomyelitis include pathologic fracture, secondary amyloidosis, endocarditis, sepsis, and the development of squamous cell carcinoma in the draining sinus tracts and sarcoma in the infected bone.

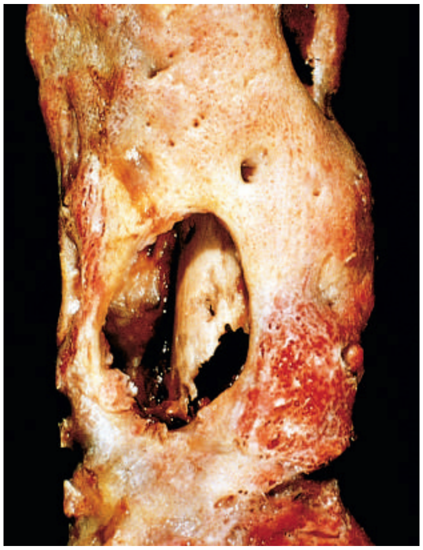

Fig. 21.14 Resected femur in a person with draining osteomyelitis. The drainage tract in the subperiosteal shell of viable new bone (involucrum) shows the inner native necrotic cortex (sequestrum).

Mycobacterial Osteomyelitis

Mycobacterial osteomyelitis, historically a problem in developing countries, has increased in incidence in the developed world because of immigration patterns and immunocompromised patients. Overall, approximately 1% to 3% of individuals with pulmonary or extrapulmonary tuberculosis exhibit osseous infection.

The organisms are usually blood borne and originate from a focus of active visceral disease during the initial stages of primary infection. Direct extension (e.g., from a pulmonary focus into a rib or from tracheobronchial nodes into adjacent vertebrae) also may occur. The bone infection may persist for years before being recognized. Typically, affected individuals present with localized pain, low-grade fevers, chills, and weight loss. Infection is usually solitary except in immunocompromised individuals. The histologic findings, namely caseous necrosis and granulomas, are typical of tuberculosis. Mycobacterial osteomyelitis tends to be more destructive and resistant to control than pyogenic osteomyelitis.

Tuberculous spondylitis (Pott disease) is a destructive infection of vertebrae. The spine is involved in 40% of cases of mycobacterial osteomyelitis. The infection breaks through intervertebral discs to affect multiple vertebrae and extends into the soft tissues. Destruction of discs and vertebrae frequently results in permanent compression

fractures that produce scoliosis or kyphosis and neurologic deficits secondary to spinal cord and nerve compression.

BONE TUMORS AND TUMORLIKE LESIONS

The rarity of primary bone tumors and the often-disfiguring surgery required to treat a bone malignancy make this group of disorders especially challenging. About 2400 primary bone sarcomas are diagnosed annually in the United States. Therapy aims to optimize survival while maintaining the function of affected body parts. The predilection of specific types of tumors for certain age groups and particular anatomic sites provides important diagnostic clues. For example, osteosarcoma peaks during adolescence and most frequently involves the knee, whereas chondrosarcoma affects older adults and involves the pelvis and proximal extremities.

Bone tumors may present in a number of ways. The more common benign lesions are often asymptomatic incidental findings. Many tumors, however, produce pain or a slow-growing mass. In some circumstances the first hint of a tumor's presence is a pathologic fracture. Radiographic imaging studies have an important role in diagnosing these lesions. In addition to providing the exact location and extent of the tumor, imaging studies can detect features that narrow the diagnostic possibilities. In almost all instances biopsy is necessary for definitive diagnosis.

When possible, bone tumors are classified according to the normal cell or matrix they produce. Lesions that do not have normal tissue counterparts are grouped according to their clinicopathologic features (Table 21.1). *Benign tumors greatly outnumber their malignant counterparts* and occur with greatest frequency within the first three decades of life. In older adults, a bone tumor is more likely to be malignant.

Bone-Forming Tumors

Tumors in this category all produce unmineralized osteoid or mineralized woven bone.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma are benign bone-producing tumors that have similar histologic features but differ clinically and radiographically. Osteoid osteomas are, by definition, less than 2 cm in diameter, and are most common in young men. About 50% of cases involve the femur or tibia, wherein they typically arise in the cortex. Usually, there is a thick rim of reactive cortical bone that may be the only clue radiographically. Despite their small size, they present with severe nocturnal pain that is relieved by aspirin and other nonsteroidal anti-inflammatory agents. The pain is probably caused by prostaglandin E_2 produced by osteoblasts. Osteoblastoma is larger than 2 cm and involves the posterior components of the vertebrae (laminae and pedicles) more frequently. The pain is unresponsive to aspirin, and the tumor usually does not induce a marked bony reaction. Osteoid osteoma is frequently treated by radiofrequency ablation, whereas osteoblastoma is usually curetted or excised. Malignant transformation is rare.

MORPHOLOGY

Osteoid osteoma and osteoblastoma are round-to-oval masses of hemorrhagic gritty tan tissue. They are well circumscribed and composed of randomly interconnecting delicate trabeculae

Table 21.1 Classification of Selected Primary Bone Tumors

Category	Behavior	Tumor Type	Common Locations	Age (yr)	Morphology
Cartilage forming	Benign	Osteochondroma	Metaphysis of long bones	10–30	Bony excrescence with cartilage cap
—	—	Chondroma	Small bones of hands and feet	30–50	Circumscribed hyaline cartilage nodule in medulla
—	Malignant	Chondrosarcoma (conventional)	Pelvis, shoulder	40–60	Extends from medulla through cortex into soft tissue, chondrocytes with increased cellularity and atypia
Bone forming	Benign	Osteoid osteoma	Metaphysis of long bones	10–20	Cortical, interlacing microtrabeculae of woven bone
—	—	Osteoblastoma	Vertebral column	10–20	Posterior elements of vertebra, histology similar to osteoid osteoma
—	Malignant	Osteosarcoma	Metaphysis of distal femur, proximal tibia	10–20	Extends from medulla to lift periosteum, malignant cells producing woven bone
Unknown origin	Benign	Giant cell tumor	Epiphysis of long bones	20–40	Destroys medulla and cortex, sheets of osteoclasts
—	—	Aneurysmal bone cyst	Proximal tibia, distal femur, vertebra	10–20	Vertebral body, hemorrhagic spaces separated by cellular, fibrous septae
—	Malignant	Ewing sarcoma	Diaphysis of long bones	10–20	Sheets of primitive small round cells

Adapted from Unni KK, Inwards CY: *Dahlin's Bone Tumors*, ed 6. Philadelphia, 2010, Lippincott-Williams & Wilkins; by permission of Mayo Foundation.

of woven bone that are prominently rimmed by a single layer of osteoblasts (Fig. 21.15). The stroma surrounding the neoplastic bone consists of loose connective tissue that contains many dilated and congested capillaries. The relatively small size, well-defined margins, and benign cytologic features of the neoplastic osteoblasts help distinguish these tumors from osteosarcoma. Osteoid osteomas elicit the formation of a large amount of reactive bone, which encircles the lesion.

Osteosarcoma

Osteosarcoma is a malignant tumor that produces osteoid matrix or mineralized bone. Excluding hematopoietic tumors (myeloma and lymphoma), osteosarcoma is the most common primary malignant tumor of bone. Osteosarcoma has a bimodal age distribution; 75% of osteosarcomas occur in persons younger than 20 years of age. The smaller second peak occurs in older adults, who frequently suffer from conditions known to predispose to osteosarcoma, such as Paget disease, bone infarcts, and previous radiation. These are referred to as secondary osteosarcomas. Overall, men are more commonly affected than women (1.6:1). The most common sites in adolescents are the metaphyseal regions of the distal femur and proximal tibia.

Osteosarcomas present as painful, progressively enlarging masses. Sometimes a pathologic fracture is the first indication. Radiographs usually show a large, destructive, mixed lytic and sclerotic mass with infiltrative margins (Fig. 21.16). The tumor frequently breaks through the cortex and lifts the periosteum, resulting in reactive subperiosteal bone formation. The triangular shadow between the cortex and raised ends of periosteum, known radiographically as *Codman triangle*, is indicative of an aggressive tumor, but is not pathognomonic of osteosarcoma.

Pathogenesis

Approximately 70% of osteosarcomas have acquired genetic abnormalities such as complex structural and numerical chromosomal aberrations. Molecular studies have shown that these tumors usually have mutations in well-known tumor suppressors and oncogenes:

- *RB* is a critical negative regulator of the cell cycle. Patients with germline mutations in *RB* have a 1000-fold increased risk of osteosarcoma, and somatic *RB* mutations are present in up to 70% of sporadic osteosarcomas.
- *TP53* is a gene whose product functions as the guardian of genomic integrity by promoting DNA repair and apoptosis of irreversibly damaged cells. Patients with Li-Fraumeni syndrome, who have germline *TP53* gene mutations, have a greatly elevated incidence of osteosarcoma, and abnormalities that interfere with p53 function are common in sporadic tumors.
- *CDKN2A* is inactivated in many osteosarcomas. This gene encodes two tumor suppressors, p16 (a negative regulator of cyclin-dependent kinases) and p14 (which augments p53 function).
- *MDM2* and *CDK4*, which are cell cycle regulators that inhibit p53 and RB function, respectively, are overexpressed in many low-grade osteosarcomas.

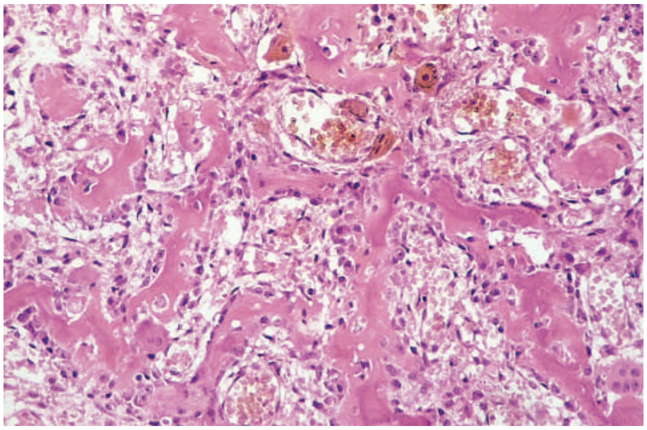

Fig. 21.15 Osteoid osteoma composed of haphazardly interconnecting trabeculae of woven bone that are rimmed by prominent osteoblasts. The intertrabecular spaces are filled by vascularized loose connective tissue.

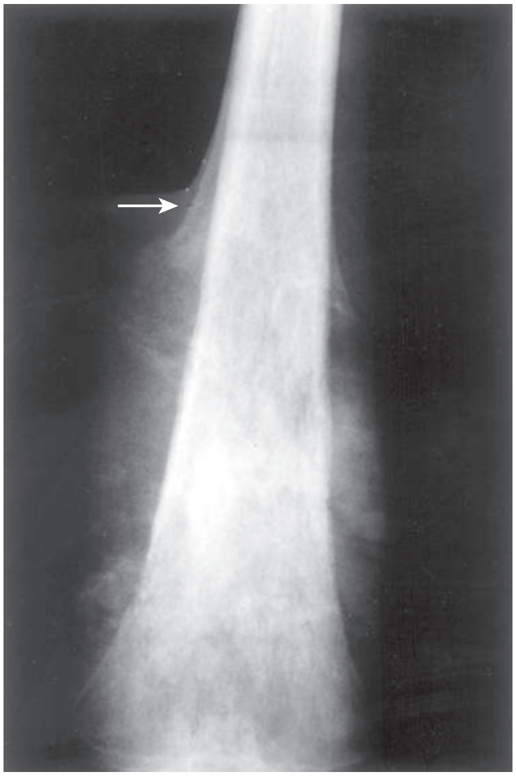

Fig. 21.16 Distal femoral osteosarcoma with prominent bone formation extending into the soft tissues. The periosteum, which has been lifted, has laid down a triangular shell of reactive bone known as a Codman triangle *(arrow)*.

It also is noteworthy that osteosarcomas peak in incidence around the time of the adolescent growth spurt and occur most frequently in the region of the growth plate in bones with the fastest growth. The increased proliferation at these sites may predispose to osteosarcoma development.

MORPHOLOGY

Osteosarcomas are bulky tumors that are gritty, gray-white, and often contain areas of hemorrhage and cystic degeneration (Fig. 21.17). The tumors frequently destroy the surrounding cortices and produce soft tissue masses. They spread extensively in the medullary canal, infiltrating and replacing the marrow.

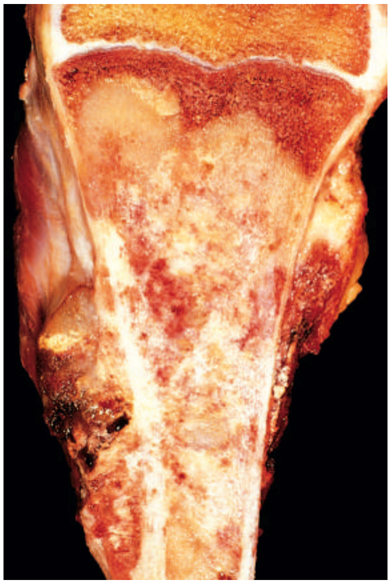

Fig. 21.17 Osteosarcoma of the proximal tibia. The tan-white tumor fills most of the medullary cavity of the metaphysis and proximal diaphysis. It has infiltrated through the cortex, lifted the periosteum, and formed soft tissue masses on both sides of the bone.

Infrequently they penetrate the epiphyseal plate or enter the joint.

The formation of osteoid matrix or mineralized bone by malignant tumor cells is diagnostic of osteosarcoma (Fig. 21.18). The neoplastic bone usually has a fine, lacelike configuration but also may be deposited in broad sheets or as primitive trabeculae. The tumor cells vary in size and shape *(pleomorphic)* and frequently have large hyperchromatic nuclei. Bizarre tumor giant cells, vascular invasion, and necrosis are common. Mitotic activity is high, including abnormal forms (e.g., tripolar mitoses).

Clinical Course

Osteosarcoma is treated with a multimodality approach that consists of (1) neoadjuvant chemotherapy, (2) surgery, and (3) chemotherapy. The amount of chemotherapy-induced necrosis found at surgical resection is an important prognostic finding. These aggressive neoplasms spread hematogenously to the lungs. Although the prognosis has improved substantially since the advent of chemotherapy, with 5-year survival rates reaching 60% to 70% in patients without detectible metastases at initial diagnosis, the outcome for patients with metastases, recurrent disease, or secondary osteosarcoma is still poor.

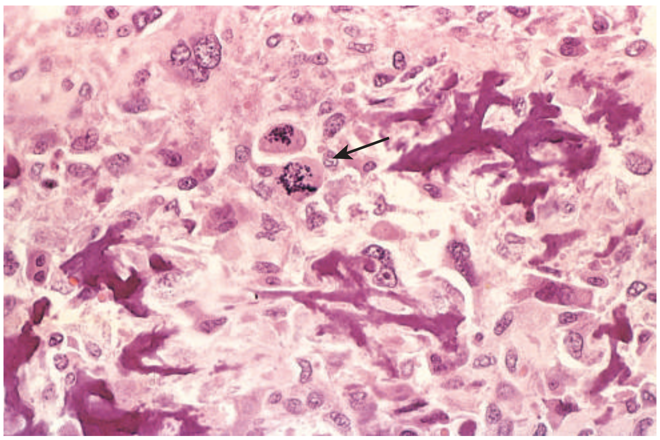

Fig. 21.18 Fine, lacelike pattern of neoplastic bone produced by anaplastic malignant tumor cells in an osteosarcoma. Note the abnormal mitotic figure *(arrow)*.

Cartilage-Forming Tumors

These tumors are characterized by the formation of hyaline cartilage. Benign cartilaginous tumors are much more common than malignant ones.

Osteochondroma

Osteochondroma, known clinically as exostosis, is a benign cartilage-capped tumor that is attached to the underlying skeleton by a bony stalk. About 85% are solitary. The remainder are seen as part of the *multiple hereditary exostoses syndrome* (see later). Solitary osteochondromas are usually first diagnosed in late adolescence and early adulthood, but multiple osteochondromas become apparent during childhood. Men are affected three times more often than women. Osteochondromas develop in bones of endochondral origin and arise from the metaphysis near the growth plate of long tubular bones, especially near the knee (Fig. 21.19). They present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases they are detected incidentally. In multiple hereditary exostoses, the underlying bones may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth.

Pathogenesis

Hereditary exostoses are associated with germline loss-of-function mutations in either the *EXT1* or the *EXT2* gene and subsequent loss of the remaining wild-type allele in chondrocytes of the growth plate. Reduced expression of *EXT1* or *EXT2* also has been observed in sporadic osteochondromas. These genes encode enzymes that synthesize heparan sulfate glycosaminoglycans. The reduced or abnormal glycosaminoglycans may prevent normal diffusion of Hedgehog factors, which are local regulators of cartilage growth, thereby disrupting chondrocyte differentiation and skeletal development.

MORPHOLOGY

Osteochondromas are sessile or pedunculated, and they range in size from 1 to 20 cm. The cap is composed of benign hyaline cartilage (Fig. 21.20) and is covered peripherally by perichondrium. The cartilage has the appearance of a disorganized growth plate and undergoes endochondral ossification, with the newly made bone forming the inner portion of the head and stalk. The cortex of the stalk merges with the cortex of the host bone resulting in continuity between the medulla of the osteochondroma and the host bone.

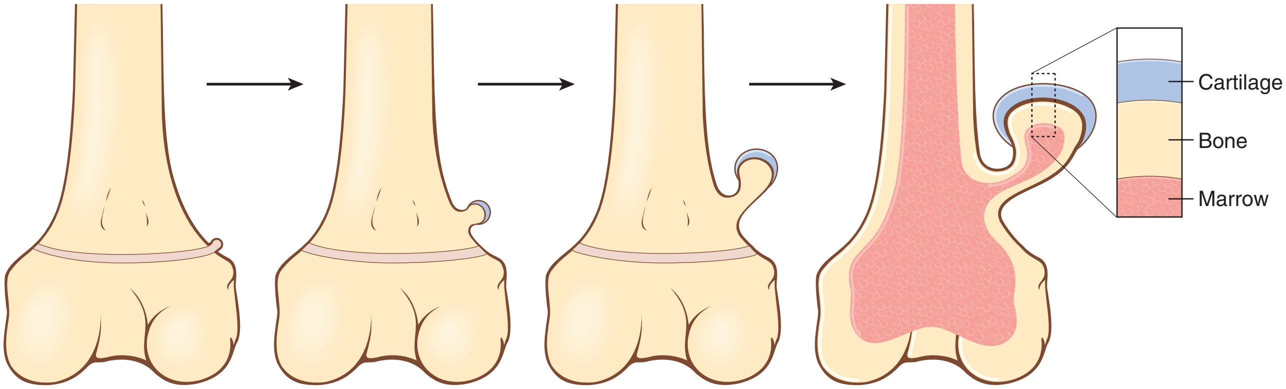

Fig. 21.19 The development of an osteochondroma, beginning with an outgrowth from the epiphyseal cartilage.

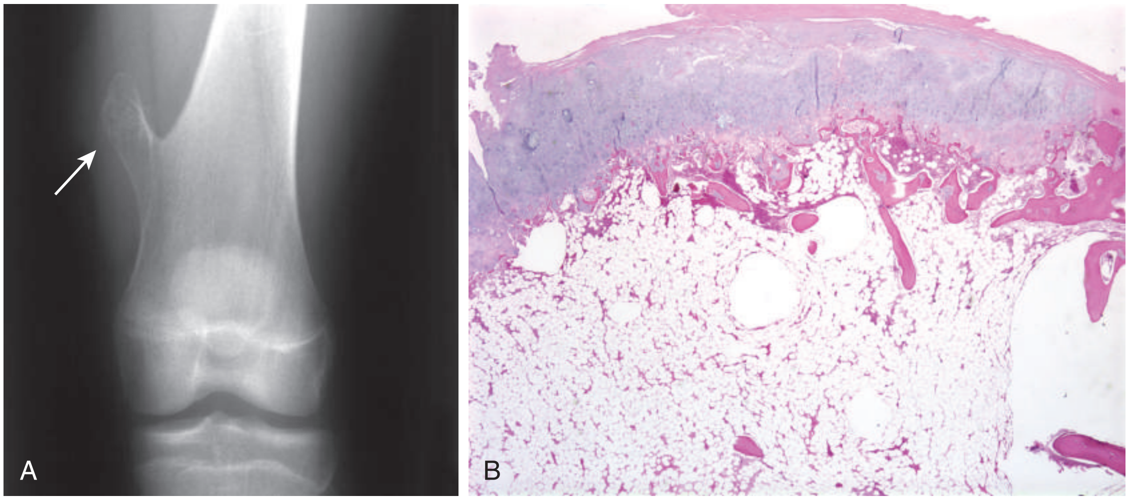

Fig. 21.20 Osteochondroma. (A) Radiograph of an osteochondroma arising from the distal femur *(arrow)*. (B) The cartilage cap has the histologic appearance of disorganized growth plate–like cartilage.

Clinical Course

Osteochondromas usually stop growing at the time of growth plate closure. Symptomatic tumors are cured by simple excision. Rarely in sporadic cases, but more commonly in those with multiple hereditary exostosis (5%–20%), osteochondromas progress to chondrosarcoma.

Chondroma

Chondromas are benign tumors of hyaline cartilage that usually occur in bones of endochondral origin. They arise within the medullary cavity *(enchondroma)* or on the cortical surface *(juxtacortical chondroma)*. Enchondromas are usually diagnosed in individuals 20 to 50 years of age. Typically, they appear as solitary metaphyseal lesions of the tubular bones of the hands and feet. The radiographic features consist of a circumscribed lucency with central irregular calcifications, a sclerotic rim, and an intact cortex (Fig. 21.21). *Ollier disease* and *Maffucci syndrome* are disorders characterized by multiple enchondromas (enchondromatosis). Maffucci syndrome also is associated with other rare tumors.

Most enchondromas of large bones are asymptomatic and are detected incidentally. Occasionally, they are painful and cause pathologic fracture. The tumors in

Fig. 21.21 Enchondroma of the proximal phalanx. The radiolucent nodule of cartilage with central calcification thins but does not penetrate the cortex.

enchondromatosis may be numerous and large, producing severe deformities, especially of the digits.

Pathogenesis

Heterozygous gain of function mutations in the *IDH1* and *IDH2* genes, coding for the enzymes isocitrate dehydrogenases, have been identified in the chondrocytes of syndromic and solitary enchondromas. Patients with enchondroma syndromes are mosaics, harboring *IDH* mutations in only a subset of otherwise normal cells throughout their bodies. The mutations confer a new enzymatic activity on the IDH proteins that leads to the synthesis of 2-hydroxyglutarate. As discussed in Chapter 6, this so-called "oncometabolite" interferes with regulation of DNA methylation and is also implicated in certain glial tumors and a subset of acute myeloid leukemias.

MORPHOLOGY

Enchondromas are usually smaller than 3 cm and are gray-blue and translucent. They are composed of well-circumscribed nodules of hyaline cartilage containing benign chondrocytes (Fig. 21.22). The peripheral portion of the nodules may undergo endochondral ossification, and the center can calcify and infarct. Syndromic enchondromas are sometimes more cellular with more atypia than sporadic enchondromas.

Clinical Course

The growth potential of chondromas is limited. Treatment depends on the clinical situation and usually includes observation or curettage. Solitary chondromas rarely undergo sarcomatous transformation, but those associated with enchondromatosis do so more frequently. Individuals with Maffucci syndrome also are at risk of developing other neoplasms, including brain gliomas.

Chondrosarcoma

Chondrosarcomas are malignant tumors that produce cartilage. They are subclassified into *conventional* (hyaline cartilage–producing), *dedifferentiated, clear cell,* and *mesenchymal* types. Approximately 90% of chondrosarcomas are of the conventional type. Chondrosarcoma is about half as common as osteosarcoma. Individuals with conventional chondrosarcoma are usually in their 40s or older. These tumors affect men twice as frequently as women. The clear cell and especially the mesenchymal variants occur in children and young adults. Chondrosarcomas commonly arise in the axial skeleton, especially the pelvis, shoulder, and ribs. Unlike benign enchondroma, the distal extremities are rarely involved. On imaging, the calcified cartilage appears as foci of flocculent densities that may destroy the cortex and form a soft tissue mass. About 15% of conventional chondrosarcomas are secondary, arising from a preexisting enchondroma or osteochondroma.

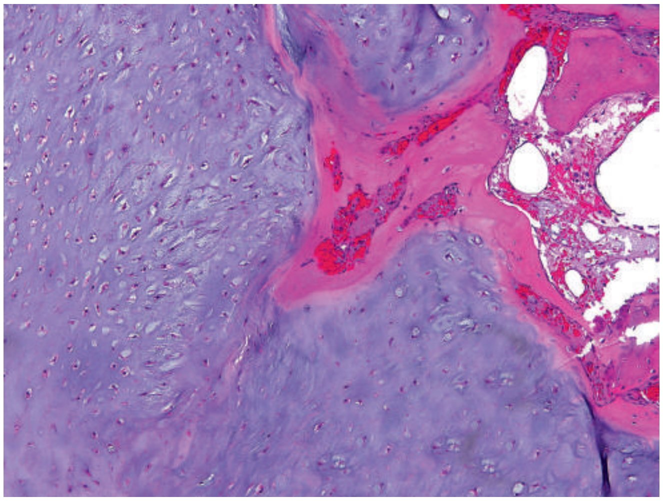

Fig. 21.22 Enchondroma composed of a nodule of hyaline cartilage encased by a thin layer of reactive bone.

Pathogenesis

Although chondrosarcomas are genetically heterogeneous, a few reproducible abnormalities have been identified. Chondrosarcomas arising in multiple osteochondroma syndrome exhibit mutations in the *EXT* genes, and both chondromatosis-related and sporadic chondrosarcomas may have *IDH1* and *IDH2* mutations. Mutation of the collagen *COL2A1* gene and silencing of the *CDKN2A* tumor suppressor gene by DNA methylation are also relatively common in sporadic tumors.

MORPHOLOGY

Conventional chondrosarcomas are large bulky tumors composed of nodules of glistening gray-white, translucent cartilage, along with gelatinous or myxoid areas (Fig. 21.23A). Spotty calcifications are typically present, and central necrosis may create cystic spaces. The tumor spreads through the cortex into surrounding muscle or fat. Histologically, the cartilage infiltrates the marrow space and entraps normal bony trabeculae (Fig. 21.23B). The tumors vary in cellularity, cytologic atypia, and mitotic activity and are assigned a grade from 1 to 3. Grade 1 tumors have relatively low cellularity, and the chondrocytes have plump vesicular nuclei with small nucleoli. By contrast, grade 3 chondrosarcomas are characterized by high cellularity, extreme pleomorphism with bizarre tumor giant cells, and mitoses.

Clinical Course

Chondrosarcomas usually present as painful, progressively enlarging masses. Tumor grade predicts outcome, which ranges from 80% 5-year survival for Grade 1 tumors to 43% for Grade 3 tumors. Grade 1 chondrosarcomas rarely metastasize, whereas 70% of grade 3 tumors spread hematogenously, especially to the lungs. The treatment of conventional chondrosarcoma is wide surgical excision. The mesenchymal and dedifferentiated tumors are also excised and are additionally treated with chemotherapy because of their more aggressive clinical course.

Tumors of Unknown Origin

Ewing Sarcoma

Ewing sarcoma is a malignant tumor composed of primitive round cells with varying degrees of neuroectodermal

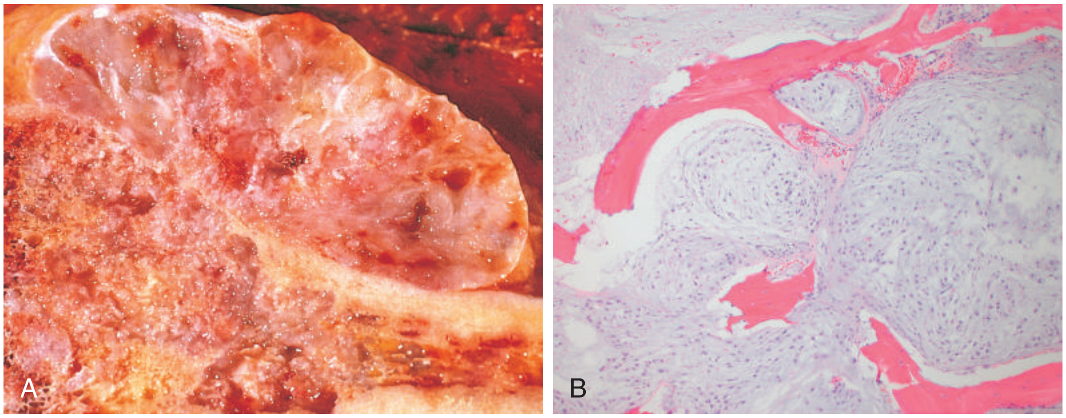

Fig. 21.23 Chondrosarcoma. (A) Nodules of hyaline and myxoid cartilage permeating throughout the medullary cavity, growing through the cortex, and forming a relatively well-circumscribed soft tissue mass. (B) Conventional chondrosarcoma entraps native lamellar bone as a confluent mass of cartilage.

differentiation and a characteristic molecular signature (see later). Entities previously classified as **primitive neuroectodermal tumor** (PNET) and Askin tumor have been unified into the single category of Ewing sarcoma.

Ewing sarcoma accounts for approximately 10% of primary malignant bone tumors and follows osteosarcoma as the second most common bone sarcoma in children. Of all bone sarcomas, Ewing sarcomas have the youngest average age at presentation (80% are younger than 20 years). Boys are affected slightly more frequently than girls, and there is a predilection for Caucasians. The tumors usually arise in the diaphysis of long tubular bones but 20% are extraskeletal. They present as painful enlarging masses, and the affected site is frequently tender, warm, and swollen. Plain radiographs show a destructive lytic tumor with permeative margins that extends into the surrounding soft tissues. The characteristic periosteal reaction produces layers of reactive bone deposited in an *onion-skin* fashion.

Pathogenesis

The vast majority (85%) of Ewing sarcomas contain a balanced (11;22) (q24;q12) translocation generating in-frame fusion of the *EWSR1* gene on chromosome 22 to the *FLI1* gene on chromosome 11. Variant translocations fuse *EWSR1* to other members of the ETS transcription factor family. How EWS fusion proteins contribute to transformation remains unsettled; effects on transcription, RNA splicing, and the cell cycle machinery have all been proposed. Similarly, the cell of origin still remains to be identified; the leading candidates are mesenchymal stem cells and primitive neuroectodermal cells.

MORPHOLOGY

Arising in the medullary cavity, Ewing sarcoma usually invades the cortex, periosteum, and soft tissue. The tumor is soft, tan-white, and frequently contains areas of hemorrhage and necrosis. It is one of the small, round blue cell tumors found in children (Chapter 7). Like other tumors in this group, Ewing sarcoma is composed of sheets of uniform small, round cells that are slightly larger and more cohesive than lymphocytes (Fig. 21.24). They have scant cytoplasm, which may appear clear because it is rich in glycogen. Homer-Wright rosettes (round groupings of cells with a central fibrillary core) may be present and indicate a greater degree of neuroectodermal differentiation. The tumor cells do not produce bone or cartilage.

Clinical Course

Ewing sarcomas are aggressive malignancies treated with neoadjuvant chemotherapy followed by surgical excision with or without radiation. With chemotherapy, 5-year survival of 75% and long-term cure in 50% of patients is possible.

Giant Cell Tumor

Giant cell tumor is so named because **multinucleated osteoclast-type giant cells dominate the histology.** It is a locally aggressive neoplasm that almost exclusively affects adults. Giant cell tumors arise in the epiphyses of long bones, most commonly the distal femur and proximal tibia. The typical location of these tumors near joints frequently

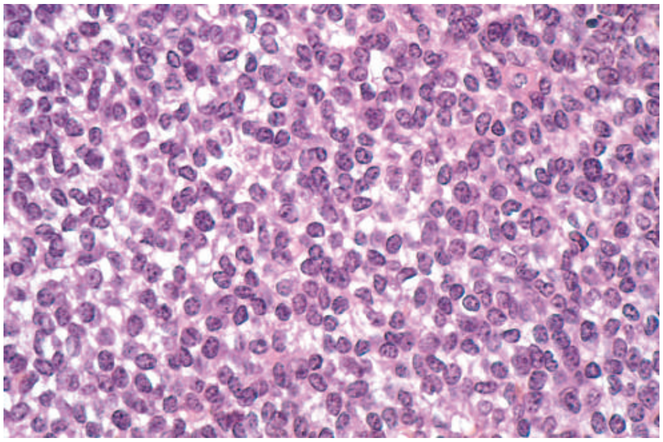

Fig. 21.24 Ewing sarcoma composed of sheets of small round cells with small amounts of clear cytoplasm.

causes arthritis-like symptoms. Occasionally, they present with pathologic fractures.

Pathogenesis

Experimental evidence suggests that the neoplastic cells of the giant cell tumor are osteoblast precursors, which represent only a minority of the cells in the tumor. The neoplastic cells express high levels of RANKL, which promotes the proliferation and differentiation of normal osteoclast precursors into osteoclasts. The osteoclasts in turn cause localized but highly destructive resorption of bone.

MORPHOLOGY

Giant cell tumors often destroy the overlying cortex, producing a bulging soft tissue mass delineated by a thin shell of reactive bone (Fig. 21.25). Grossly, they are red-brown masses that frequently undergo cystic degeneration. Microscopically, the tumor conspicuously lacks bone or cartilage, consisting of numerous osteoclast-type giant cells with 100 or more nuclei with uniform, oval mononuclear tumor cells in between (Fig. 21.26).

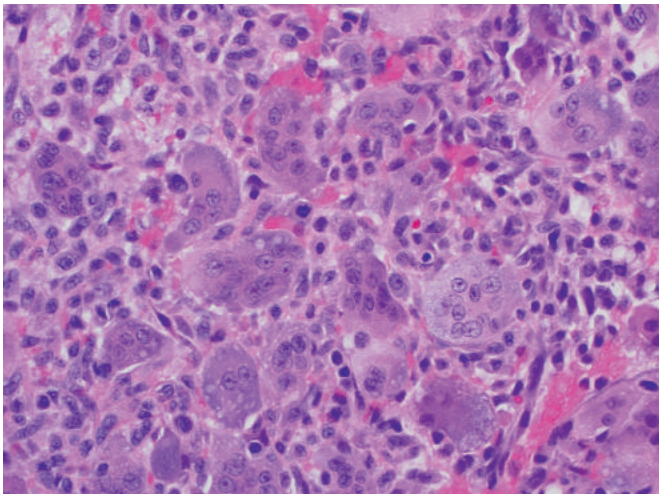

Fig. 21.26 Giant cell tumor illustrating an abundance of multinucleated giant cells with background mononuclear stromal cells.

Clinical Course

Giant cell tumors are typically treated with curettage, but 40% to 60% recur locally. Up to 4% of tumors metastasize to the lungs, but these sometimes spontaneously regress and they are seldom fatal. The RANKL inhibitor, Denosumab, has shown promise in treating giant cell tumor.

Aneurysmal Bone Cyst

Aneurysmal bone cyst (ABC) is a benign tumor characterized by multiloculated blood-filled cystic spaces. ABC generally occurs during the first 2 decades of life and has no sex predilection. It most frequently develops in the metaphysis of long bones and the posterior elements of vertebral bodies. Pain and swelling are common.

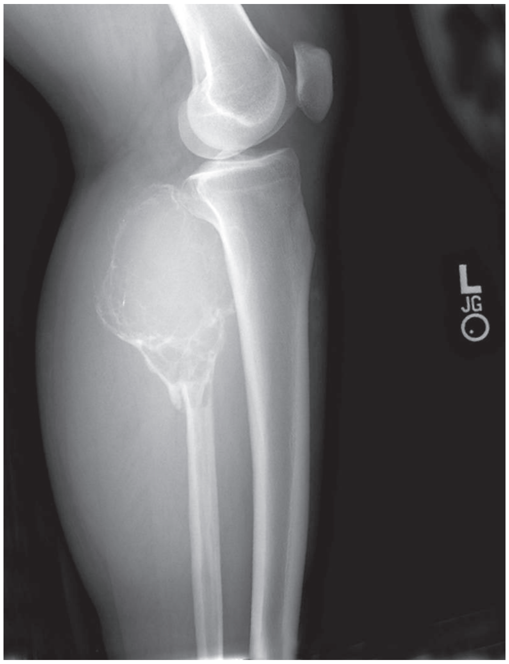

Fig. 21.25 Radiographically, giant cell tumor of the proximal fibula is predominantly lytic, expansile with destruction of the cortex. A pathologic fracture is also present.

Radiographically, ABC is usually an eccentric, expansile, lytic, metaphyseal lesion with well-defined margins (Fig. 21.27A). Computed tomography and magnetic resonance imaging may demonstrate internal septa and characteristic fluid-fluid levels (Fig. 21.27B).

Pathogenesis

The spindle-shaped cells of primary ABC frequently demonstrate rearrangements of chromosome 17p13 resulting in fusion of the coding region of *USP6* to the regulatory elements of genes that are highly expressed in osteoblasts, leading to USP6 overexpression. *USP6* encodes an enzyme that removes ubiquitin residues from proteins (a deubiquitinase). It is proposed that increased USP6 expression enhances the activity of the transcription factor NF-κB. Increased NF-κB activity may upregulate matrix metalloproteases, leading to cystic resorption of bone.

MORPHOLOGY

Aneurysmal bone cyst consists of multiple blood-filled cystic spaces separated by thin, tan-white septae (Fig. 21.28). The septae are composed of plump uniform fibroblasts, multinucleated osteoclast-like giant cells, and reactive woven bone, but they are not covered by endothelium.

Clinical Course

The treatment of ABC is surgical. Curettage is effective with low risk of recurrence.

Lesions Simulating Primary Neoplasms

Nonossifying Fibroma

Nonossifying fibroma (NOF) is a benign, likely reactive, mesenchymal proliferation that may be present in

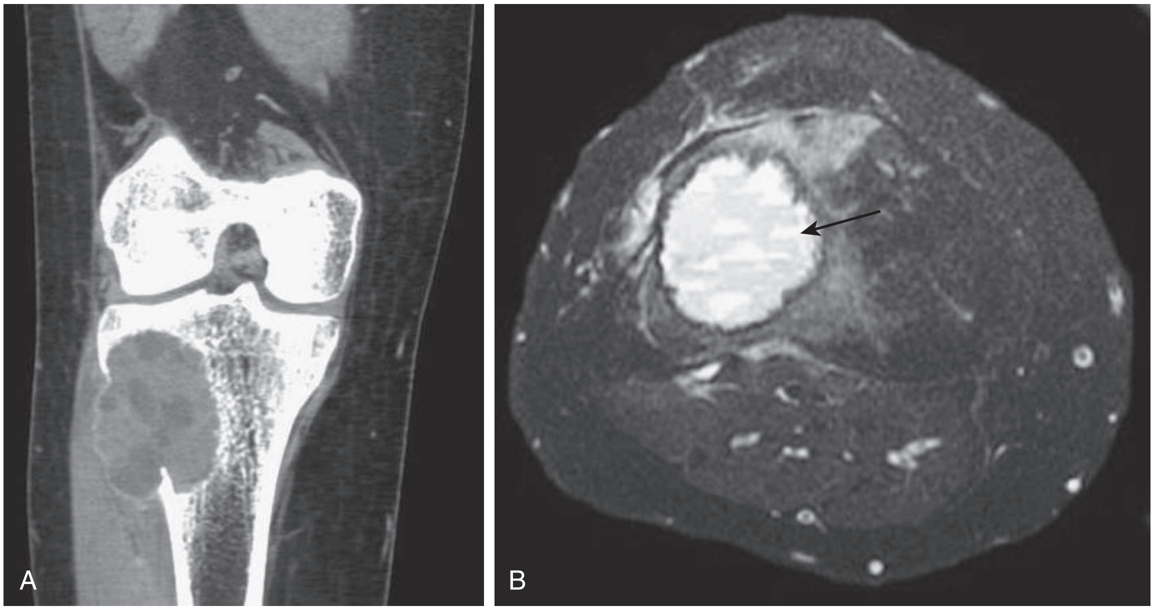

Fig. 21.27 (A) Coronal computed axial tomography scan showing eccentric aneurysmal bone cyst of tibia. The soft tissue component is delineated by a thin rim of reactive subperiosteal bone. (B) Axial magnetic resonance image demonstrating characteristic fluid-fluid levels *(arrow)*.

as many as 50% of children and young adults aged 2–25 years. It is synonymous with **fibrous cortical defect** or **metaphyseal fibrous defect** if localized to the cortex or medulla, respectively. The vast majority arises eccentrically in the metaphysis of the distal femur and proximal tibia. Plain radiographs show a sharply demarcated oval radiolucency with the long axis parallel to the cortex (Fig. 21.29). The findings are sufficiently specific on plain radiography that biopsy is rarely necessary. NOFs form gray to yellow-brown cellular lesions containing fibroblasts and macrophages. The cytologically bland fibroblasts are frequently arranged in a storiform (pinwheel) pattern, and the macrophages may take the form of clustered cells with foamy cytoplasm or multinucleated giant cells (Fig. 21.30). Hemosiderin is commonly present. Most small NOFs undergo spontaneous resolution within several years.

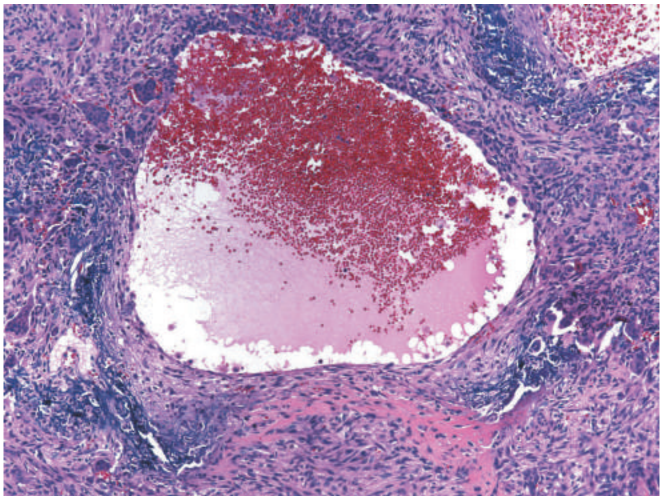

Fig. 21.28 Aneurysmal bone cyst with blood-filled cystic space surrounded by a fibrous wall containing proliferating fibroblasts, reactive woven bone, and osteoclast-type giant cells.

Fibrous Dysplasia

Fibrous dysplasia is a benign tumor that has been likened to a localized developmental arrest of bone constituents. The lesions arise during skeletal development, and they appear in several distinctive but sometimes overlapping clinical patterns:

- *Monostotic*: involvement of a single bone
- *Polyostotic*: involvement of multiple bones

Fig. 21.29 Nonossifying fibroma of the distal tibia metaphysis producing an eccentric lobulated radiolucency surrounded by a sclerotic margin.

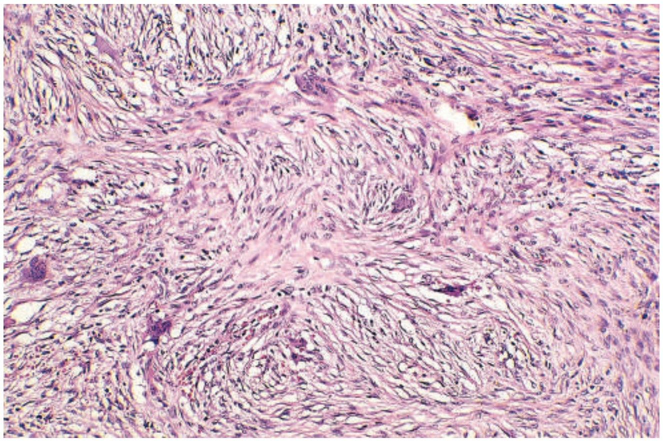

Fig. 21.30 Storiform pattern created by benign spindle cells with scattered osteoclast-type giant cells characteristic of a fibrous cortical defect.

- *Mazabraud syndrome*: fibrous dysplasia and soft tissue myxoma
- *McCune-Albright syndrome*: polyostotic fibrous dysplasia, café-au-lait skin pigmentations, and endocrine abnormalities, especially precocious puberty

Pathogenesis

All of the aforementioned variants result from a somatic gain-of-function mutation in *GNAS1*, the gene that is also mutated in pituitary adenomas (Chapter 20). The mutations produce a constitutively active G_s-protein that promotes cellular proliferation by increasing cellular levels of cAMP. The phenotype depends on the stage of embryogenesis when the mutation is acquired and on the fate of the cell harboring the mutation. A mutation during early embryogenesis produces the McCune-Albright syndrome, whereas a mutation during or after formation of the skeleton in an osteoblast precursor results in monostotic fibrous dysplasia. The skeletal manifestations arise from a cAMP–mediated interruption of normal osteoblast differentiation.

MORPHOLOGY

The lesions of fibrous dysplasia are well circumscribed, intramedullary, and vary greatly in size. Larger lesions expand and distort the bone. The lesional tissue is composed of curvilinear trabeculae of woven bone surrounded by a moderately cellular fibroblastic proliferation. The trabeculae lack prominent osteoblastic rimming (Fig. 21.31). Cystic degeneration, hemorrhage, and foamy macrophages are other common findings.

Clinical Course

Monostotic fibrous dysplasia often stops enlarging at the time of growth plate closure. The lesion is frequently asymptomatic and is usually discovered incidentally, but it may cause pain, fracture, and discrepancies in limb length. Symptomatic lesions are cured by curettage.

Polyostotic fibrous dysplasia may continue to cause problems into adulthood. If it involves the limb girdles, it can cause crippling deformities and fractures. The *McCune-Albright syndrome* usually presents with precocious sexual development, most often in girls. The skeletal manifestations are managed as for other polyostotic fibrous dysplasia, whereas the endocrinopathies are treated medically.

Metastatic Tumors

Metastatic tumors greatly outnumber primary bone cancers. The pathways of tumor spread to bone include (1) direct extension, (2) lymphatic or hematogenous dissemination, and (3) intraspinal seeding (via the Batson plexus of veins). Any cancer can spread to bone, but in adults more than 75% of skeletal metastases originate from cancers of the prostate, breast, kidney, and lung. In children, metastases to bone originate from neuroblastoma, Wilms tumor, and rhabdomyosarcoma.

Skeletal metastases are typically multifocal and involve the axial skeleton, especially the vertebral column. The radiographic appearance of metastases may be purely *lytic* (bone destroying), purely *blastic* (bone forming), or *mixed.* Bidirectional interactions between metastatic cancer cells and native bone cells account for the changes that manifest in the bone matrix. Tumor cells secrete substances such as prostaglandins, cytokines, and PTH-like peptide that upregulate RANKL on osteoblasts and stromal cells thereby stimulating osteoclast activity. At the same time, tumor cell growth is supported by the release of matrix-bound growth factors (e.g., TGF-β, IGF-1, and FGF) as bone is resorbed. Tumor cells secreting WNT proteins that stimulate osteoblastic bone formation may produce sclerotic metastases.

The presence of bone metastases carries a poor prognosis. Therapeutic options include systemic chemotherapy, radiation, and bisphosphonates. Surgery may be necessary to stabilize pathologic fractures.

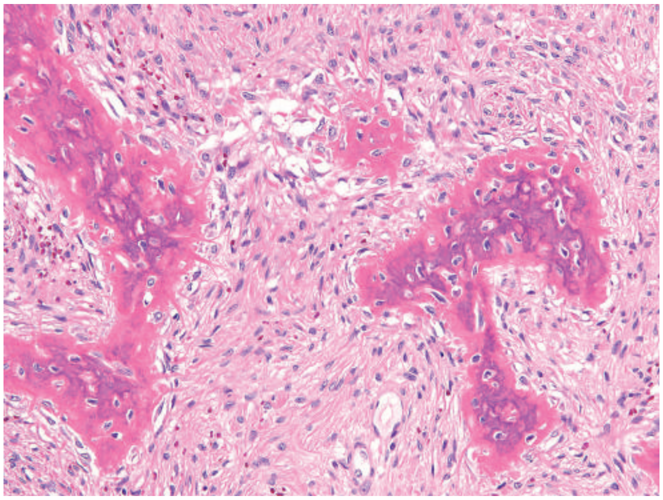

Fig. 21.31 Fibrous dysplasia composed of curvilinear trabeculae of woven bone that lack conspicuous osteoblastic rimming and arise in a background of fibrous tissue.

SUMMARY

BONE TUMORS AND TUMORLIKE LESIONS

Primary bone tumors are classified according to the cell of origin or the matrix that they produce. The remainder is grouped according to clinicopathologic features. Most primary bone tumors are benign. Metastases, especially from lung, prostate, kidneys, and breast, are far more common than primary bone neoplasms.

Major categories of primary bone tumors include

- **Bone forming:** Osteoblastoma and osteoid osteoma consist of benign osteoblasts that synthesize osteoid. Osteosarcoma is an aggressive tumor of malignant osteoblasts, predominantly occurring in adolescents.
- **Cartilage forming:** Osteochondroma is an exostosis with a cartilage cap. Sporadic and syndromic forms arise from mutations in the *EXT* genes. Chondromas are benign tumors producing hyaline cartilage, usually arising in the digits. Chondrosarcomas are malignant tumors of chondroid cells that involve the axial skeleton in adults.
- **Ewing sarcomas** are aggressive, malignant, small round cell tumors most often associated with t(11;22).
- **Fibrous dysplasia** is an example of a disorder caused by gain-of-function mutations that occur during development.

Joints

Joints allow movement while providing mechanical stability. They are classified as *solid (nonsynovial)* and *cavitated (synovial)*. The solid joints, also known as *synarthroses*, provide structural integrity and allow only minimal movement. They lack a joint space and are grouped according to the type of connective tissue (fibrous tissue or cartilage) that bridges the ends of the bones. Fibrous synarthroses include the cranial sutures and the bonds between roots of teeth and the jawbones. Cartilaginous synarthroses (synchondroses) are represented by the symphyses between the sternum and the ribs and between bones of the pelvis. Synovial joints, in contrast, have a joint space that allows for a wide range of motion. Synovial membranes enclose these joints. The membranes are lined by type A synoviocytes that are specialized macrophages with phagocytic activity and type B synoviocytes that are similar to fibroblasts and synthesize hyaluronic acid and various proteins. The synovial lining lacks a basement membrane, which allows for efficient exchange of nutrients, wastes, and gases between blood and synovial fluid. Synovial fluid is a plasma filtrate containing hyaluronic acid produced by synovial cells that acts as a viscous lubricant and provides nutrition for the articular cartilage.

Hyaline cartilage is a unique connective tissue ideally suited to serve as an elastic shock absorber and wear-resistant surface. It lacks a blood supply, lymphatic drainage, and innervation. Hyaline cartilage is composed of water (70%), type II collagen (10%), proteoglycans (8%), and chondrocytes. The collagen resists tensile stresses and transmits vertical loads. The water and proteoglycans resist compression and limit friction. The chondrocytes synthesize the matrix as well as enzymatically digest it. Chondrocytes secrete degradative enzymes in inactive forms and enrich the matrix with enzyme inhibitors.

ARTHRITIS

Osteoarthritis

Osteoarthritis (OA), also called degenerative joint disease, is characterized by degeneration of cartilage that results in structural and functional failure of synovial joints. It is the most common disease of joints. Although the term *osteoarthritis* implies an inflammatory disease, it is considered an intrinsic disorder of cartilage in which chondrocytes respond to biochemical and mechanical stresses resulting in the breakdown of the matrix and failure of its repair. Nevertheless there is little doubt that inflammatory mediators (described later) whose release is triggered by joint injury perpetuate and worsen the damage.

In most instances OA appears insidiously, without apparent initiating cause, as an aging phenomenon *(idiopathic* or *primary osteoarthritis)*. In these cases the disease is usually oligoarticular (affects few joints). In about 5% of cases, OA appears in younger individuals with some predisposing condition, such as joint deformity, a previous joint injury, or an underlying systemic disease that places joints at risk. In these settings the disease is called *secondary osteoarthritis*. The prevalence of OA increases exponentially beyond the age of 50, and about 40% of people older than 70 are affected.

Pathogenesis

The lesions of OA stem from degeneration of the articular cartilage and its disordered repair. Articular cartilage serves as a low-friction surface that transmits loads to the underlying bone. Cartilage resists compression through the viscoelastic properties of the extracellular matrix (principally type II collagen, proteoglycans, and water) secreted by chondrocytes. Repeated biomechanical stress contributes to development of OA, but genetic factors, including genes encoding components of the matrix and signaling molecules, also play a role. These factors are thought to predispose to chondrocyte injury, which in turn leads to alteration of the extracellular matrix (Fig. 21.32). Although chondrocytes proliferate and continuously synthesize and secrete proteoglycans, degradation ultimately exceeds synthesis, and the composition of proteoglycans changes as the disease progresses. Meanwhile, MMPs secreted by chondrocytes degrade the type II collagen network. Cytokines and diffusible factors from chondrocytes and synovial cells, particularly TGF-β (which induces MMPs), TNF,

prostaglandins, and nitric oxide, have been implicated in OA (Fig. 21.32). Chronic, low-level inflammation contributes to the progression of the disease. Ultimately, chondrocyte loss and a severely degraded matrix mark the late stage of the disease.

Clinical Course

MORPHOLOGY

In the early stages of OA, chondrocytes proliferate, forming clusters. Concurrently, the water content of the matrix increases and the concentration of proteoglycans decreases. The normally horizontally arranged collagen type II fibers are cleaved, yielding fissures and clefts at the articular surface (Fig. 21.33). This manifests as a granular soft articular surface. Eventually, full-thickness portions of the cartilage are sloughed. The dislodged pieces of cartilage and subchondral bone tumble into the joint, forming loose bodies *(joint mice)*. The exposed subchondral bone plate becomes the new articular surface, and friction with the opposing surface burnishes the exposed bone, giving it the appearance of polished ivory *(bone eburnation)* (Fig. 21.33). Small fractures through the articulating bone are common, and the fracture gaps allow synovial fluid to be forced into the subchondral regions in a one-way, ball valve–like mechanism forming fibrous-walled cysts. Outgrowths *(osteophytes)* develop at the margins of the articular surface and are capped by fibrocartilage and hyaline cartilage that gradually ossify. The synovium is usually only mildly congested and fibrotic, and it may have scattered chronic inflammatory cells.

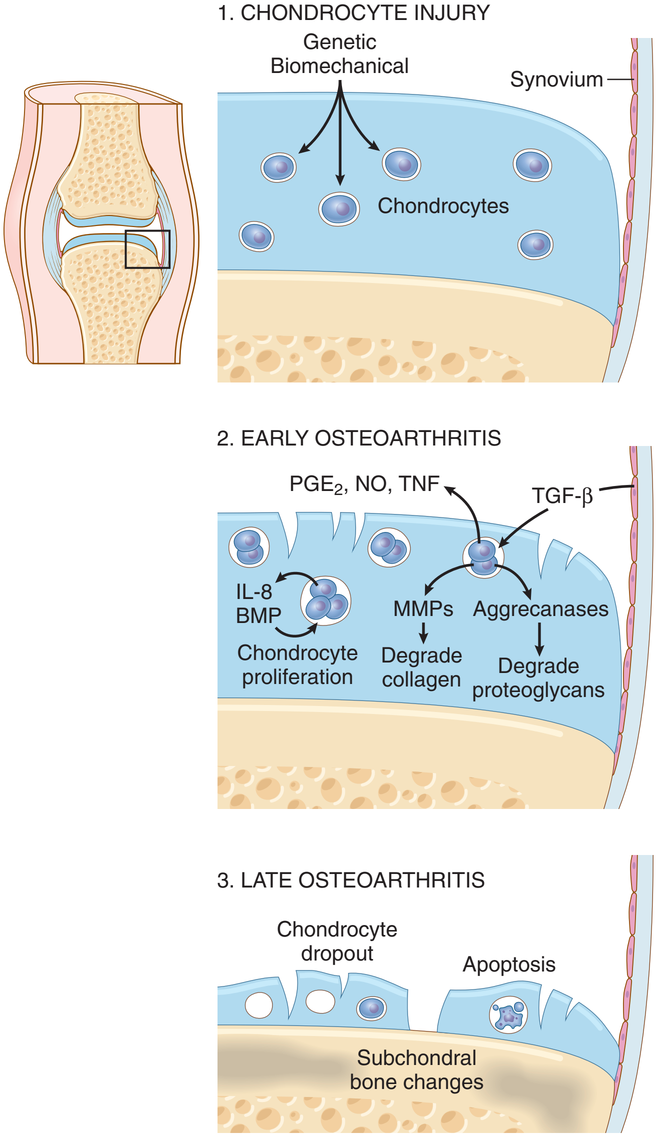

Fig. 21.32 Schematic view of osteoarthritis (OA). OA is thought to be initiated by chondrocyte injury (1) in a genetically predisposed patient leading to changes in the extracellular matrix. (2) Although chondrocytes may proliferate and attempt to repair damaged matrix, continued degradation exceeds repair in early OA. (3) Late OA is evidenced by loss of both matrix and chondrocytes with subchondral bone damage.

Primary OA usually presents in patients they are in their 50s. If a young person has significant manifestations of OA, a search for some underlying cause should be made. Characteristic symptoms include joint pain that worsens with use, morning stiffness, crepitus, and limitation of range of movement. Impingement on spinal foramina by osteophytes results in cervical and lumbar nerve root compression and radicular pain, muscle spasms, muscle atrophy, and neurologic deficits. The joints commonly involved include the hips (Fig. 21.34), knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints. *Heberden nodes*, prominent osteophytes at the distal interphalangeal joints, are common in women (but not in men). With time, joint deformity can occur, but unlike rheumatoid arthritis (discussed next), joint fusion does not take place (Fig. 21.35). The level of disease severity detected radiographically, however, does not correlate well with pain and disability. There are still no satisfactory means of preventing primary OA, and there are no effective methods of halting its progression. Therapy includes management of pain, NSAIDs to reduce inflammation, intra-articular corticosteroids, activity modification, and, for severe cases, arthroplasty.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory disorder of autoimmune origin that principally attacks the joints, producing a nonsuppurative proliferative and inflammatory synovitis. RA often progresses to the destruction of the articular cartilage and, in some cases ankylosis (adhesion) of the joints. Extraarticular lesions may occur in the skin, heart, blood vessels, and lungs. The prevalence in the United States is approximately 1%, and it is three times more common in women than in men. The peak incidence is in the third through fifth decades of life.

Pathogenesis

As in other autoimmune diseases, genetic predisposition and environmental factors contribute to the development, progression, and chronicity of the disease. The pathologic changes are mediated by antibodies against self-antigens

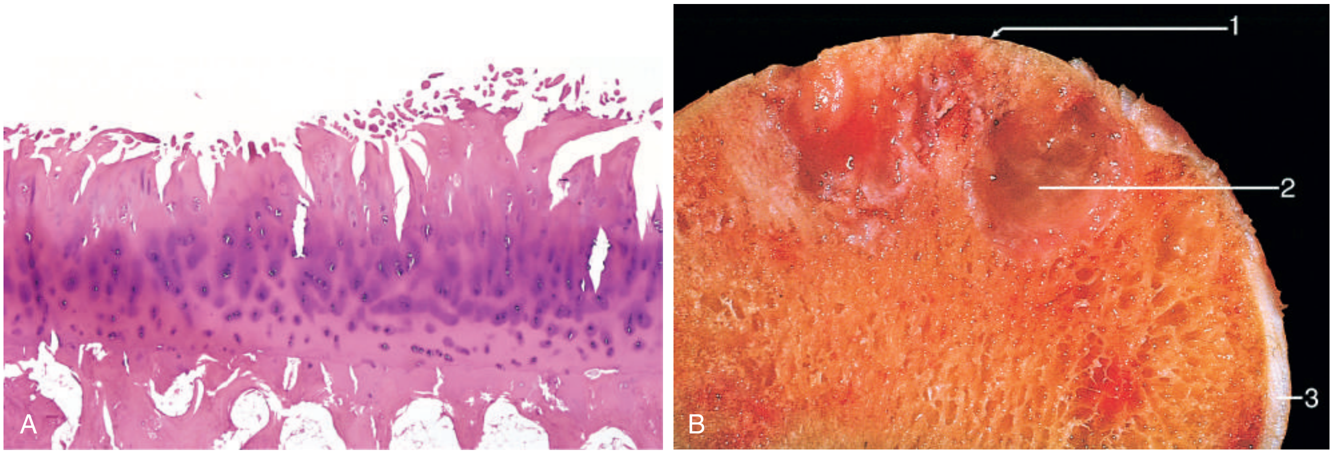

Fig. 21.33 Osteoarthritis. (A) Histologic demonstration of the characteristic fibrillation of the articular cartilage. (B) Eburnated articular surface exposing subchondral bone (1), subchondral cyst (2), and residual articular cartilage (3).

and inflammation caused by cytokines, predominantly secreted by CD4+ T cells (Fig. 21.36).

CD4+ T helper (T_H) cells may initiate the autoimmune response in RA by reacting with an arthritogen, perhaps microbial or a chemically modified self-antigen. The T cells produce cytokines that stimulate other inflammatory cells to effect tissue injury:

- IFN-γ from T_H1 cells activates macrophages and synovial cells.
- IL-17 from T_H17 cells recruits neutrophils and monocytes.
- RANKL expressed on activated T cells stimulates osteoclasts and bone resorption.
- TNF and IL-1 from macrophages stimulate resident synovial cells to secrete proteases that destroy hyaline cartilage.

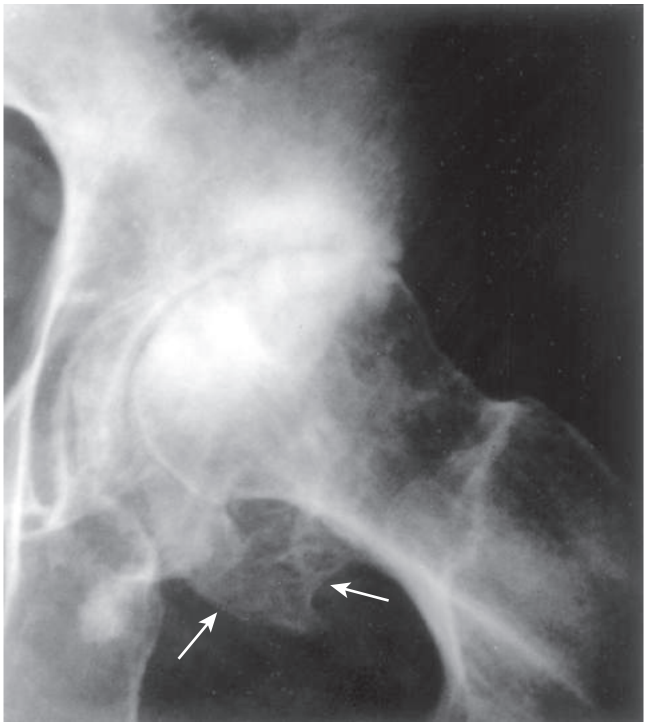

Fig. 21.34 Severe osteoarthritis of the hip. The joint space is narrowed, and there is subchondral sclerosis with scattered oval radiolucent cysts and peripheral osteophyte lipping *(arrows)*.

Of these, TNF has been most firmly implicated in the pathogenesis of RA, and TNF antagonists have proved to be effective therapies for the disease (see later).

The synovium of RA contains germinal centers with secondary follicles and abundant plasma cells that produce antibodies, some of which may be against self-antigens. Many of the serum autoantibodies detected in patients are specific for *citrullinated peptides* in which arginine residues are posttranslationally converted to citrulline. In RA, complexes of antibodies with citrullinated fibrinogen, type II collagen, α-enolase, and vimentin deposit in the joints. Evidence suggests that the anti-citrullinated protein antibodies (ACPA) in combination with a T cell response to the citrullinated proteins contribute to disease chronicity. Approximately 30% of RA patients do not have ACPA in the blood. About 80% of patients have serum IgM or IgA autoantibodies that bind to the Fc portions of their own IgG. These autoantibodies are called *rheumatoid factor* and may also deposit in joints as immune complexes, although they are not uniformly present in all patients with RA and can be found in patients without the disease.

It is estimated that 50% of the risk of developing RA is related to inherited genetic susceptibility. The *HLA* class II locus is associated with ACPA-positive RA. Evidence suggests that an epitope on a citrullinated protein, vinculin, mimics an epitope on many microbes and is the target of CD4+ T cells when presented by predisposing HLA-DQ alleles. A second gene linked to RA, *PTPN22,* encodes a protein tyrosine phosphatase that is postulated to inhibit T cell activation. Numerous other genetic associations have been reported.

Many candidate environmental factors whose antigens promote autoimmunity have been postulated. At least 70% of RA patients have ACPA in their blood, which may

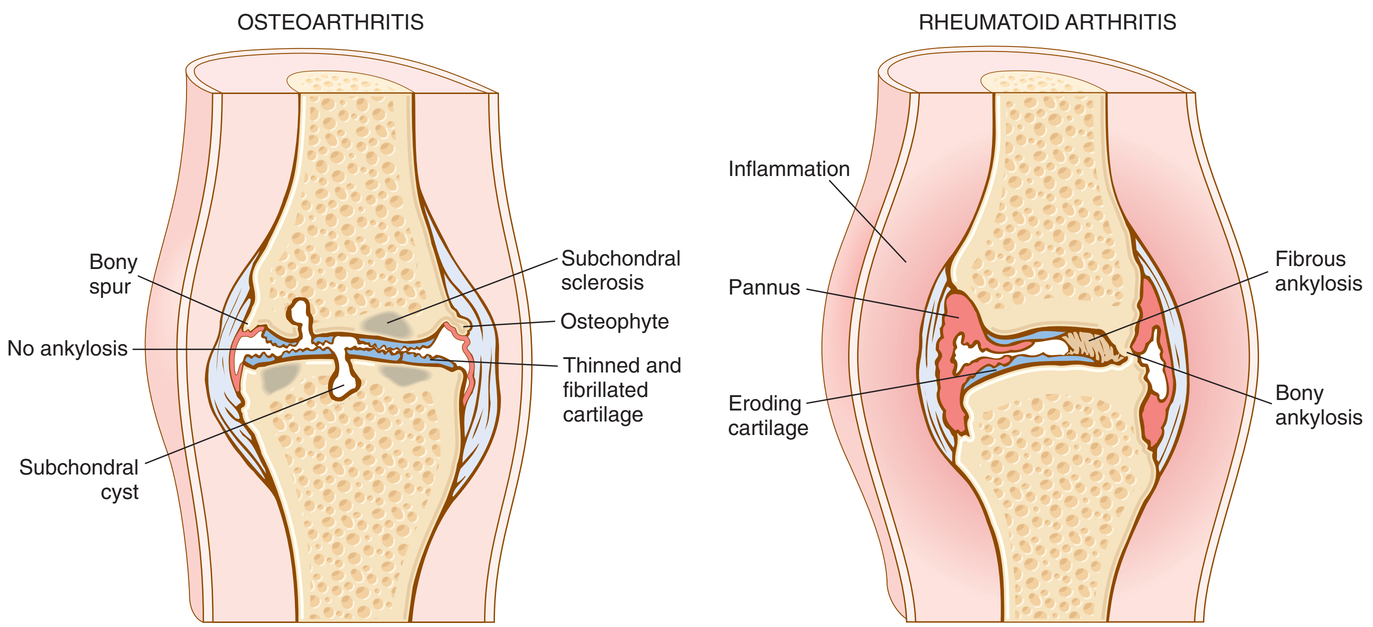

Fig. 21.35 Comparison of the morphologic features of rheumatoid arthritis and osteoarthritis.

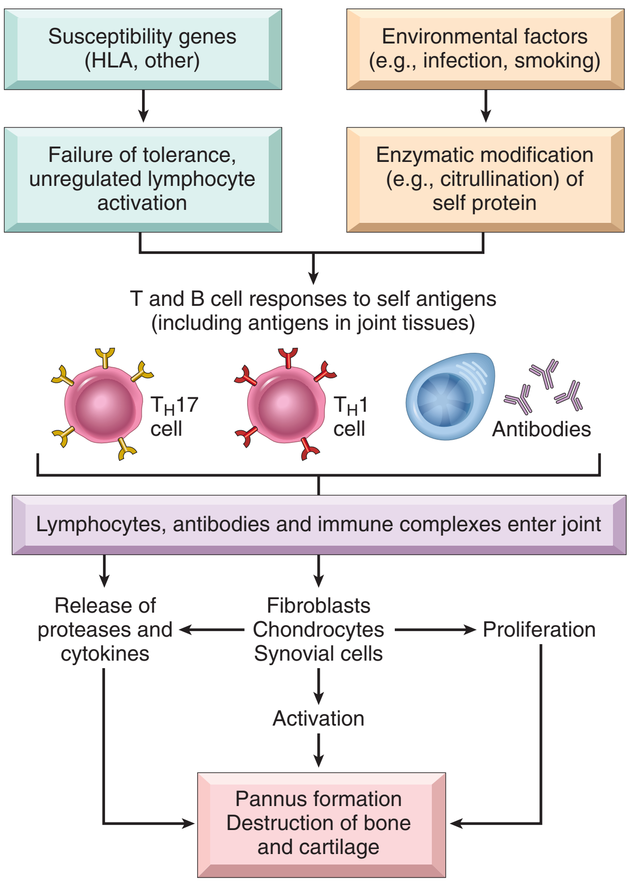

Fig. 21.36 Major processes involved in the pathogenesis of rheumatoid arthritis.

be produced during inflammation. Insults such as infection (including periodontitis) and smoking may promote citrullination of self-proteins, creating new epitopes that trigger autoimmune reactions.

The inflammation localizes to the joint, recruiting macrophages and triggering activation and/or proliferation of synovial cells, chondrocytes, and fibroblasts. The production of proteolytic enzymes and cytokines contributes to the destruction of cartilage and, through increased osteoclast activity, bone (Fig. 21.36).

MORPHOLOGY

RA typically manifests as symmetric arthritis principally affecting the small joints of the hands and feet. Grossly, the synovium becomes edematous, thickened, and hyperplastic, transforming its smooth contour to one covered by delicate and bulbous villi (Fig. 21.37A–B). The characteristic histologic features include (1) **synovial cell hyperplasia** and proliferation; (2) **dense inflammatory infiltrates** of CD4+ helper T cells, B cells, plasma cells, dendritic cells, and macrophages (Fig. 21.37C); (3) increased vascularity resulting from angiogenesis; (4) neutrophils and aggregates of organizing fibrin on the synovial and joint surfaces; (5) osteoclastic activity in underlying bone, allowing the synovium to penetrate into the bone, causing periarticular erosions and subchondral cysts. Together, the aforementioned changes produce a **pannus:** a mass of edematous synovium, inflammatory cells, granulation tissue, and fibroblasts that grows over the articular cartilage and causes its erosion. In advanced untreated cases the pannus can bridge the bones to form a **fibrous ankylosis**, which may later ossify as a **bony ankylosis** (Fig. 21.35).

Rheumatoid nodules are an infrequent manifestation of RA and typically occur in subcutaneous tissue including the forearm, elbows, occiput, and lumbosacral area. Microscopically, they resemble necrotizing granulomas (Fig. 21.38). Rarely, RA can involve the lungs (rheumatoid nodules, interstitial lung disease).

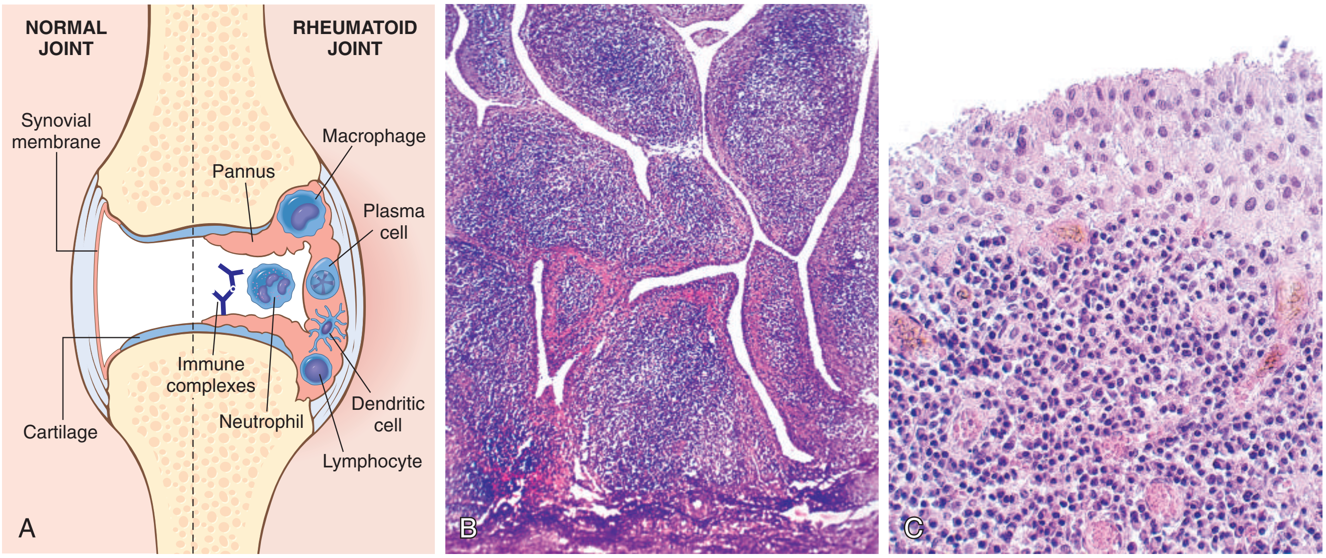

Fig. 21.37 Rheumatoid arthritis. (A) Schematic view of the joint lesion. (B) Low magnification shows marked synovial hypertrophy with formation of villi. (C) At higher magnification, subsynovial tissue containing a dense lymphoid aggregate. *(A, Modified from Feldmann M: Development of anti-TNF therapy for rheumatoid arthritis.* Nat Rev Immunol *2:364, 2002.)*

Clinical Course

RA can be distinguished from other forms of polyarticular inflammatory arthritis by the presence of ACPA and by characteristic radiographic findings. In about half of patients, RA begins slowly and insidiously with malaise, fatigue, and generalized musculoskeletal pain. After several weeks to months, the joints become involved. The pattern of joint involvement is generally symmetrical and the hands and feet, wrists, ankles, elbows, and knees are most commonly affected. The metacarpophalangeal and proximal interphalangeal joints are frequently involved (in contrast to OA, see earlier).

Involved joints are swollen, warm, and painful. In contrast to OA, the joints are stiff when patient rises in the morning or following inactivity. The typical patient has progressive joint enlargement and decreased range of motion pursuing a chronic waxing and waning course. In a minority of patients, especially those lacking RF and ACPA, the disease may stabilize or even regress.

Inflammation in the tendons, ligaments, and occasionally the adjacent skeletal muscle frequently accompanies the arthritis and produces the characteristic ulnar deviation of the fingers and flexion-hyperextension of the fingers (swan-neck deformity, boutonnière deformity). Radiographic hallmarks are joint effusions and juxtaarticular osteopenia with erosions and narrowing of the joint space and loss of articular cartilage (Fig. 21.39).

The treatment for RA consists of corticosteroids, other immunosuppressants such as methotrexate, and, most notably, TNF antagonists. However, anti-TNF agents are not curative, and patients must be maintained on TNF antagonists to avoid disease flares. Long term treatment with TNF antagonists carries with it increased risk of infections with organisms such as *M. tuberculosis*.

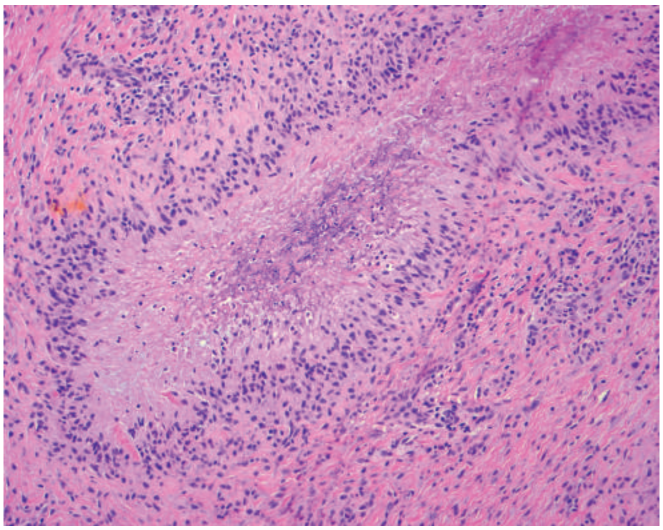

Fig. 21.38 Rheumatoid nodule composed of central necrosis rimmed by palisaded histiocytes.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a heterogeneous group of disorders of unknown cause that present with arthritis before age 16 and persist for at least 6 weeks. In contrast to RA, in JIA: (1) oligoarthritis is more common, (2) systemic disease is more frequent, (3) large joints are affected more often than small joints, (4) rheumatoid nodules and rheumatoid factor are usually absent, and (5) anti-nuclear antibody (ANA) seropositivity is common. The pathogenesis is unknown but similar to adult RA; risk factors include *HLA* and *PTPN22* variants. Also, like adult RA, damage in JIA appears to be caused by T_H1 and T_H17 cells and cytokines produced by these and other inflammatory cells. Treatment is similar to adult RA with some success in using an IL-6 receptor antibody in the systemic form. Long-term prognosis of JIA is very variable. Although many affected individuals have

Fig. 21.39 Rheumatoid arthritis of the hand. Characteristic features include diffuse osteopenia, marked loss of the joint spaces of the carpal, metacarpal, phalangeal, and interphalangeal joints, periarticular bony erosions, and ulnar drift of the fingers.

chronic disease, only about 10% develop serious functional disability.

Seronegative Spondyloarthropathies

The spondyloarthropathies are a heterogeneous group of disorders that share the following features:

- Absence of rheumatoid factor
- Pathologic changes in the ligamentous attachments rather than synovium
- Involvement of sacroiliac joints, with or without other joints
- Association with HLA-B27
- Bony proliferation leading to ankylosis (fusion of joints)

The manifestations are immune mediated and are triggered by a T cell response presumably directed against an undefined antigen, possibly infectious, that may cross-react with antigens expressed on cells of the musculoskeletal system.

Ankylosing spondylitis, the prototypical spondyloarthritis, causes destruction of articular cartilage and bony ankylosis, especially of the sacroiliac joints. The disease becomes symptomatic in the second and third decades of life as lower back pain and spinal immobility. Involvement of peripheral joints, such as the hips, knees, and shoulders, occurs in at least one-third of affected individuals. Approximately 90% of patients are HLA-B27 positive, but how the B27 allele contributes to the disease is not known. An anti-IL-17 antibody has shown some efficacy in this disease.

Reactive arthritis is defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis. Most affected individuals are men in their 20s or 30s, and more than 80% are HLA-B27 positive. The disease is probably caused by an autoimmune reaction initiated by previous infection of the genitourinary system *(Chlamydia)* or the gastrointestinal tract *(Shigella*, *Salmonella*, *Yersinia*, *Campylobacter)*. Within several weeks of urethritis or diarrhea, patients experience low back pain. The ankles, knees, and feet are affected most often, frequently in an asymmetric pattern. Patients with severe chronic disease have involvement of the spine that is indistinguishable from ankylosing spondylitis.

Infectious Arthritis

Joints can become infected from hematogenous dissemination, direct inoculation through the skin, or from contiguous spread from a soft tissue abscess or osteomyelitis. Infectious arthritis is potentially serious, because it can cause rapid, permanent joint destruction.

Suppurative Arthritis

Bacterial infections that cause acute suppurative arthritis usually enter the joints from distant sites by hematogenous spread. In neonates, however, contiguous spread from underlying epiphyseal osteomyelitis may occur. *H. influenza* arthritis predominates in children younger than 2 years of age, *S. aureus* is the main agent in older children and adults, and gonococcus is prevalent during late adolescence and young adulthood. Individuals with sickle cell disease are prone to infection with *Salmonella*. These joint infections affect the sexes equally except for gonococcal arthritis, which is seen mainly in sexually active women. Individuals with deficiencies of complement components (C5, C6, C7, or C9) are susceptible to disseminated gonococcal infections and hence arthritis.

The classic presentation is the sudden development of an acutely painful, warm, and swollen joint that has a restricted range of motion. Systemic findings of fever, leukocytosis, and elevated sedimentation rate are common. In 90% of nongonococcal cases, the infection involves only a single joint, most commonly the knee, followed in decreasing frequency by the hip, shoulder, elbow, wrist, and sternoclavicular joints. The axial joints are more often involved in drug users. Joint aspiration is diagnostic if it yields purulent fluid in which the causative agent can be identified. As mentioned earlier, cartilage has limited repair potential, so prompt recognition and effective anti-microbial therapy is vital to prevent permanent joint destruction.

Lyme Arthritis

Lyme arthritis is the leading arthropod-borne disease in the United States, predominantly affecting New England and mid-Atlantic states, but the geographic range and incidence are increasing. It is caused by infection with the spirochete *Borrelia burgdorferi*, which is transmitted by deer ticks of the *Ixodes ricinus* complex. In its classic form, Lyme disease progressively involves multiple organ systems through three clinical phases (Fig. 21.40). The initial infection of the skin, or *early localized stage,* is followed by *an*

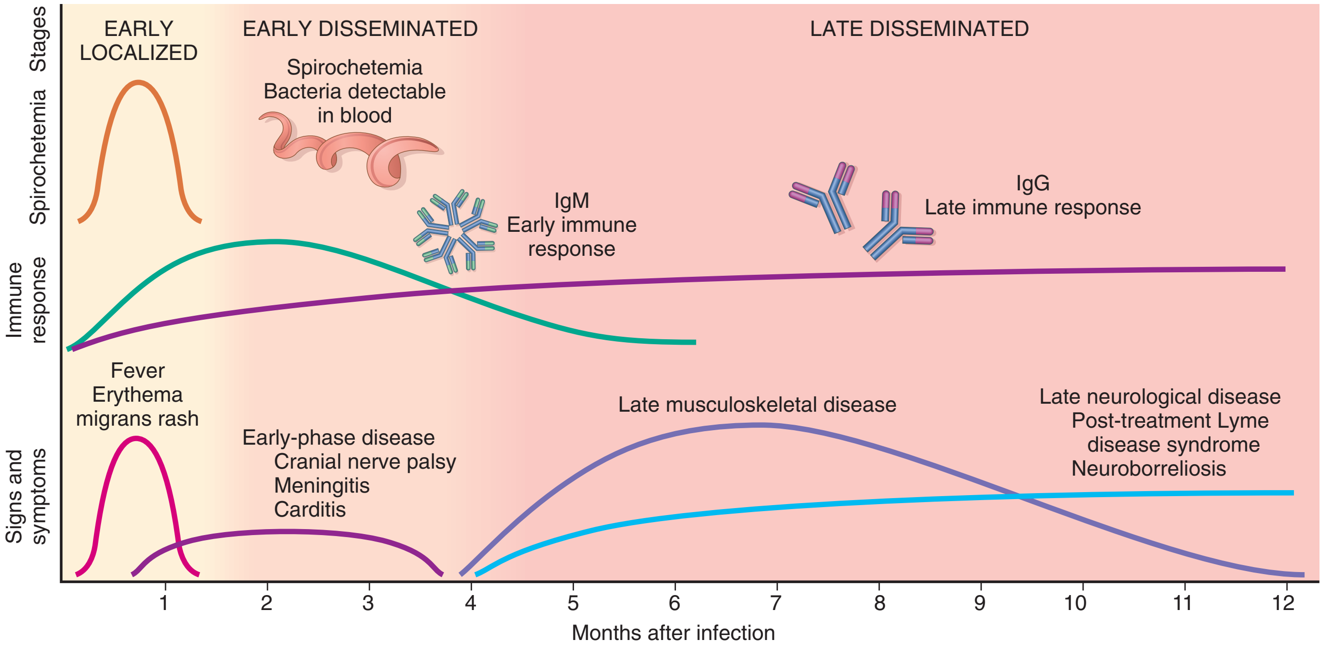

Fig. 21.40 Lyme disease progresses through three clinically recognizable phases: early localized, early disseminated, and late persistent. Although initial manifestations result directly from spirochete infection, later signs and symptoms are likely immune-mediated. *(Figure modified from Dr. Charles Chiu, University of California San Francisco, San Francisco, California. Used with permission.)*

early disseminated stage involving skin, cranial nerves, heart, and meninges. If left untreated, arthritis, especially of the knee, occurs weeks to months after infection.

Currently, arthritis occurs in less than 10% of cases because most patients are cured at an earlier stage. However, if left untreated approximately 60% to 80% of individuals develop a migratory arthritis *(Lyme arthritis)* lasting for weeks to months. Spirochetes can only be identified in about 25% of joints with arthritis, but the diagnosis can be confirmed by serologic testing for anti-*Borrelia* antibodies. Treatment of Lyme disease consists of antibiotics with activity against *Borrelia*. Cure rates of 90% have been achieved with standard regimens. A vaccine is under development. However, a chronic arthritis that is antibiotic refractory can develop in the *late disseminated stage*. In many of these patients, *Borrelia* cannot be detected in the joint fluid even by PCR. It has been proposed that cellular (especially T_H1) and humoral responses to *Borrelia* outer surface protein A may initiate this late, autoimmune, arthritis. The chronic manifestations, in addition to joint pain, can include nonspecific symptoms (fatigue, cognitive complaints), known collectively as *posttreatment Lyme disease syndrome* (PTLDS).

Infected synovium exhibits a chronic synovitis marked by synoviocyte hyperplasia, fibrin deposition, mononuclear cell infiltrates (especially CD4+ T cells), and onion-skin thickening of arterial walls. The morphology in severe cases can closely resemble that of RA.

Crystal-Induced Arthritis

Articular crystal deposits are associated with a variety of joint disorders. Endogenous crystals shown to be pathogenic include monosodium urate (MSU) *(gout)*, calcium pyrophosphate dehydrate *(pseudogout)*, and basic calcium phosphate. Exogenous crystals, such as silicone, polyethylene, and methyl methacrylate used in prosthetic joints, and the debris that accumulates with their erosion, may result in local arthritis. Crystals produce disease by triggering an inflammatory reaction that destroys cartilage.

Gout

Gout is marked by transient attacks of acute arthritis initiated by urate crystals deposited within and around joints. Whether gout is primary or secondary to some other underlying disease, the common feature is excessive uric acid in tissues and body fluids. In the primary form (90% of cases), gout is the major manifestation of the disease and the cause is usually unknown.

Pathogenesis

Hyperuricemia (plasma urate level above 6.8 mg/dL) is necessary, but not sufficient, for the development of gout. Uric acid metabolism can be summarized as follows:

- *Synthesis.* Uric acid is the end product of purine catabolism. Increased synthesis typically reflects some abnormality in purine production. The synthesis of purine nucleotides, in turn, involves two interlinked pathways. In the de novo pathway, purine nucleotides are synthesized from nonpurine precursors, and in salvage pathways they are synthesized from free purine bases obtained through the diet or the catabolism of purine nucleotides.
- *Excretion.* Uric acid is filtered from the circulation by the glomerulus and virtually completely resorbed by the proximal tubule of the kidney. A small fraction of the resorbed uric acid is secreted by the distal nephron and excreted in the urine.

In primary gout, elevated uric acid most commonly results from reduced excretion, the basis of which is unknown in most patients. A small minority of primary gout is caused by uric acid overproduction as a result of identifiable enzymatic defects. For example, partial deficiency of hypoxanthine guanine phosphoribosyl transferase (HGPRT) interrupts the salvage pathway, so purine metabolites cannot be salvaged and are, instead, degraded into uric acid. Complete absence of HGPRT also results in hyperuricemia, but significant neurologic manifestations of this condition *(Lesch-Nyhan syndrome)* dominate the clinical picture so it is classified as secondary gout. Secondary gout can also be caused by increased production (rapid cell lysis during chemotherapy for leukemia, so-called tumor lysis syndrome) or decreased excretion (chronic renal disease).

The inflammation in gout is triggered by precipitation of urate crystals in the joints, stimulating the production of cytokines that recruit leukocytes (Fig. 21.41). Macrophages and neutrophils phagocytose the crystals, which activates a cytosolic sensor, the inflammasome (Chapter 5). The inflammasome activates caspase-1, which is involved in the production of active IL-1β. IL-1 is proinflammatory, and promotes accumulation of more neutrophils and macrophages in the joint. These cells, in turn, release other cytokines, free radicals, proteases, and arachidonic acid metabolites. The ingested crystals also damage the membranes of phagolysosomes, leading to leakage of these mediators. Activation of complement by the alternative pathway may contribute to more leukocyte recruitment. The result is an acute arthritis, which typically remits spontaneously in days to weeks. Repeated attacks of acute arthritis lead eventually to the formation of tophi, aggregates of urate crystals and inflammatory tissue, in the inflamed synovial membranes and periarticular tissue. Severe damage to the cartilage develops and the function of the joints is compromised.

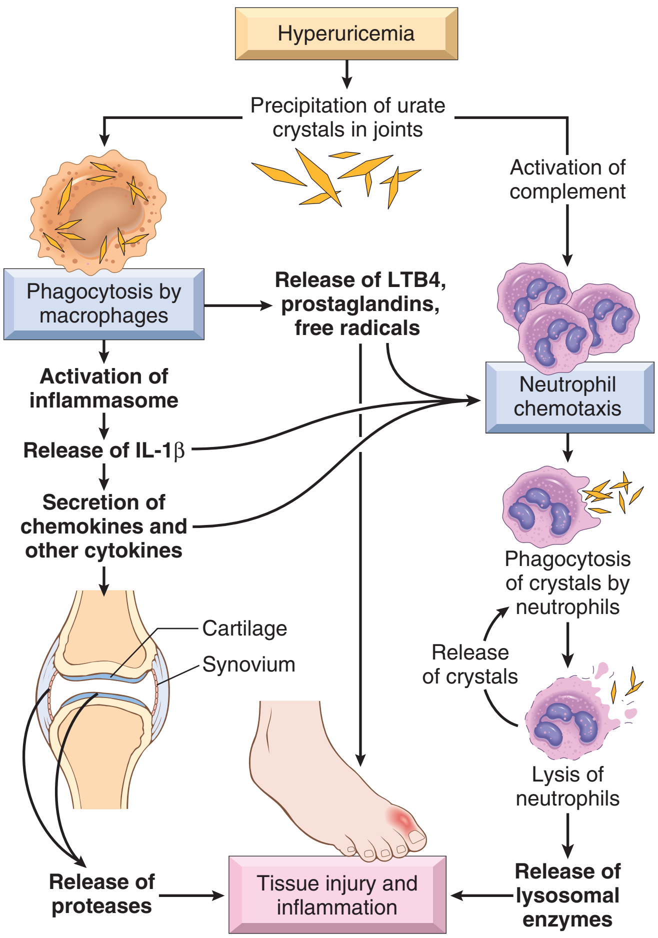

Fig. 21.41 Pathogenesis of acute gouty arthritis. Urate crystals are phagocytosed by macrophages and stimulate the production of various inflammatory mediators that elicit the inflammation characteristic of gout. Note that IL-1, one of the major pro-inflammatory cytokines, in turn stimulates the production of chemokines and other cytokines from a variety of tissue cells. *LTB4*, Leukotriene B4; *IL-1β*, interleukin 1β.

Only about 10% of patients with hyperuricemia develop clinical gout. Other factors contribute symptomatic gout:

- *Age* of the individual and duration of the hyperuricemia. Gout usually appears after 20 to 30 years of hyperuricemia.
- *Genetic predisposition.* In addition to the well-defined X-linked abnormalities of HGPRT, polymorphisms in genes involved with urate or ion transport and possibly inflammation are also associated with gout.
- *Alcohol* consumption.
- *Obesity*.
- *Drugs* (e.g., thiazides) that reduce excretion of urate.

MORPHOLOGY

The distinctive morphologic changes in gout are (1) acute arthritis, (2) chronic tophaceous arthritis, (3) tophi in various sites, and (4) gouty nephropathy.

Acute arthritis is characterized by a dense inflammatory infiltrate that permeates the synovium and synovial fluid. Urate crystals are frequently found in the cytoplasm of the neutrophils and are arranged in small clusters in the synovium. They are long, slender, and needle-shaped, and are negatively birefringent. The synovium is edematous and congested, and it also contains scattered lymphocytes, plasma cells, and macrophages.

Chronic tophaceous arthritis evolves from the repetitive precipitation of urate crystals during acute attacks. The crystals encrust the articular surface and form visible chalky deposits in the synovium (Fig. 21.42A). The synovium becomes hyperplastic, fibrotic, and thickened by inflammatory cells and forms a pannus that destroys the underlying cartilage.

Tophi in the articular cartilage, ligaments, tendons, and bursae are pathognomonic of gout. They are formed by large aggregations of urate crystals surrounded by an intense foreign body giant cell reaction (Fig. 21.42B–C).

Gouty nephropathy refers to the renal complications caused by urate crystals or tophi in the renal medullary interstitium or tubules. Complications include uric acid nephrolithiasis and pyelonephritis.

Clinical Course

Gout is associated with male sex, obesity, metabolic syndrome, excess alchohol intake, renal failure, and age greater than 30 years. Four clinical stages are recognized:

- *Asymptomatic hyperuricemia* appears around puberty in men and after menopause in women.
- *Acute arthritis* presents after several years as sudden onset excruciating joint pain, localized hyperemia, and

warmth. Most first attacks are monoarticular; 50% occur in the first metatarsophalangeal joint. Untreated, acute gouty arthritis may last for hours to weeks, but gradually there is complete resolution.

- *Asymptomatic intercritical period*: Resolution of the acute arthritis leads to a symptom-free interval. In the absence of appropriate therapy, the attacks recur at decreasing intervals and frequently become polyarticular.

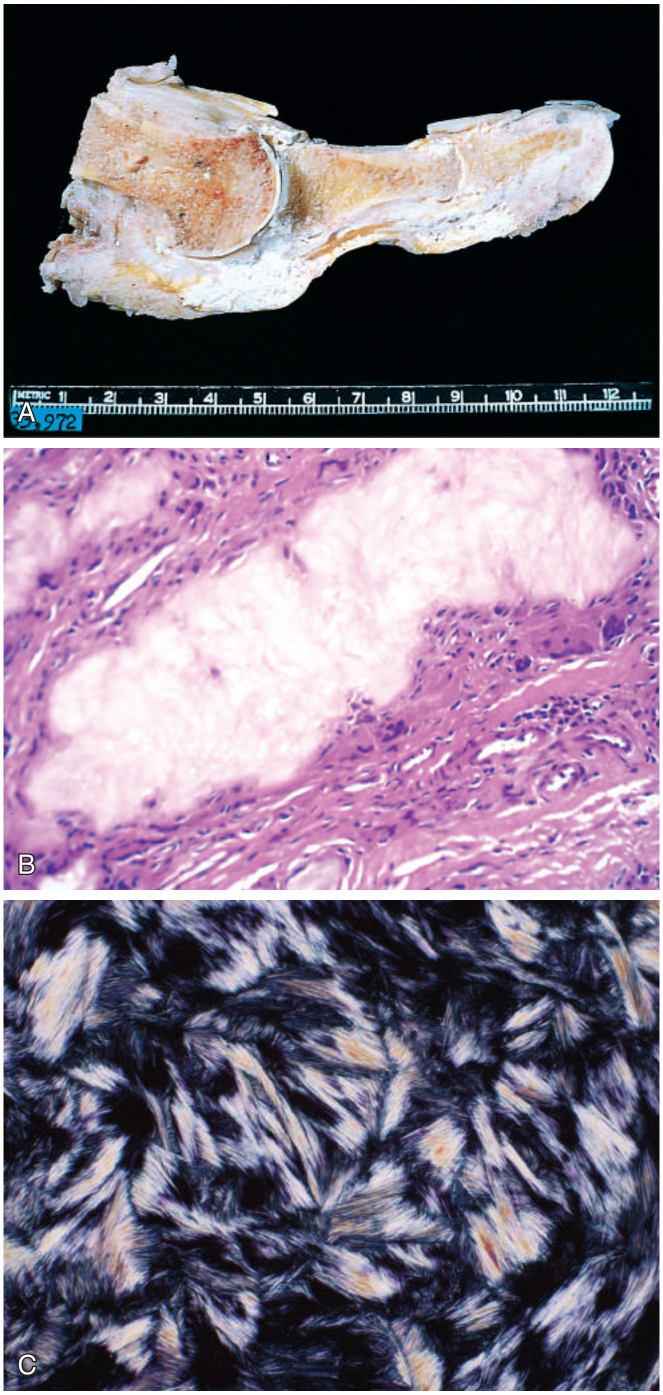

Fig. 21.42 Gout. (A) Amputated great toe with white tophi involving the joint and soft tissues. (B) Gouty tophus—an aggregate of dissolved urate crystals is surrounded by reactive fibroblasts, mononuclear inflammatory cells, and giant cells. (C) Urate crystals are needle shaped and negatively birefringent under polarized light.

- *Chronic tophaceous gout* develops on average about 12 years after the initial acute attack. At this stage, radiographs show characteristic juxtaarticular bone and loss of the joint space.

Treatment of gout aims at lifestyle modification and medication to reduce symptoms (e.g., NSAIDs) and lower urate levels (e.g., xanthine oxidase inhibitor).

Calcium Pyrophosphate Crystal Deposition Disease (Pseudogout)

Calcium pyrophosphate crystal deposition disease (CPPD), also known as *pseudogout,* usually occurs in individuals more than 50 years old and becomes more common with increasing age. The genders and races are equally affected. CPPD is divided into sporadic (idiopathic), hereditary, and secondary types. The autosomal dominant variant is caused by germline mutations in the pyrophosphate transport channel resulting in crystal deposition and arthritis relatively early in life. Various disorders, including previous joint damage, hyperparathyroidism, hemochromatosis, and diabetes, predispose to the secondary form. Studies suggest that articular cartilage proteoglycans, which normally inhibit mineralization, are degraded, allowing crystallization around chondrocytes. As in gout, inflammation is caused by activation of the inflammasome in macrophages.

MORPHOLOGY

The crystals first develop in the articular cartilage, menisci, and intervertebral discs, and as the deposits enlarge they may rupture and seed the joint. The crystals form chalky, white friable deposits, which are seen histologically in hematoxylin- and eosin-stained preparations as oval blue-purple aggregates (Fig. 21.43A). Individual crystals are rhomboid, 0.5 to 5 μm in greatest dimension (Fig. 21.43B), and are positively birefringent. Inflammation is usually milder than in gout.

Clinical Course

CPPD is frequently asymptomatic. However, it may produce acute, subacute, or chronic arthritis that can be confused clinically with OA or RA. The joint involvement may last from several days to weeks and may be monoarticular or polyarticular; the knees, followed by the wrists, elbows, shoulders, and ankles, are most commonly affected. Ultimately, approximately 50% of affected individuals experience significant joint damage. Therapy is supportive. There is no known treatment that prevents or slows crystal formation.

SUMMARY

ARTHRITIS

- **Osteoarthritis (OA, degenerative joint disease),** the most common disease of joints, is a degenerative process of articular cartilage in which matrix breakdown exceeds synthesis. Inflammation is minimal and typically secondary. Local production of inflammatory cytokines may contribute to the progression of joint degeneration.
- **Rheumatoid arthritis (RA)** is a chronic autoimmune inflammatory disease that affects mainly small joints, but can

be systemic. RA is caused by a cellular and humoral immune response against self-antigens, particularly citrullinated proteins. TNF plays a central role and antagonists against TNF are of clinical benefit.

- **Seronegative spondyloarthropathies** are a heterogeneous group of likely autoimmune arthritides that preferentially involve the sacroiliac and vertebral joints and are associated with HLA-B27.
- **Suppurative arthritis** describes direct infection of a joint space by bacterial organisms.
- **Lyme disease** is a systemic infection by *Borrelia burgdorferi*, which manifests, in part, as an infectious arthritis, possibly with an autoimmune component in chronic stages.
- **Gout and pseudogout** result from inflammatory responses triggered by precipitation of urate or calcium pyrophosphate, respectively.

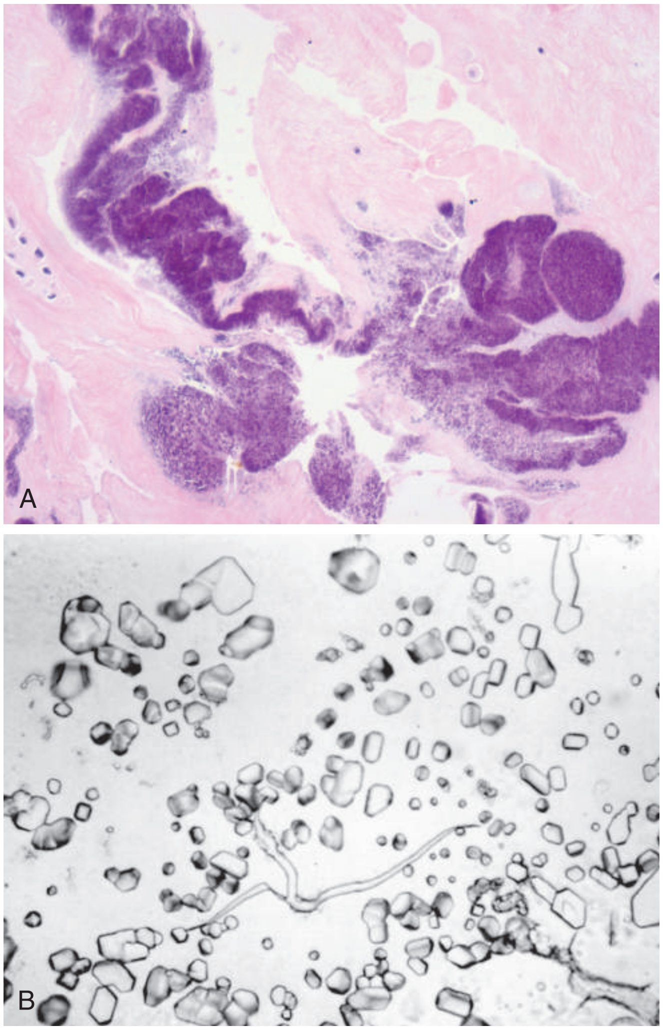

Fig. 21.43 Pseudogout. (A) Deposits are present in cartilage and consist of amorphous basophilic material. (B) Smear preparation of calcium pyrophosphate crystals.

JOINT TUMORS AND TUMORLIKE CONDITIONS

Reactive tumorlike lesions, such as ganglions, synovial cysts, and osteochondral loose bodies, commonly involve joints and tendon sheaths. They usually result from trauma or degenerative processes and are much more common than neoplasms. Primary neoplasms are rare, usually benign, and tend to recapitulate the cells and tissue types (synovial membrane, fat, blood vessels, fibrous tissue, and cartilage) native to joints and related structures. Synovial sarcoma, although once thought to be related to or derived from the tissues of the joint, is now recognized as a sarcoma of uncertain origin and is discussed later with soft tissue tumors.

Ganglion and Synovial Cysts

A *ganglion* is a small (1–1.5 cm) cyst that is almost always located near a joint capsule or tendon sheath. A common location is around the joints of the wrist, where it appears as a firm, fluctuant, pea-sized translucent nodule. It arises as a result of cystic or myxoid degeneration of connective tissue; hence the cyst wall lacks a cell lining. The lesion may be multilocular and enlarges through coalescence of adjacent areas of myxoid change. The fluid that fills the cyst is similar to synovial fluid; however, there is no communication with the joint space. Despite the name, the lesion is unrelated to ganglia of the nervous system.

Herniation of synovium through a joint capsule or massive enlargement of a bursa may produce a *synovial cyst*. A well-recognized example is the synovial cyst that forms in the popliteal space in the setting of RA or OA *(Baker cyst)*. The synovial lining may be hyperplastic and contain inflammatory cells and fibrin.

Tenosynovial Giant Cell Tumor

Tenosynovial giant cell tumor is the term for a benign neoplasm that develops in the synovial lining of joints, tendon sheaths, and bursae. Clinical variants of tenosynovial giant cell tumor include the *diffuse type* (previously known as *pigmented villonodular synovitis*), and the *localized type*. Whereas the diffuse form tends to involve large joints, the localized type usually occurs as a discrete nodule attached to a tendon sheath, commonly in the hand.

Pathogenesis

Diffuse and localized types of this tumor both harbor a reciprocal somatic chromosomal translocation, t(1;2)(p13;q37), resulting in fusion of the type VI collagen α-3 promoter to the M-CSF gene. Consequently, the tumor cells overexpress M-CSF, which, through autocrine and paracrine effects, stimulates proliferation of macrophages in a manner similar to giant cell tumor of bone (described previously).

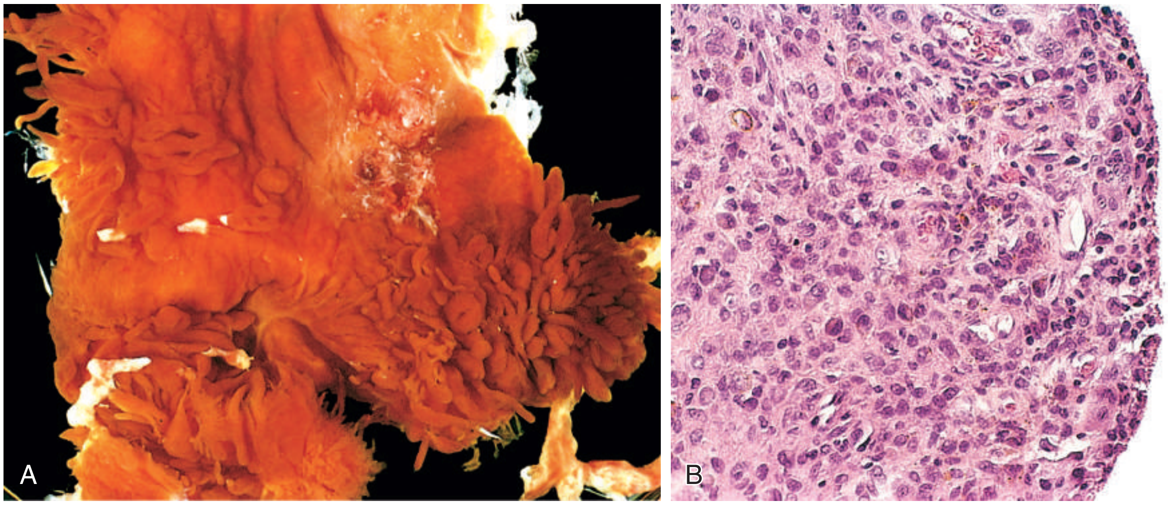

Fig. 21.44 Tenosynovial giant cell tumor, diffuse type. (A) Excised synovium with fronds and nodules typical of pigmented villonodular synovitis. (B) Sheets of proliferating cells in tenosynovial giant cell tumor bulging the synovial lining.

MORPHOLOGY

In diffuse tumors the normally smooth joint synovium is converted into a tangled mat by red-brown folds, fingerlike projections, and nodules (Fig. 21.44A). In contrast, localized (nodular) tumors are well circumscribed. The neoplastic cells, which account for only a minority of the cells in the mass, are polygonal, moderately sized, and resemble synoviocytes (Fig. 21.44B). Both diffuse and localized variants are heavily infiltrated by macrophages containing hemosiderin and foamy lipid, or are multinucleated.

Clinical Course

Diffuse tenosynovial giant cell tumor presents in the knee in 80% of cases. Affected individuals typically complain of pain, locking, and recurrent swelling similar to monoarticular arthritis. Sometimes, a palpable mass is appreciated. The localized variant manifests as a solitary, slow-growing, painless mass that frequently involves the hand. Both types are amenable to surgical excision, but recurrence is more common in the diffuse form. Clinical trials are investigating antagonists of the M-CSF signaling pathway for patients with unresectable disease.

Soft Tissue Tumors

By convention, soft tissue refers to non-epithelial tissue excluding the skeleton, joints, central nervous system, hematopoietic and lymphoid tissues Although nonneoplastic conditions can involve soft tissue, they are seldom confined to this compartment, so the area of soft tissue pathology is restricted to neoplasms.

With the exception of skeletal muscle neoplasms, benign soft tissue tumors outnumber their malignant counterparts, the sarcomas, by 100-fold. In the United States, the incidence of soft tissue sarcomas is approximately 12,000 per year, which is less than 1% of all cancers. Sarcomas, however, cause 2% of all cancer mortality, reflecting their aggressive behavior. Most soft tissue tumors arise in the extremities, especially the thigh. Approximately 15% arise in children but the incidence increases with age.

Pathogenesis

Most sarcomas are sporadic and have no known predisposing cause. A small minority of soft tissue neoplasms are associated with germline mutations in tumor suppressor genes (neurofibromatosis 1, Gardner syndrome, Li-Fraumeni syndrome, Osler-Weber Rendu syndrome). A few tumors can be linked to known environmental exposures such as radiation, burns, or toxins.

Unlike tumors such as colorectal carcinomas that usually arise from recognized precursor lesions, the origin of sarcomas is unknown. The best guess is that the tumors arise from pluripotent mesenchymal stem cells, which acquire somatic "driver" mutations. Despite heterogeneous mechanisms of tumorigenesis among sarcomas, some generalizations can be made based on their genomic complexity:

- *Simple karyotype* (15%–20% of sarcomas): Like many leukemias and lymphomas, sarcomas are often euploid tumors with a single or limited number of chromosomal changes that occur early in tumorigenesis and are specific enough to serve as diagnostic markers. Tumors with these features most commonly arise in younger patients and tend to have a monomorphic appearance microscopically. Examples include Ewing sarcoma, described earlier, and synovial sarcoma. In some cases, the oncogenic effect of these rearrangements is reasonably well understood. In others, the mechanisms are unknown. Oncogenic tumor-specific fusion proteins represent potential molecular targets for therapy.
- *Complex karyotype* (80%–85% of sarcomas): These tumors are usually aneuploid or polyploid and demonstrate multiple chromosomal gains and losses, a feature that suggests underlying genomic instability. Examples

include leiomyosarcoma and undifferentiated pleomorphic sarcoma. Such tumors are more common in adults and tend to be microscopically pleomorphic.

Classification of soft tissue tumors continues to evolve as new molecular genetic abnormalities are identified. Clinically, soft tissue tumors range from benign, self-limited lesions that require minimal treatment to intermediate grade, locally aggressive tumors with minimal metastatic risk to highly aggressive malignancies with significant metastatic risk and mortality. All highly aggressive malignancies are classified as *sarcomas* but this term is less consistently used among the locally aggressive, rarely metastasizing category. Pathologic classification integrates morphology (e.g., muscle differentiation), immunohistochemistry, and molecular diagnostics. In addition to accurate diagnosis, grade (degree of differentiation) and stage (size and depth) are important prognostic indicators.

With this as a primer, we will consider representative or especially illustrative soft tissue tumors.

TUMORS OF ADIPOSE TISSUE

Lipoma

Lipoma, a benign tumor of fat, is the most common soft tissue tumor in adults. The conventional lipoma is the most common subtype, from which rare variants are distinguished according to characteristic morphologic and/or genetic features. Conventional lipoma is a well-encapsulated mass of mature adipocytes. It usually arises in the subcutis of the proximal extremities and trunk, most frequently during middle adulthood. Infrequently, lipomas are large, intramuscular, and poorly circumscribed. Most lipomas are usually cured by simple excision.

Liposarcoma

Liposarcomas are malignant tumors of adipose tissue. Liposarcoma is one of the most common sarcomas of adulthood. It occurs mainly in people in their 50s to 60s in the deep soft tissues and retroperitoneum.

MORPHOLOGY

Liposarcomas are divided into three subtypes:

- Well-differentiated liposarcoma contains adipocytes with scattered atypical spindle cells (Fig. 21.45A). The tumors harbor amplification of chromosome region 12q13-q15, which includes the gene for *MDM2*. You will recall MDM2 encodes a potent inhibitor of p53.
- Myxoid liposarcoma contains abundant basophilic extracellular matrix, arborizing capillaries, and primitive cells at various stages of adipocyte differentiation reminiscent of fetal fat (Fig. 21.45B). The t(12;16) translocation characterizes myxoid liposarcoma. The resultant fusion gene arrests adipose differentiation.
- Pleomorphic liposarcoma consists of sheets of anaplastic cells, bizarre nuclei, and variable amounts of immature adipocytes (lipoblasts). These tumors have complex karyotypes.

Clinical Course

All types of liposarcoma recur locally and often repeatedly unless adequately excised. The well-differentiated variant is relatively indolent, the myxoid/round cell type is intermediate in its malignant behavior, whereas the pleomorphic variant usually is aggressive and frequently metastasizes.

FIBROUS TUMORS

Nodular Fasciitis

Nodular fasciitis is a self-limited fibroblastic and myofibroblastic proliferation that typically occurs the upper extremities of young adults. A history of trauma is present in approximately 25% to 50% of cases, and the tumors grow rapidly during a period of several weeks or months. Whereas nodular fasciitis was historically considered a purely reactive lesion, identification of a t(17;22) translocation producing a *MYH9-USP6* fusion gene indicates that it is a clonal, yet self-limited, proliferation. It is hypothesized that the proliferating cells lack some key hallmark of cancer, perhaps the ability to avoid senescence. Intriguingly, ABC (discussed earlier), another tumor that sits in a gray zone between reactive and neoplastic proliferations, also contains a *USP6* fusion gene. Nodular fasciitis can spontaneously regress and, if excised, rarely recurs. Malignant transformation is virtually nonexistent.

MORPHOLOGY

Nodular fasciitis arises in the deep dermis, subcutis, fascia, or muscle. Grossly the lesion is less than 5 cm, circumscribed, or slightly infiltrative. It is highly cellular containing plump, immature-appearing fibroblasts and myofibroblasts arranged in a pattern reminiscent of cultured fibroblasts (Fig. 21.46). A gradient of maturation *(zonation)* from cellular, loose, and myxoid to organized and fibrous is typical. The cells vary in size and shape (spindle to stellate) and have conspicuous nucleoli; mitotic figures are abundant. Lymphocytes and extravasated red blood cells are common but neutrophils are unusual.

Fibromatoses

Superficial Fibromatosis

Superficial fibromatosis is an infiltrative proliferation that can cause local deformity but has an innocuous clinical course. All forms of superficial fibromatosis affect males more frequently than females. They are characterized by nodular or poorly defined broad fascicles of fibroblasts in long, sweeping fascicles, surrounded by abundant dense collagen. Several clinical subtypes have been identified:

- *Palmar (Dupuytren contracture)*. Irregular or nodular thickening of the palmar fascia either unilaterally or bilaterally.
- *Plantar*. Common in young patients, unilateral and without contractures.

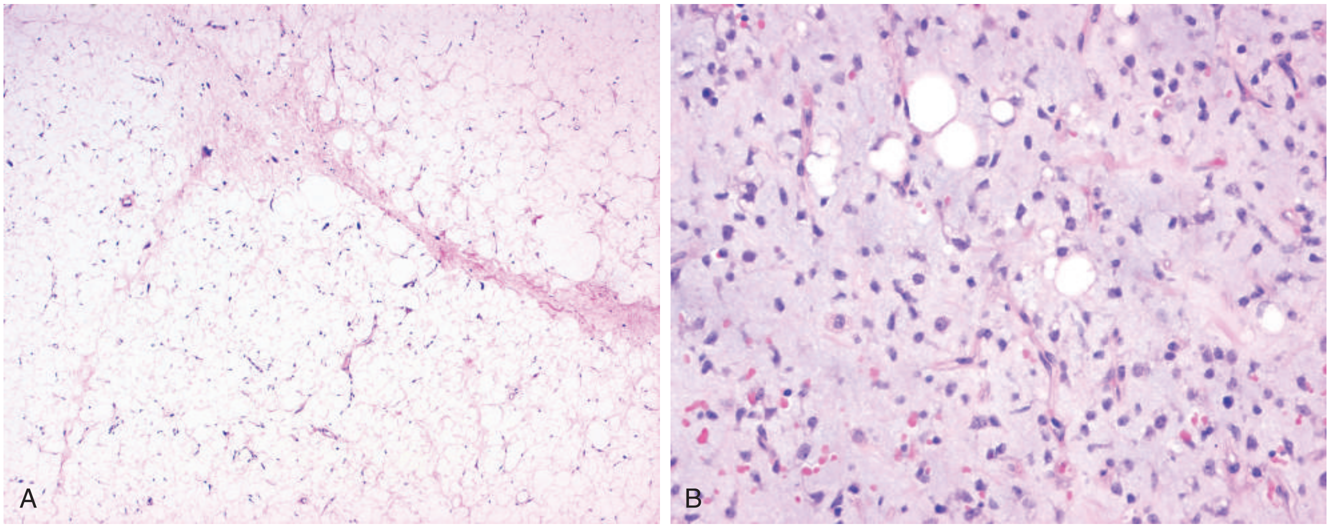

Fig. 21.45 Liposarcoma. (A) The well-differentiated subtype consists of mature adipocytes and scattered spindle cells with hyperchromatic nuclei. (B) Myxoid liposarcoma with abundant ground substance and a rich capillary network in which there are scattered immature adipocytes and more primitive round-to-stellate cells.

- *Penile (Peyronie disease)*. Palpable induration or mass on the dorsolateral aspect of the penis.

In about 20% to 25% of cases, the palmar and plantar fibromatoses stabilize and do not progress, in some instances resolving spontaneously. Some recur after excision, particularly the plantar variant.

Deep Fibromatosis

Deep fibromatoses, also called desmoid tumors, are large, infiltrative masses that frequently recur but do not metastasize. They most frequently occur in the teenage years to 30s, predominantly in women. Abdominal fibromatosis generally arises in the musculoaponeurotic structures of the anterior abdominal wall but tumors can arise in the limb girdles or the mesentery. Deep fibromatoses contain mutations in the *CTNNB1* (β-catenin) or *APC* genes, leading to increased Wnt signaling. Most tumors are sporadic, but individuals with familial adenomatous polyposis (Gardner syndrome, Chapter 16) who have germline *APC* mutations are predisposed to deep fibromatosis.

MORPHOLOGY

Fibromatoses are gray-white, firm, poorly demarcated masses varying from 1 to 15 cm in greatest diameter. They are rubbery and tough, and have marked infiltration of surrounding muscle, nerve and fat. Cytologically bland fibroblasts arranged in broad sweeping fascicles amid dense collagen are the characteristic histologic pattern (Fig. 21.47). The histology resembles a scar.

Because of the extensively infiltrative nature, complete excision is often difficult. Recent efforts have concentrated on medical therapy and radiation as alternatives to surgery.

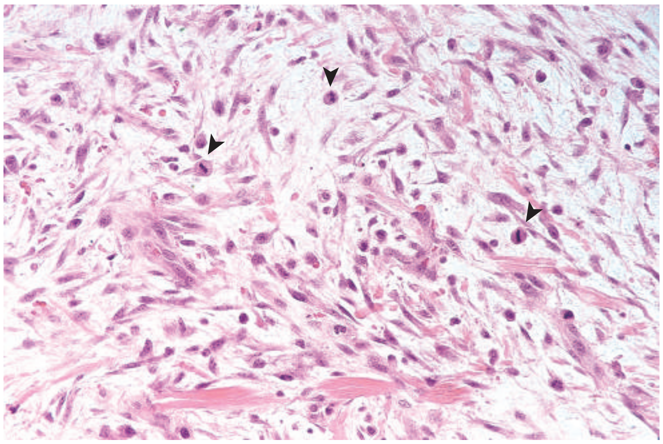

Fig. 21.46 Nodular fasciitis with plump, randomly oriented spindle cells surrounded by myxoid stroma. Note the mitotic activity *(arrowheads)*.

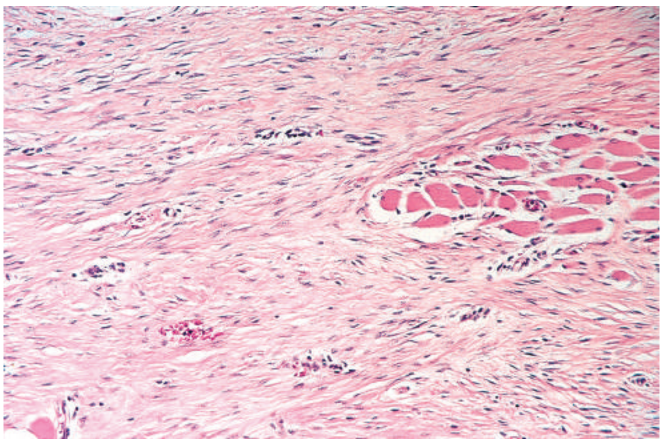

Fig. 21.47 Deep fibromatosis infiltrating between skeletal muscle cells.

SKELETAL MUSCLE TUMORS

Skeletal muscle neoplasms, in contrast to tumors of other lineages, are almost all malignant. The benign rhabdomyoma is more frequent in individuals with tuberous sclerosis.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant mesenchymal tumor with skeletal muscle differentiation. Three main subtypes are recognized: *alveolar* (20%), *embryonal* (60%), and *pleomorphic* (20%). Rhabdomyosarcoma (alveolar and embryonal) is the most common soft tissue sarcoma of childhood and adolescence, usually appearing before age 20. Pleomorphic rhabdomyosarcoma is seen predominantly in adults. The pediatric forms often arise in the sinuses, head and neck, and genitourinary tract, locations that do not normally contain much skeletal muscle, underscoring the notion that sarcomas do not arise from mature, terminally differentiated mesenchymal cells. The embryonal and pleomorphic subtypes are genetically heterogeneous.

Alveolar rhabdomyosarcoma frequently contains fusions of the *FOXO1* gene to either the *PAX3* or the *PAX7* gene, rearrangements marked by the presence of (2;13) or (1;13) translocations, respectively. PAX3 is a transcription factor that initiates skeletal muscle differentiation, and it appears that the chimeric PAX3-FOXO1 fusion protein interferes with differentiation, a mechanism similar to many of the transcription factor fusion proteins that are found in acute leukemias.

MORPHOLOGY

Embryonal rhabdomyosarcoma presents as a soft gray infiltrative mass. The tumor cells mimic skeletal muscle at various stages of differentiation and consist of sheets of both primitive round and spindled cells (Fig. 21.48A). Rhabdomyoblasts with straplike cytoplasm and visible cross-striations may be present. **Sarcoma botryoides** is a variant of embryonal rhabdomyosarcoma that develops in the walls of hollow viscera such as the urinary bladder and vagina.

In **alveolar rhabdomyosarcoma,** a network of fibrous septae divide the cells into clusters or aggregates, creating a crude resemblance to pulmonary alveoli. The tumor cells are uniformly round with little cytoplasm and they are only minimally cohesive (Fig. 21.48B).

Pleomorphic rhabdomyosarcoma is characterized by numerous large, sometimes multinucleated, bizarre eosinophilic tumor cells that can resemble other pleomorphic sarcomas. Immunohistochemical identification of muscle specific proteins such as myogenin is usually necessary to confirm rhabdomyoblastic differentiation.

Rhabdomyosarcomas are aggressive neoplasms that are usually treated with surgery and chemotherapy, with or without radiation therapy. The botryoid variant of embryonal rhabdomyosarcoma has the best prognosis, whereas the pleomorphic subtype is often fatal.

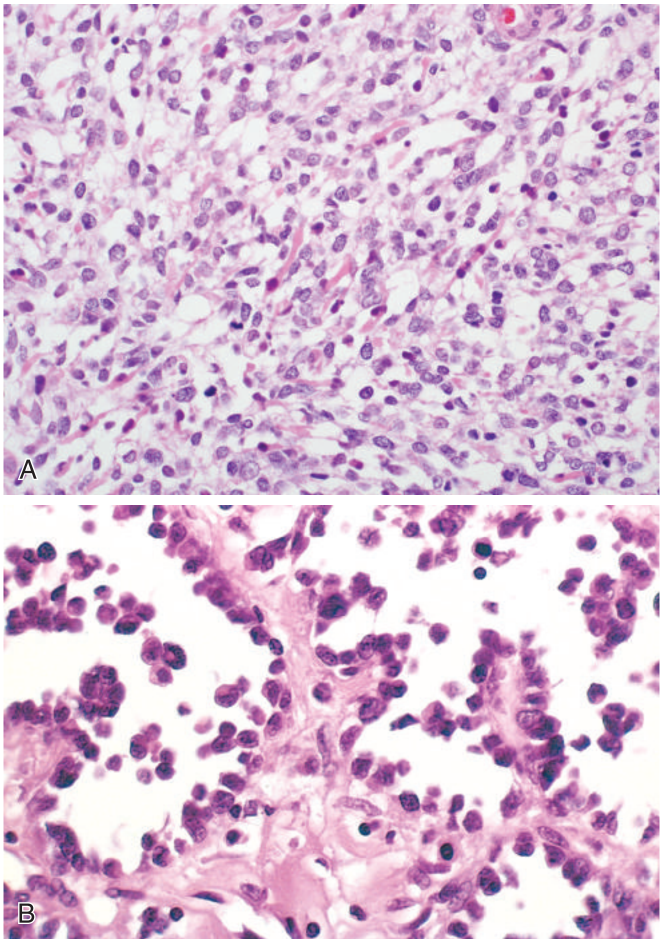

Fig. 21.48 Rhabdomyosarcoma. (A) Embryonal subtype composed of malignant cells ranging from primitive and round to densely eosinophilic with skeletal muscle differentiation. (B) Alveolar rhabdomyosarcoma with numerous spaces lined by discohesive, uniform round tumor cells.

SMOOTH MUSCLE TUMORS

Leiomyoma

Leiomyoma, a benign tumor of smooth muscle, is most common in the uterus but can arise in any soft tissue site. Uterine leiomyomas (Chapter 19) are common and may cause a variety of symptoms including infertility and menorrhagia. Leiomyomas also may arise from the erector pili muscles *(pilar leiomyomas)* in the skin and rarely in the deep somatic soft tissues or gastrointestinal tract. A germline loss-of-function mutation in the fumarate hydratase (FH) gene located on chromosome 1q42.3 leads to multiple cutaneous leiomyomas, uterine leiomyomas, and renal cell carcinoma. FH is an enzyme of the Krebs cycle, and this association constitutes another intriguing example of the link between metabolic abnormalities and neoplasia.

Soft tissue leiomyomas are usually 1 to 2 cm in size and are composed of fascicles of densely eosinophilic spindle cells that tend to intersect each other at right angles. The

tumor cells have blunt-ended, elongated nuclei and show minimal atypia and few mitotic figures. Solitary lesions are cured with surgery.

Leiomyosarcoma

Soft tissue leiomyosarcoma accounts for 10% to 20% of soft tissue sarcomas. They occur in adults and affect women more frequently than men. Most develop in the deep soft tissues of the extremities and retroperitoneum or arise from the great vessels. Leiomyosarcomas have complex genotypes that stem from acquired defects that lead to profound genomic instability.

MORPHOLOGY

Leiomyosarcomas present as painless firm masses. Retroperitoneal tumors may be large and bulky and cause abdominal symptoms. They consist of eosinophilic spindle cells with blunt-ended, hyperchromatic nuclei arranged in interweaving fascicles. They express smooth muscle proteins (actin, desmin, caldesmon), which can be detected by immunohistochemistry. Unlike leiomyomas, mitotic activity and necrosis are common in leiomyosarcoma.

Clinical Course

Treatment depends on tumor size, location, and grade. Superficial leiomyosarcomas are usually small and have a good prognosis, whereas those of the retroperitoneum are difficult to control and cause death by both local extension and metastatic spread, especially to the lungs.

TUMORS OF UNCERTAIN ORIGIN

Although many soft tissue tumors can be assigned to recognizable histologic types, a large proportion of tumors do not recapitulate any known mesenchymal lineage. This group includes examples with simple or complex karyotypes; one of each type is described here.

Synovial Sarcoma

Synovial sarcoma was so-named because the first described cases arose in the soft tissues near the knee joint and a morphologic relationship to synovium was postulated. However, this name is a misnomer, as these tumors can present in locations that lack synovium and their morphologic features are inconsistent with an origin from synoviocytes. Synovial sarcomas account for approximately 10% of all soft tissue sarcomas. Most occur in people in their 20s to 40s. Patients usually present with a deep-seated mass that has been present for several years. Most synovial sarcomas show a characteristic chromosomal translocation t(x;18)(p11;q11) producing fusion genes composed of portions of the *SS18* gene and one of three *SSX* genes that encode chimeric transcription factors that derail cell cycle control.

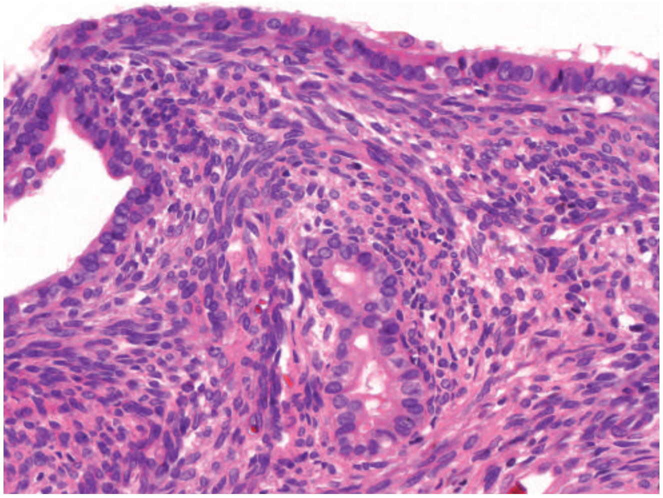

Fig. 21.49 Synovial sarcoma showing the classic biphasic spindle cell and glandlike histologic appearance.

MORPHOLOGY

Synovial sarcomas are microscopically monophasic or biphasic. Monophasic synovial sarcoma consists of uniform spindle cells with scant cytoplasm and dense chromatin growing in short, tightly packed fascicles. The biphasic type contains glandlike structures composed of cuboidal to columnar epithelioid cells in addition to the aforementioned spindle cell component (Fig. 21.49). Immunohistochemistry is helpful in identifying these tumors, since the tumor cells, especially in the biphasic type, are positive for epithelial antigens (e.g., keratins), differentiating them from many other sarcomas.

Synovial sarcomas are treated aggressively with limb-sparing surgery and frequently chemotherapy. The 5-year survival varies from 25% to 62%, related to stage and patient age. Common sites of metastases are the lung and, unusual for sarcomas, regional lymph nodes.

Undifferentiated Pleomorphic Sarcoma

Undifferentiated pleomorphic sarcoma (UPS) includes malignant mesenchymal tumors with high-grade, pleomorphic cells that cannot be classified into another category by a combination of histomorphology, immunophenotype, ultrastructure, and genetics. Most arise in the deep soft tissues of the extremity, especially the thigh of middle-aged or older adults. The diagnosis of *malignant fibrous histiocytoma* (MFH), sometimes used interchangeably with UPS, has fallen out of use because (1) the category included both undifferentiated tumors and others that could be reclassified with immunohistochemistry and genetics, and (2) no consensus exists for the morphologic definition of fibrohistiocytic lineage. Most tumors are aneuploid with multiple structural and numerical chromosomal changes.

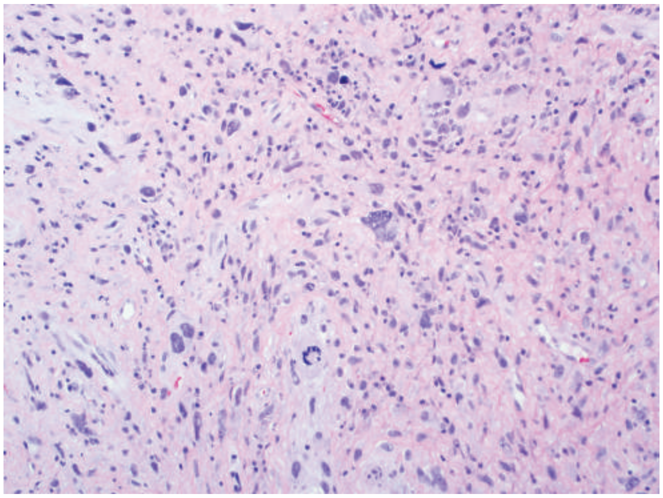

Fig. 21.50 Undifferentiated pleomorphic sarcoma showing anaplastic spindled to polygonal cells.

MORPHOLOGY

UPSs are usually large, grey-white fleshy masses that can grow quite large (10–20 cm) depending on the anatomic compartment. Necrosis and hemorrhage are common. Microscopically, they are some of the most pleomorphic malignancies encountered. UPSs consist of sheets of large, anaplastic, spindled to polygonal cells with hyperchromatic irregular, sometimes bizarre nuclei (Fig. 21.50). Mitotic figures, including atypical nonsymmetric forms, are abundant as is necrosis. By definition, tumor cells lack differentiation along recognized lineages or characteristic genetic defects.

UPSs are aggressive malignancies that are treated with surgery and adjuvant chemotherapy and/or radiation. The prognosis is generally poor, with metastases arising in 30% to 50% of cases.

SUMMARY

SOFT TISSUE TUMORS

- The category of soft tissue neoplasia describes tumors that arise from non-epithelial tissues, excluding the skeleton, joints, central nervous system, and hematopoietic and lymphoid tissues. A sarcoma is a malignant mesenchymal tumor.
- Although all soft tissue tumors probably arise from pluripotent mesenchymal stem cells, rather than mature cells, they can be classified as
  - Tumors that recapitulate a mature mesenchymal tissue (e.g., fat). These can be further subdivided into benign and malignant forms.
  - Tumors composed of cells for which there is no normal counterpart (e.g., synovial sarcoma, UPS).
- Sarcomas with simple karyotypes demonstrate reproducible, chromosomal, and molecular abnormalities that contribute to pathogenesis and are sufficiently specific to have diagnostic use.
- Most adult sarcomas have complex karyotypes, tend to be pleomorphic, and are genetically heterogeneous with a poor prognosis.

ACKNOWLEDGMENT

We thank Dr. Andrew Rosenberg for his outstanding contribution to previous editions of this chapter.

CHAPTER 22

Peripheral Nerves and Muscles

CHAPTER OUTLINE

The peripheral nerves and skeletal muscles permit purposeful movement and provide the brain with sensory information about our surroundings. Both the anatomic distribution of lesions and their associated signs and symptoms are helpful in classifying neuromuscular diseases. The following discussion of neuromuscular disorders is organized along anatomic lines and traces the neuromuscular system from proximal to distal by discussing disorders of peripheral nerves, neuromuscular junctions, and skeletal muscle.

DISORDERS OF PERIPHERAL NERVES

The two major functional elements of peripheral nerves are axonal processes and their myelin sheaths, which are made by Schwann cells. Axonal diameter and myelin thickness are correlated with each other and with conduction velocity. These characteristics are used to distinguish different types of axons, which mediate distinct sensory inputs and motor function. Light touch, for example, is transmitted by thickly myelinated large-diameter axons with fast conduction velocities, whereas temperature sensation is transmitted by slow, unmyelinated thin axons. In the case of myelinated axons, one Schwann cell makes and maintains exactly one myelin segment, or internode, along a single axon (Fig. 22.1A). Adjacent internodes are separated by the nodes of Ranvier along which saltatory conduction occurs. Any given nerve contains axons of different sizes and axons serving different functions. These are arranged into fascicles ensheathed by a layer of perineurial cells. Perineurial cells form a barrier between endoneurium on the inside of the fascicle and epineurium on the outside.

Patterns of Peripheral Nerve Injury

Peripheral neuropathies are often subclassified as axonal or demyelinating, even though many diseases exhibit mixed features. **Axonal neuropathies are caused by insults that directly injure the axon.** The entire distal portion of an affected axon degenerates. Axonal degeneration is associated with secondary myelin loss (Fig. 22.1B). The term *Wallerian degeneration* is borrowed from experimental studies involving the transection of nerves to describe analogous changes observed in axonal neuropathies. Regeneration takes place through axonal regrowth and subsequent remyelination of the distal axon (Fig. 22.1C). The morphologic hallmark of axonal neuropathies is a decrease in the density of axons, which in electrophysiologic studies correlates with a decrease in the signal strength or amplitude of nerve impulses.

Demyelinating neuropathies are characterized by damage to Schwann cells or myelin with relative axonal sparing, resulting in abnormally slow nerve conduction velocities but preserved amplitude. Demyelination typically occurs discontinuously, affecting individual internodes along the length of an axon in a random distribution. This process is termed *segmental demyelination* (Fig. 22.1B). Morphologically, demyelinating neuropathies show a relatively normal density of axons and features of segmental demyelination and repair. This is recognized by the presence of axons with abnormally thin myelin sheaths and short internodes (Fig. 22.1C). The discontinuous nature

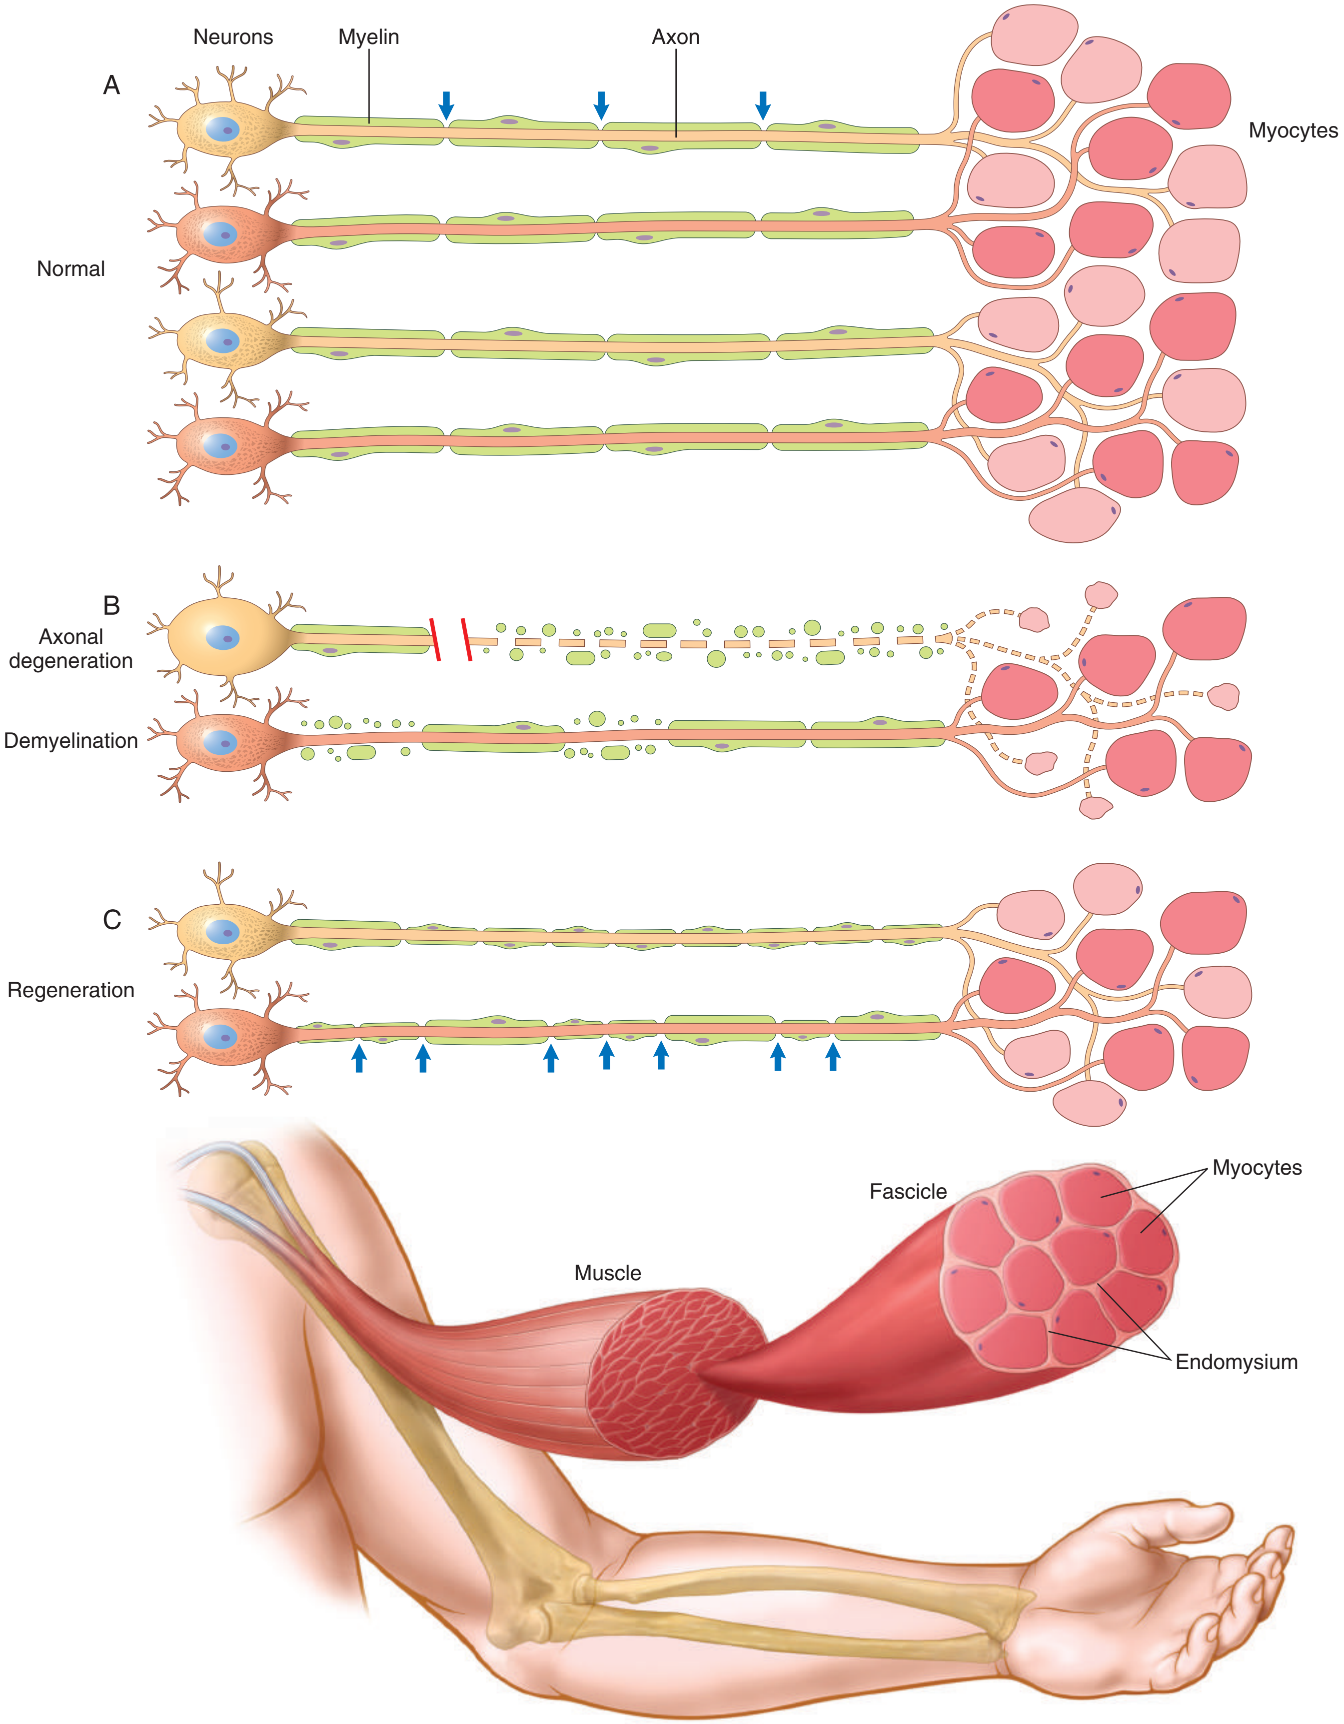

Fig. 22.1 Patterns of peripheral nerve damage. (A) In normal motor units, type I and type II myofibers (see Table 22.2 later) are arranged in a "checkerboard" distribution. The internodes, separated by nodes of Ranvier *(arrows)* along the motor axons are uniform in thickness and length. (B) Acute axonal injury *(upper axon)* results in degeneration of the distal axon and its associated myelin sheath, with atrophy of denervated myofibers. By contrast, acute demyelinating disease *(lower axon)* produces random segmental degeneration of individual myelin internodes, while sparing the axon. (C) Regeneration of axons after injury *(upper axon)* allows connections with myofibers to re-form. The regenerated axon is myelinated by proliferating Schwann cells, but the new internodes are shorter and the myelin sheaths are thinner than the original ones. (Nodes Ranvier are marked by *arrows*; compare with panel A.) Remission of demyelinating disease *(lower axon)* allows remyelination to take place, but the new internodes also are shorter and have thinner myelin sheaths than flanking normal undamaged internodes.

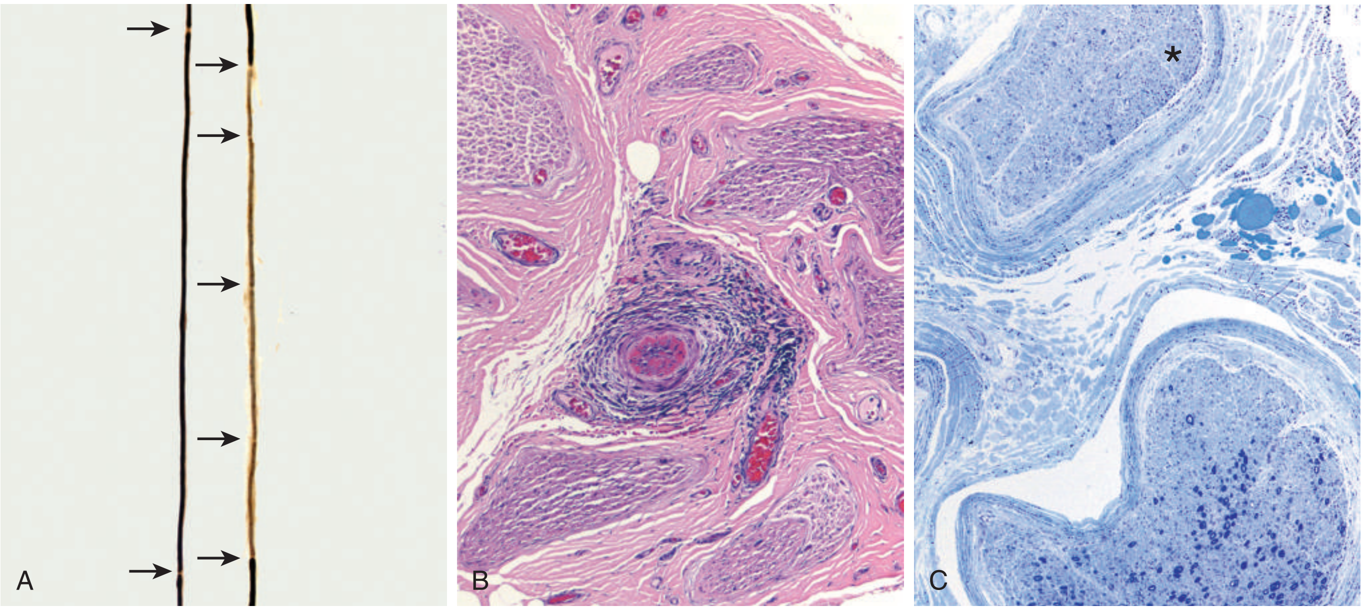

Fig. 22.2 Pathologic changes in peripheral neuropathies. (A) Regeneration after segmental demyelination. Teased fiber preparations allow for examination of individual axons of peripheral nerves. A normal axon *(left)* with a long thick dark myelin internode flanked by nodes of Ranvier (*arrows*; compare with Fig. 22.1A). All myelin internodes along his axon would be expected to be of similar length and width. The right axon, by contrast, shows a segment surrounded by a series of thinly myelinated internodes of uneven length flanked on both ends by normal thicker myelin internodes (*arrows* mark nodes of Ranvier; compare with Fig. 22.1C). (B–C) Vasculitic neuropathy. In (B), the perineurial connective tissue contains an inflammatory infiltrate around small blood vessels that has obliterated a vessel. In (C), a special stain that colors myelinated axons dark blue hue shows that the nerve fascicle in the upper portion of this field *(asterisk)* has lost almost all of its large myelinated axons, in contrast with the other fascicle shown. Such interfascicular variation in axonal density is often seen in neuropathies resulting from vascular injury.

of damage to random internodes is best visualized when examining a series of internodes along individual axons in teased fiber preparations (Fig. 22.2A).

Peripheral neuropathies exhibit several anatomic patterns.

- *Polyneuropathies* usually affect peripheral nerves in a symmetric, length-dependent fashion. Axonal loss is typically more pronounced in the distal segments of the longest nerves. Patients commonly present with loss of sensation and paresthesias that start in the toes and spread upward. By the time the sensory changes reach the level of the knees, the hands are also affected, resulting in a picture described as "stocking-and-glove" distribution. This pattern is often encountered with toxic and metabolic damage.
- *Mononeuritis multiplex,* in which the damage randomly affects individual nerves, resulting (for example) in a right radial nerve palsy and wrist drop and, at a separate point in time, a left foot drop. Mononeuritis multiplex is often caused by vasculitis.
- A simple *mononeuropathy* only involves a single nerve and is most commonly the result of traumatic injury, entrapment (e.g., carpal tunnel syndrome), or certain infections such as Lyme disease.

Disorders Associated With Peripheral Nerve Injury

Many different diseases may be associated with peripheral neuropathy (Table 22.1). We next discuss selected entities that are prototypical for a specific type of polyneuropathy or that are particularly common.

Table 22.1 Peripheral Neuropathies

Etiologic Category	Causative Disorders/Agents
Nutritional and metabolic	Diabetes mellitus Uremia Vitamin deficiencies—thiamine, vitamin B6, vitamin B12
Toxic	Drugs, including vinblastine, vincristine, paclitaxel, colchicine, and isoniazid Toxins—alcohol, lead, aluminum, arsenic, mercury, acrylamide
Vasculopathic	Vasculitis Amyloidosis
Inflammatory	Autoimmune diseases Guillain-Barré syndrome Chronic inflammatory demyelinating polyneuropathy (CIDP)
Infections	Herpes zoster Leprosy HIV infection Lyme disease
Inherited	Charcot-Marie-Tooth neuropathy, type I, type II, and X-linked Hereditary neuropathy with liability to pressure palsy
Others	Paraneoplastic, some leukodystrophies

Guillain-Barré Syndrome

Guillain-Barré syndrome is a rapidly progressive acute demyelinating disorder affecting motor axons, resulting in ascending weakness that can lead to death from failure of respiratory muscles within days of onset of symptoms. It is one of the most common life-threatening diseases of the peripheral nervous system. Guillain-Barré syndrome appears to be triggered by an infection or vaccination that breaks down self-tolerance, thereby leading to an autoimmune response. Associated infectious agents include Campylobacter jejuni, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus (HIV), and, most recently Zika virus. The injury is most extensive in the nerve roots and proximal nerve segments and is associated with mononuclear cell infiltrates rich in macrophages. Both humoral and cellular immune responses are believed to play a role in the disease process. Treatments include plasmapheresis (to remove offending antibodies), intravenous immunoglobulin infusions (which suppress immune responses through unclear mechanisms), and supportive care, such as ventilatory support. Patients who survive the initial acute phase of the disease usually recover with time.

Chronic Inflammatory Demyelinating Polyneuropathy (CIDP)

CIDP is the most common chronic acquired inflammatory peripheral neuropathy, characterized by symmetrical mixed sensorimotor polyneuropathy that persists for 2 months or more. Both motor and sensory abnormalities are common, such as weakness, difficulty in walking, numbness, and pain or tingling sensations. Like Guillain-Barré syndrome, CIDP is immune mediated. But in contrast to Guillain-Barré syndrome, CIDP follows a chronic, relapsing-remitting, or progressive course. It occurs with increased frequency in patients with other immune disorders, such as systemic lupus erythematosus and HIV infection. The peripheral nerves show segments of demyelination and remyelination (Fig. 22.2A). In long-standing cases, repeated activation and proliferation of Schwann cells with episodes of regeneration result in the concentric arrangement of multiple Schwann cells around individual axons to produce multilayered structures likened to onion bulbs. Treatment includes plasmapheresis and administration of immunosuppressive agents. Some patients recover completely, but more often recurrent bouts of symptomatic disease lead to permanent loss of nerve function.

Diabetic Peripheral Neuropathy

Diabetes is the most common cause of peripheral neuropathy, usually developing with long-standing disease. Diabetic neuropathies include several forms that can occur singly or together.

- *Autonomic neuropathy* is characterized by changes in bowel, bladder, cardiac, or sexual function.
- *Lumbosacral radiculopathy* usually manifests with asymmetric pain that can progress to lower extremity weakness and muscle atrophy.
- *Distal symmetric sensorimotor polyneuropathy* is the most common form of diabetic neuropathy. Sensory axons are more severely affected than motor axons, resulting in a clinical presentation dominated by paresthesias and numbness. This form of diabetic polyneuropathy results from the length-dependent degeneration of peripheral nerves and does not neatly fit into the axonal or demyelinating category but instead often exhibits features of both. The pathogenesis of diabetic neuropathy is complex; accumulation of advanced glycosylation end products resulting from hyperglycemia, increased levels of reactive oxygen species, microvascular changes, and changes in axonal metabolism, all have been implicated. Strict glycemic control is the best form of therapy.

Toxic, Vasculitic, and Inherited Forms of Peripheral Neuropathy

There are diverse other causes of peripherlal neuropathy (Table 22.1), some of which merit brief discussion.

- *Drugs* and *environmental toxins* that interfere with axonal transport or cytoskeletal function often produce peripheral neuropathies. The longest axons are most susceptible, hence symptoms appear first and are most pronounced in the distal extremities.
- Peripheral nerves are damaged in many different forms of *systemic vasculitis* (Fig. 22.2B) (Chapter 10), including polyarteritis nodosa, Churg-Strauss syndrome, and polyangiitis with granulomatosis. Overall, peripheral nerve damage is seen in about a third of all patients with vasculitis at the time of presentation. The most common clinical picture is that of *mononeuritis multiplex* with a painful asymmetric mixed sensory and motor peripheral neuropathy. Patchy involvement also is apparent at the microscopic level, as single nerves may show considerable interfascicular variation in the degree of axonal damage (Fig. 22.2C).
- *Inherited diseases of peripheral nerves* are a heterogeneous but relatively common group of disorders, with a prevalence of 1 to 4 in 10,000. They can be demyelinating or axonal. Many such disorders manifest in adulthood and follow a slowly progressive course that may mimic that of acquired polyneuropathies. The most common causes are mutations in the genes encoding myelin-associated proteins.

SUMMARY

PERIPHERAL NEUROPATHIES

- Peripheral neuropathies may result in weakness and/or sensory deficits in patterns described as polyneuropathy, mononeuritis multiplex, and mononeuropathy.
- Axonal and demyelinating peripheral neuropathies can be distinguished on the basis of clinical and pathologic features. Some disorders are associated with a mixed pattern of injury.
- Diabetes is the most common cause of peripheral neuropathy.
- Guillain-Barré syndrome and chronic idiopathic demyelinating polyneuropathy are immune-mediated demyelinating diseases that follow acute and chronic courses, respectively.
- Metabolic diseases, drugs, toxins, connective tissue diseases, vasculitides, and infections all can result in peripheral neuropathy.
- A number of mutations cause peripheral neuropathy. Many of these are adult-onset diseases that may mimic acquired ones.

DISORDERS OF NEUROMUSCULAR JUNCTION

The neuromuscular junction is a complex specialized structure located at the interface of motor nerve axons and skeletal muscle that serves to control muscle contraction. Here the distal ends of peripheral motor nerves branch into small processes that terminate in bulbous synaptic boutons. Nerve impulses depolarize the presynaptic membrane, stimulating calcium influx and the release of acetylcholine into the synaptic cleft. Acetylcholine diffuses across the synaptic cleft to bind its receptor on the postsynaptic membrane, leading to depolarization of the myofiber and contraction through electromechanical coupling. Often disorders of the neuromuscular junction produce functional deficits in the absence of any significant alterations in morphology beyond ultrastructural changes. Considered in this section are some of the more common or pathogenically interesting disorders that disrupt the transmission of signals across the neuromuscular junction.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease with fluctuating muscle weakness that is caused by autoantibodies that target the neuromuscular junction. The most common antigenic target is the postsynaptic acetylcholine receptor (AChR). Other pathogenic antibodies recognize muscle-specific kinase (MuSK) and low-density lipoprotein receptor-related protein (LRP4). These antibodies lead to loss of receptors and damage to the structure of the junctions. The disease has an incidence of approximately 2 in 100,000 persons. Anti-AChR mediated cases have bimodal age distribution with somewhat distinctive clinical features. Early onset before age 50 years is more common in females and is frequently associated with enlargement of the thymus due to the presence of B cell follicles and germinal centers (follicular thymic hyperplasia). Late-onset cases show a more equal gender distribution and are associated with thymoma (Chapter 12), a neoplasm derived from thymic epithelium. Both of these thymic lesions are believed to perturb tolerance to self-antigens, setting the stage for the generation of autoreactive T and B cells.

Clinically, myasthenia gravis frequently manifests with *ptosis* (drooping eyelids) or *diplopia* (double vision) because of weakness in the extraocular muscles. This pattern of weakness is distinctly different from that of most primary myopathic diseases, in which there is relative sparing of facial and extraocular muscles. The severity of the weakness often fluctuates rapidly, sometimes over periods of a few minutes. Characteristically, repetitive firing of muscles makes the weakness more severe, whereas cholinesterase inhibitors improve strength markedly, features that are are diagnostically useful. Effective treatments include cholinesterase inhibitors, immunosuppression, plasmapheresis, and (in patients with thymic lesions) thymectomy. These interventions have improved the 5-year survival rate to greater than 95%.

Lambert-Eaton Syndrome

Lambert-Eaton syndrome is caused by autoantibodies that inhibit the function of presynaptic calcium channels, thereby reducing the release of acetylcholine into the synaptic cleft. Patients with Lambert-Eaton syndrome experience improvement in weakness with repetitive stimulation, in contrast to those suffering from myasthenia gravis. Repetitive stimulation serves to build up sufficient intracellular calcium to facilitate acetylcholine release. *Lambert-Eaton syndrome often arises as a paraneoplastic disorder,* particularly in patients with small cell lung carcinoma. Cholinesterase inhibitors are not effective, and therapy is therefore directed toward reducing the titer of causative antibodies, through either plasmapheresis or immunosuppression. The prognosis is worse than that of myasthenia gravis because of the frequent coexistence of an underlying malignancy.

Miscellaneous Neuromuscular Junction Disorders

Several other neuromuscular junction disorders merit brief mention.

- *Congenital myasthenic syndromes* comprise a heterogeneous group of diseases that result from mutations that disrupt the function of various neuromuscular junction proteins. Depending on the affected protein, the defects may occur at the level of acetylcholine release (presynaptic), the transport of acetylcholine across the synaptic cleft (synaptic), or the responsiveness of skeletal muscle (postsynaptic). Hence they may present with symptoms mimicking Lambert-Eaton syndrome or myasthenia gravis. Some forms respond to treatment with acetylcholinesterase inhibitors.
- *Infections with exotoxin-producing bacteria* may be associated with defects in neural transmission and muscle contraction. *Clostridium tetani* and *Clostridium botulinum* (Chapter 9) both release extremely potent neurotoxins that interfere with neuromuscular transmission. Tetanus toxin (known as tetanospasmin) blocks the action of inhibitory neurons, leading to the increased release of acetylcholine and sustained muscle contraction and spasm (tetanus). Botulinum toxin, by contrast, inhibits acetylcholine release, producing a flaccid paralysis. The purified toxin (Botox) is remarkably stable after injection, an attribute that has led to its widespread use as an antidote for wrinkles and a variety of other conditions associated with unwanted muscular activity (e.g., blepharospasm and strabismus).

SUMMARY
NEUROMUSCULAR JUNCTION DISORDERS

- Disorders of neuromuscular junctions manifest with weakness that often affects facial and extraocular muscles and may show rapid fluctuation in severity.
- Both myasthenia gravis and Lambert-Eaton syndrome, which are the most common forms, are immune mediated, being caused by antibodies that typically target postsynaptic acetylcholine receptors and presynaptic calcium channels, respectively.

- Myasthenia gravis often is associated with thymic hyperplasia or thymoma. Lambert-Eaton syndrome is a paraneoplastic disorder in the majority of the cases; the strongest association is with small cell lung cancer.
- Genetic defects in neuromuscular junction proteins and bacterial toxins also can cause symptomatic disturbances in neuromuscular transmission.

DISORDERS OF SKELETAL MUSCLE

Patterns of Skeletal Muscle Injury and Atrophy

The principal component of the motor system is the *motor unit*, which is composed of one lower motor neuron together with the associated axon, its neuromuscular junctions, and the skeletal muscle fibers it innervates. Skeletal muscle consists of different fiber types broadly classified as slow twitch type I and fast twitch type II fibers (Table 22.2). The fiber type is dependent on the innervation. All myofibers of a motor unit therefore share the same fiber type. Normally the fibers of different types are distributed in checkerboard patterns (Fig. 22.1A). A number of proteins and protein complexes are crucial for the unique structure and function of skeletal muscles. These include proteins that make up the sarcomeres and the dystrophin-glycoprotein complex (Fig. 22.3), as well as enzymes that allow muscle to meet it unusual metabolic requirements.

Primary muscle diseases or myopathies have to be distinguished from secondary neuropathic changes caused by disorders that disrupt muscle innervation. Both are associated with altered muscle function and morphology, but each has distinctive features (Fig. 22.4). Myopathic conditions are often associated with segmental necrosis and regeneration of individual muscle fibers (Fig. 22.4B). Some myopathies are also associated with other morphologic features, such as inflammatory infiltrates or intracellular inclusions. Disruption of muscle by endomysial fibrosis and fatty replacement is reflective of disease chronicity that can occur both in myopathic as well as neuropathic conditions.

Both neuropathic and myopathic processes cause *muscle fiber atrophy*. However, certain disorders are associated with particular patterns of atrophy, as follows:

- *Neuropathic changes*. Loss of innervation causes atrophy of myofibers. The two main morphologic hallmarks of neurogenic changes, *grouped atrophy* and *fiber type grouping* (Fig. 22.4C), are the result of multiple rounds of denervation and reinnervation. Loss of an axon or lower motor neuron results in atrophy of the myofibers that are part of this motor unit (Fig. 22.4C2). Atrophic myofibers can be reinnervated by axonal branches from adjacent motor units, increasing the size of these motor units and returning trophic input to the atrophic myofibers (Fig. 22.4C3). Multiple rounds of denervation and reinnervation result in a dwindling number of motor units of increasingly larger size. In this setting loss of innervation will therefore produce large clusters of atrophic myofibers, *grouped atrophy* (Fig. 22.4C5). Because

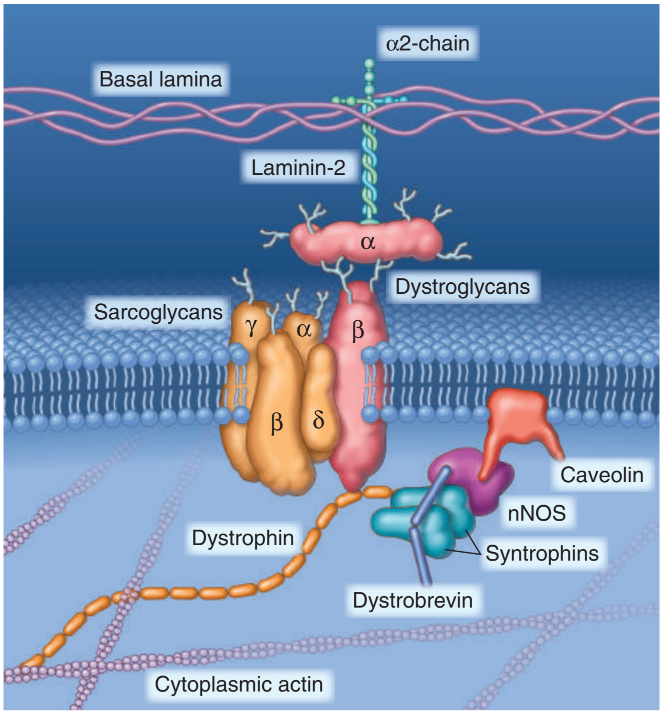

Fig. 22.3 The dystrophin-glycoprotein complex (DGC). This complex of glycoproteins serves to couple the cell membrane (the sarcolemma) to extracellular matrix proteins such as laminin-2 and the intracellular cytoskeleton. A key set of connections is made by dystrophin, a scaffolding protein that tethers the myofibrillar cytoskeleton to the transmembrane dystroglycans and sarcoglycans, and also binds signaling complexes containing dystrobrevin, syntrophin, neuronal nitric oxide synthetase (nNOS), and caveolin. Mutations in dystrophin are associated with X-linked Duchenne and Becker muscular dystrophies; mutations in caveolin and the sarcoglycan proteins with autosomal limb-girdle muscular dystrophies; and mutations in α2-laminin (merosin) with a form of congenital muscular dystrophy.

Table 22.2 Muscle Fiber Types

	Type I	Type II
Action	Sustained force	Fast movement
Activity type	Aerobic exercise	Anaerobic exercise
Power produced	Low	High
Resistance to fatigue	High	Low
Lipid content	High	Low
Glycogen content	Low	High
Energy metabolism	Low glycolytic capacity, high oxidative capacity	High glycolytic capacity, low oxidative capacity
Mitochondrial density	High	Low
Myosin heavy chain gene expressed	*MYH7*	*MYH2*, *MYH4*, *MYH1*
Color	Red (high myoglobin content)	Pale red / tan (low myoglobin content)

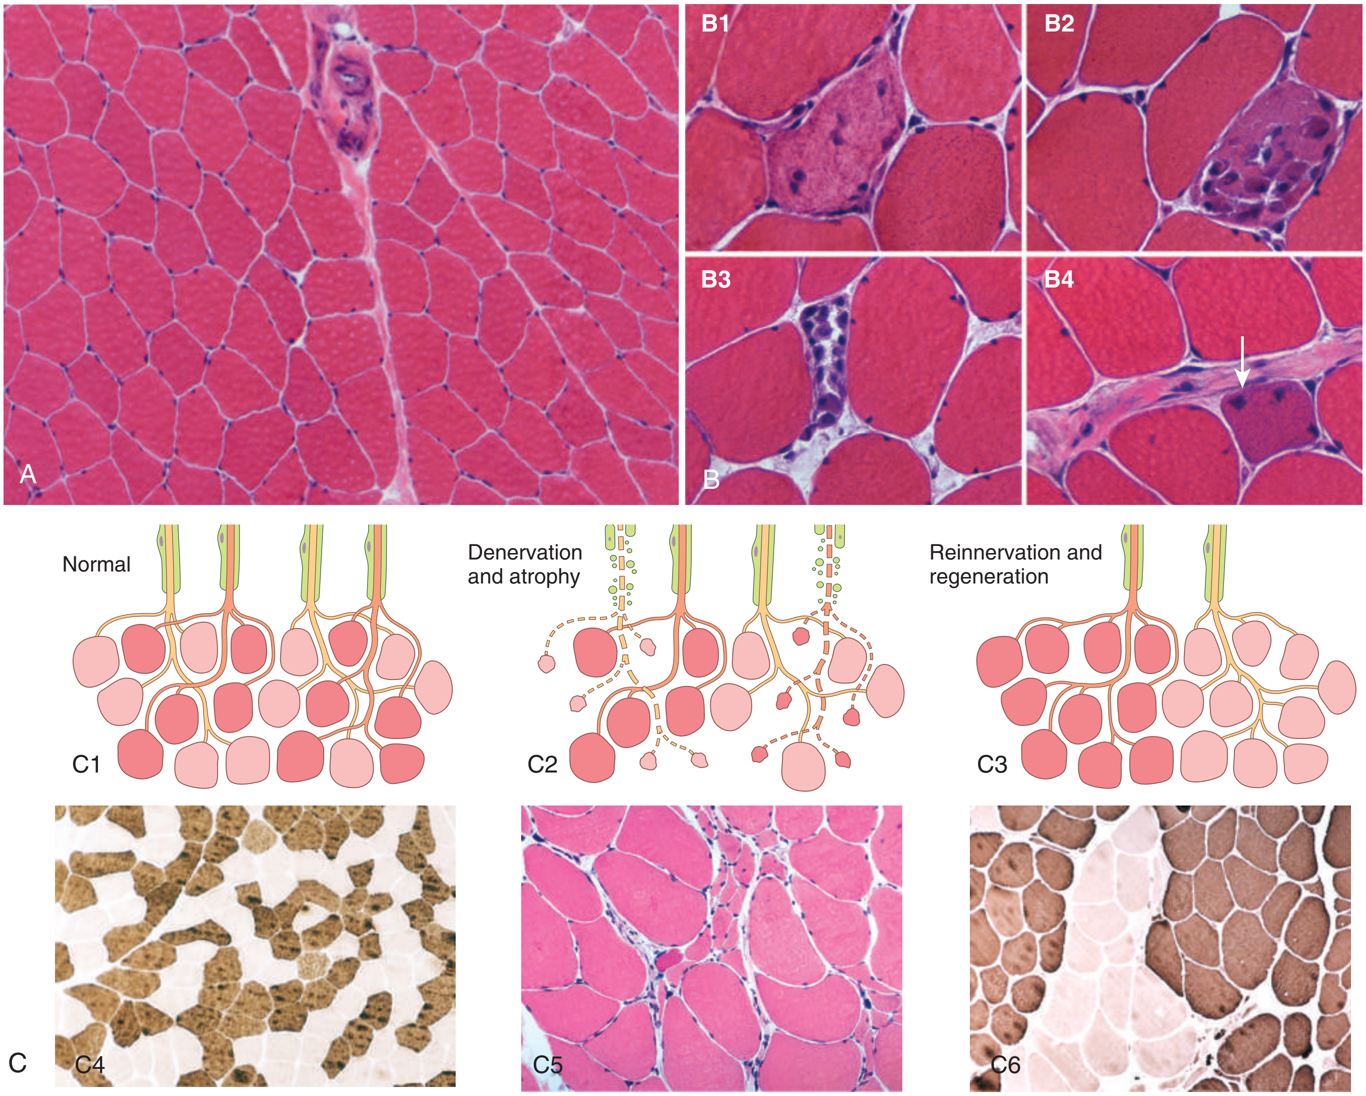

Fig. 22.4 Patterns of skeletal muscle injury. (A) Normal skeletal muscle has relatively uniform polygonal myofibers with peripherally placed nuclei that are tightly packed together into fascicles separated by scant connective tissue. A perimysial interfascicular septum containing a blood vessel is present *(top center)*. (B) Myopathic conditions often are associated with segmental necrosis and regeneration of individual myofibers. Necrotic cells (B1–B3) are infiltrated by variable numbers of inflammatory cells. Regenerative myofibers (B4, *arrow*) are characterized by cytoplasmic basophilia and enlarged nucleoli (not visible at this power). (C) Neurogenic changes. (C1) This diagrammatic representation of four normal motor units shows a checkerboard-type admixture of light and dark stained fibers of opposite type. (C2) Damage to innervating axons leads to a loss of trophic input and the atrophy of myofibers. (C3) Reinnervation of myofibers can result in a switch in fiber type and segregation of fibers of like type. As illustrated here, reinnervation is also often associated with an increase in motor unit size, with more myofibers innervated by an individual axon. (C4) Normal muscle has a checkerboard distribution of type I *(light)* and type II *(dark)* fibers on this ATPase reaction (pH9.4), corresponding to findings in (A). (C5) Clustered flattened "angulated" atrophic fibers *(grouped atrophy)* are a typical finding associated with disrupted innervation. (C6) With ongoing denervation and reinnervation, large clusters of fibers appear that all share the same fiber type *(fiber type grouping)*.

myofiber type depends on the innervating motor unit, reinnvervated fibers may change from type I to type II and vice versa. The presence of increasingly larger motor units alters the normal checkerboard type distribution of fibers by producing large clusters of the same type, *fiber type grouping* (Fig. 22.4C6).

- *Prolonged disuse of muscles* from any cause (e.g., prolonged bed rest in the sick, casting of a broken bone) may cause focal or generalized muscle atrophy, which tends to affect type II fibers more than type I fibers.
- *Glucocorticoid exposure,* whether exogenous or endogenous (e.g., in Cushing syndrome), also may cause muscle atrophy. Proximal muscles and type II myofibers are affected preferentially in this setting.

Inherited Disorders of Skeletal Muscle

Inherited mutations are responsible for a diverse collection of disorders marked by defects in skeletal muscle. In some of these disorders, skeletal muscle is the main site of

disease, while in others multiple organs are involved. Of the other organs involved, the heart is of particular importance, because cardiac involvement is common and is often life-limiting. Included in this group of inherited muscular disorders are the following:

- *Muscular dystrophies* are associated with progressive muscle injury in patients who have normal muscle function at birth.
- *Congenital muscular dystrophies,* by contrast, are progressive, early-onset diseases. Some are also associated with malformations of the central nervous system.
- *Congenital myopathies* typically present in infancy with muscle defects that tend to be static or to even improve with time. They are often associated with distinct structural abnormalities of the muscle.

The discussion of muscular dystrophies may at first glance appear confusing because of different classification systems and terminologies. This is reflective of our evolving understanding of these diseases, from a description based on phenotype and inheritance pattern, to one based on underlying genetic mutations. An additional layer of complexity stems from the fact that there is not a simple one-to-one correspondence between genotypes and phenotypes. Instead mutations in several different genes can, for example, present as autosomal recessive limb-girdle muscular dystrophy; conversely different mutations in a single gene (such as dystrophin) can lead to very different clinical phenotypes, as illustrated by Duchenne and Becker types of muscular dystrophy.

Dystrophinopathies: Duchenne and Becker Muscular Dystrophy

The most common muscular dystrophies are X-linked and are caused by mutations that disrupt the function of a large structural protein called *dystrophin*. As a result, these diseases are referred to as *dystrophinopathies*. *Duchenne muscular dystrophy* (DMD) and *Becker muscular dystrophy* (BMD) are the two most important diseases in this group. DMD has an incidence of about 1 per 3500 live male births and follows an invariably fatal course. It becomes clinically evident in early childhood; most patients are wheelchair-bound by the time they are teenagers and are dead of their disease by early adulthood. The Becker type of muscular dystrophy is less common and less severe.

MORPHOLOGY

The histologic alterations in skeletal muscles affected by DMD and BMD are similar, except that the changes are milder in BMD (Fig. 22.5). The hallmarks of these as well as other muscular dystrophies are ongoing myofiber necrosis and regeneration. Progressive replacement of muscle tissue by fibrosis and fat is the result of degeneration outpacing repair. As a result of ongoing repair, muscles typically show marked variation in myofiber size and abnormal internally placed nuclei. Both DMD and BMD also affect cardiac muscles, which show variable degrees of myocyte hypertrophy and interstitial fibrosis.

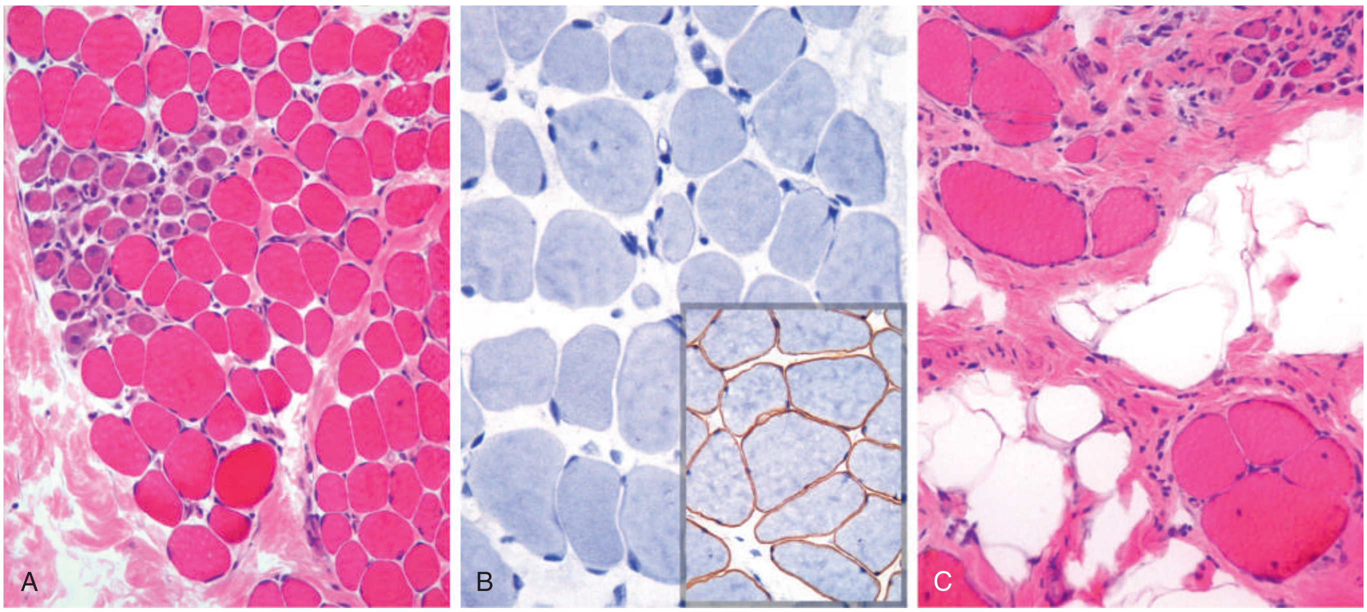

Fig. 22.5 Duchenne muscular dystrophy. Histologic images of muscle biopsy specimens from two brothers. (A–B) Specimens from a 3-year-old boy. (C) Specimen from his brother, 9 years of age. As seen in (A), at a younger age fascicular muscle architecture is maintained, but myofibers show variation in size. Additionally, there is a cluster of basophilic regenerating myofibers *(left side)* and slight endomysial fibrosis, seen as focal pink-staining connective tissue between myofibers. In (B), immunohistochemical staining shows a complete absence of membrane-associated dystrophin, seen as a brown stain in normal muscle *(inset)*. In (C), the biopsy from the older brother illustrates disease progression, which is marked by extensive variation in myofiber size, fatty replacement, and endomysial fibrosis.

Pathogenesis

Both DMD and BMD are caused by mutations disrupting the function of the *dystrophin* gene located on the short arm of the X chromosome (Xp21). Dystrophin is a very large protein (427 kD in molecular weight) found in skeletal and cardiac muscle, brain, and peripheral nerves; it is part of the dystrophin-glycoprotein complex (Fig. 22.3). This complex stabilizes the muscle cell during contraction and may be involved in cell signaling through interactions with other proteins. Dystrophin-glycoprotein complex defects are thought to make muscle cells vulnerable to transient membrane tears during contraction that lead to calcium influx, and they may also disrupt intracellular signaling. The result is myofiber degeneration that with time outpaces the capacity for repair. The dystrophin-glycoprotein complex also is important for cardiac muscle function; this explains why cardiomyopathy eventually develops in many patients.

The dystrophin gene spans roughly 2.4 megabases (about 1% of the X chromosome), making it one of the largest human genes. Its enormous size may make it more prone to sporadic mutations, which all things being equal are more likely by chance to affect large genes. The most common mutations are deletions, followed by frameshift and point mutations. Patient with DMD usually have either of the first two and show complete absence of dystrohpin on a muscle biopsy. Patients with BMD often have point mutations and make residual but defective forms. The severity of disease therefore correlates with genotype and extent of dystrohpin deficiency.

Clinical Features

Often the first symptoms of DMD are clumsiness and an inability to keep up with peers because of muscle weakness. The weakness typically begins in the pelvic girdle and next involves the shoulder girdle. Enlargement of the calves, termed pseudohypertrophy, is an early physical finding. The increased muscle bulk initially stems from myofiber hypertrophy, but as myofibers progressively degenerate, an increasing part of the muscle is replaced by adipose tissue and endomysial fibrosis. Cardiac muscle damage and fibrosis may lead to heart failure and arrhythmias, which may prove fatal. Although no structural abnormalities in the central nervous system have been described, cognitive impairment also may occur and may be severe enough to be classified as mental retardation. Owing to ongoing muscle degeneration, high serum creatine kinase levels are present at birth and persist through the first decade of life but fall as muscle mass is lost as the disease progresses. Death results from respiratory insufficiency, pneumonia, and cardiac decompensation.

BMD becomes symptomatic later in childhood or adolescence and progresses at a slower and more variable rate. Many patients live well into adulthood and have a nearly normal life span. Cardiac involvement may be the dominant clinical feature and may result in death, even in the absence of significant skeletal muscle weakness.

Treatment of patients with dystrophinopathies is challenging. Current treatment consists primarily of supportive care. Definitive therapy requires restoration of dystrophin levels in skeletal and cardiac muscle fibers. Genetic approaches to accomplish this are being tested in clinical trials. One strategy involves the expression of anti-sense RNAs that alter RNA splicing so as to cause "skipping" of exons containing deleterious mutations, thus permitting the expression of a truncated, but partially functional, dystrophin protein. A second strategy involves the use of drugs that promote ribosomal "read-through" of stop codons, another ploy that may enable the synthesis of some functional dystrophin protein.

Other X-Linked and Autosomal Muscular Dystrophies

Other forms of muscular dystrophy share features with DMD and BMD but have distinct clinical, genetic, and pathologic features.

- ***Myotonic dystrophy.* Myotonia, the sustained involuntary contraction of a group of muscles, is the cardinal neuromuscular symptom in myotonic dystrophy.** Patients often complain of stiffness and difficulty in relaxing their grip, for example, after a handshake. Myotonic dystrophy is a nucleotide repeat expansion disease (Chapter 7) that is inherited as an autosomal dominant trait. More than 95% of patients with myotonic dystrophy have mutations in the gene that encodes the dystrophia myotonica protein kinase (DMPK). In normal subjects, this gene contains 5 to 37 CTG repeats, whereas affected patients usually carry 45 to several thousand. As with other nucleotide repeat expansion diseases, myotonic dystrophy exhibits *anticipation,* characterized by worsening of the disease manifestations with each passing generation because of further trinucleotide repeat expansion. The CTG repeat is located in the 3′ untranslated region of the DMPK mRNA. Experimental studies suggest that the skeletal muscle phenotype stems from a "toxic" gain-of-function caused by the triplet repeat expansion. The mutant DMPK mRNA with the resulting CUG expansions sequesters muscleblind-like proteins involved in RNA splicing. This functional depletion of proteins involved in RNA splicing disrupts normal gene expression patterns and alters the function of diseased tissues like skeletal and cardiac muscle. Myotonic dystrophy often manifests in late childhood with gait abnormalities due to weakness of foot dorsiflexors, with subsequent progression to weakness of the intrinsic muscles of the hands and wrist extensors, atrophy of the facial muscles, and ptosis. Involvement of other organ systems results in potentially fatal cardiac arrhythmias, cataracts, early frontal balding, endocrinopathies, and testicular atrophy.
- ***Limb-girdle muscular dystrophies.* These muscular dystrophies preferentially affect the proximal musculature of the trunk and limbs.** Their genetic basis is heterogeneous. The growing list includes at least 7 dominant subtypes and 15 autosomal recessive subtypes. Some of the responsible mutations affect components of the dystrophin-glycoprotein complex other than dystrophin. Others affect proteins involved in vesicle transport and repair of cell membrane after injury (caveolin-3 and dysferlin), cytoskeletal proteins, or posttranslational modification of dystroglycan, a component of the dystrophin-glycoprotein complex.
- ***Emery-Dreifuss muscular dystrophy* (EMD) is a genetically heterogeneous disorder caused by mutations**

affecting structural proteins found in the nucleus. An X-linked form results from mutations in the gene encoding the protein emerin, whereas an autosomal dominant form is caused by mutations in the gene encoding lamin A/C. It is hypothesized that defects in these proteins compromise the structural integrity of the nucleus in cells that are subjected to repetitive mechanical stress (e.g., cardiac and skeletal muscle). These proteins may also regulate chromatin structure and thereby affect gene expression patterns. The clinical picture is characterized by progressive muscle weakness and wasting, contractures of the elbows and ankles, and cardiac disease. The cardiac involvement is severe, being associated with cardiomyopathy and arrhythmias that lead to sudden death in up to 40% of patients.

- ***Facioscapulohumeral dystrophy* is an autosomal dominant form of muscular dystrophy that is caused by complex genetic changes that allow expression of the transcription factor DUX4 that is normally repressed in mature tissues.** It is thought that the disease is caused by over expression of *DUX4* target genes, many of which are involved in the normal function of skeletal muscles. Most patients become symptomatic by the age of 20 years, usually owing to weakness in the facial muscles and the shoulder. Patients also exhibit weakness in the lower trunk and the dorsiflexors of the foot. Most affected persons have a normal life expectancy.

Channelopathies, Metabolic Myopathies, and Mitochondrial Myopathies

Other important inherited disorders of skeletal muscle are the result of defects in ion channels (channelopathies), metabolism, and mitochondrial function.

- ***Ion channel myopathies* are a group of familial disorders caused by inherited defects in ion channels that are characterized by myotonia, relapsing episodes of hypotonic paralysis associated with abnormal serum potassium levels, or both.** *Hyperkalemic periodic paralysis* results from mutations in the gene encoding the skeletal muscle sodium channel SCN4A, which regulates sodium entry during contraction. *Malignant hyperthermia* is a rare syndrome characterized by tachycardia, tachypnea, muscle spasms, and hyperpyrexia. It is triggered when patients carrying mutations in the ryanodine receptor RYR1, a calcium efflux channel, receive halogenated anesthetic agents or succinylcholine during surgery. On exposure to anesthetic, the mutated receptor leads to increased efflux of calcium from the sarcoplasmic reticulum, producing tetany and excessive heat production. There is some evidence that people carrying RYR1 mutations also are unusually susceptible to exertional hyperthermia (heat stroke).
- ***Myopathies due to inborn errors of metabolism* include disorders of glycogen synthesis and degradation** (Chapter 7) **and lipid handling.** The latter include disorders of the carnitine transport system and deficiencies of the mitochondrial dehydrogenase enzyme system, both of which can lead to accumulation of lipid in myocytes (lipid myopathies). These storage disorders may manifest as systemic disease or as a muscle-specific phenotype. Some are associated with muscle damage and weakness. Others manifest with recurring episodes of exercise- or fasting-induced muscle damage, which if severe may lead to necrosis of myoctyes (rhabdomyolysis), myoglobulinuria and acute renal failure.
- ***Mitochondrial myopathies* can stem from mutations in either the mitochondrial or nuclear genomes because both encode proteins and RNAs that are critical for mitochondrial function.** The variants caused by mitochondrial mutations show maternal inheritance (Chapter 7). Mitochondrial myopathies usually manifest in early adulthood with proximal muscle weakness and sometimes with severe involvement of the ocular musculature (external ophthalmoplegia). There may also be neurologic signs and symptoms, lactic acidosis, endocrinopathy, peripheral neuropathy, and cardiomyopathy. Some mitochondrial diseases are associated with normal muscle morphology, whereas others show aggregates of abnormal mitochondria; the latter impart a blotchy red appearance in special stains—hence the term *ragged red fibers*. On ultrastructural examination, these correspond to abnormal aggregates of mitochondria with abnormal shape and size, some containing crystalline inclusions.

Acquired Disorders of Skeletal Muscle

A diverse group of acquired disorders may manifest with muscle weakness, muscle cramping, or muscle pain. These include inflammatory myopathies, toxic muscle injuries, postinfectious rhabdomyolysis, and muscle infarction in the setting of diabetes. In most instances these are disorders of adults with acute or subacute onsets.

Inflammatory Myopathies

Polymyositis, dermatomyositis, and inclusion body myositis represent the traditional triad of inflammatory myopathies. This triad is a simplified view of complex diseases with variable phenotypes that are not always as well delineated as outlined here. Nevertheless, this approach still helps to outline key principles.

- *Polymyositis* is an autoimmune disorder associated with increased expression of MHC class I molecules on myofibers and predominantly endomysial inflammatory infiltrates containing CD8+ cytotoxic T cells. The autoimmune attack leads to myofiber necrosis and subsequent regeneration (Fig. 22.6A). Patients with polymyositis are often successfully treated with corticosteroids or other immunosuppressive agents.
- *Dermatomyositis* is the most common inflammatory myopathy in children, in whom it appears as an isolated entity. In adults, it often manifests as a paraneoplastic disorder. In both contexts, it is believed to have an autoimmune basis. The disease is typically associated with skin manifestations, as implied by the name, and may also have systemic manifestations such as interstitial lung disease. On microscopic examination and ultrastructural studies, it is associated with perivascular mononuclear cell infiltrates with plasma cells, "dropout" of capillaries, the presence of so-called "tubuloreticular inclusions" in endothelial cells, and myofiber damage in a paraseptal or perifascicular pattern (Fig. 22.6B).

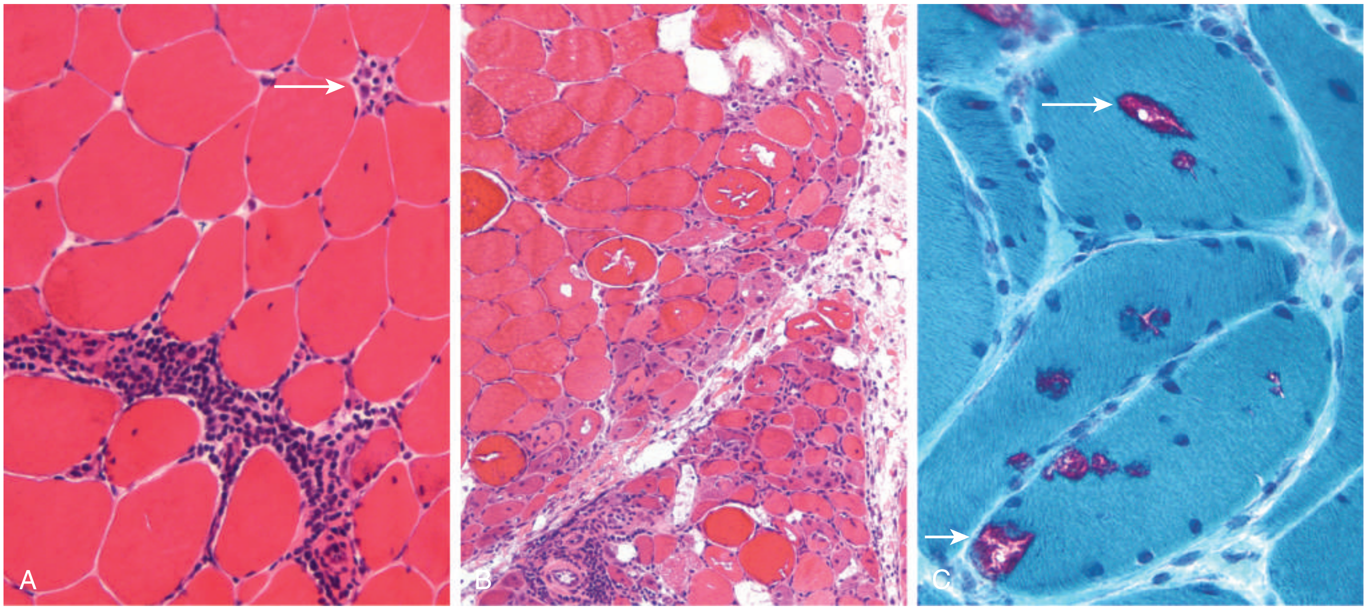

Fig. 22.6 Inflammatory myopathies. (A) Polymyositis is characterized by endomysial inflammatory infiltrates and myofiber necrosis *(arrow)*. (B) Dermatomyositis often shows prominent perifascicular and paraseptal atrophy. (C) Inclusion body myositis, showing myofibers containing rimmed vacuoles *(arrows)*. Modified Gomori trichrome stain.

As with some other autoimmune diseases such as SLE (Chapter 5), type 1 interferon-induced gene products are strongly upregulated in affected muscles. Some patients have autoantibodies that are relatively specific for dermatomyositis; these include antibodies against Mi-2 (a nuclear helicase) and p155 and p140, proteins with uncertain functions.

- *Inclusion body myositis* is the most common inflammatory myopathy in patients older than 60 years of age. It is grouped with other forms of myositis, but it has yet to be determined whether inflammation is a cause or an effect in this disorder. The morphologic hallmark of inclusion body myositis is the presence of rimmed vacuoles (Fig. 22.6C) that contain aggregates of the same proteins that accumulate in the brains of patients with neurodegenerative diseases—hyperphosphorylated tau, amyloid derived from β-amyloid precursor protein, and TDP-43 (Chapter 23)—leading some to speculate that this is a degenerative disorder of aging. Other features typical of chronic inflammatory myopathies, including myopathic changes, mononuclear cell infiltrates, endomysial fibrosis, and fatty replacement, also are evident. The disease follows a chronic, progressive course and generally does not respond well to immunosuppressive agents, another feature suggesting that inflammation is a secondary event.

Toxic Myopathies

A number of insults can cause toxic muscle injury, including intrinsic factors (e.g., thyroxine) and extrinsic factors (e.g., acute alcohol intoxication, various drugs).

- *Thyrotoxic myopathy* may take the form either of acute or chronic proximal muscle weakness, and it can be the first indication of thyrotoxicosis. Histologic findings include myofiber necrosis and regeneration.
- *Ethanol myopathy* occurs after an episode of binge drinking. The degree of rhabdomyolysis may be severe, sometimes leading to acute renal failure secondary to myoglobinuria. Patients usually complain of acute muscle pain, which may be generalized or confined to a single muscle group. Microscopically, there is myocyte swelling, necrosis, and regeneration.
- *Drug myopathy* can be produced by a variety of agents. For example, myopathy is the most common complication of statins (e.g., atorvastatin, simvastatin, pravastatin), occurring in approximately 1.5% of users. Two forms of statin associated myopathy are recognized: (1) toxicity of the drug and (2) statin-induced HMG-CoA reductase autoantibodies causing an immune mediated myopathy.

Tumors of Skeletal Muscles

These are discussed in Chapter 21 along with other tumors of soft tissues.

SUMMARY

DISORDERS OF SKELETAL MUSCLE

- Skeletal muscle function can be impaired by a primary (inherited or acquired) myopathy or secondarily because of problems with muscle innervation.
- The genetic forms of myopathy fall into several fairly distinct clinical phenotypes, including muscular dystrophy, congenital myopathy, and congenital muscular dystrophy.
- Dystrophinopathies are X-linked disorders caused by mutations in the dystrophin gene and disruption of the dystrophin-glycoprotein complex. Depending on the type of mutation, the disease may be severe, such as DMD, or mild (e.g., Becker dystrophy).
- Acquired myopathies have diverse causes, including inflammation and toxic exposures.

PERIPHERAL NERVE SHEATH TUMORS

A number of different tumors arise from peripheral nerves. Such tumors may manifest as soft tissue masses, with pain or loss of function related to impingement on nerves or other surrounding structures. In most peripheral nerve tumors, the neoplastic cells show evidence of Schwann cell differentiation. These tumors usually occur in adults and include both benign and malignant variants. An important feature is their frequent association with the familial tumor syndromes neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF2).

Schwannomas and Neurofibromatosis Type 2

Schwannomas are benign encapsulated tumors that may occur in soft tissues, internal organs, or spinal nerve roots. The most commonly affected cranial nerve is the vestibular portion of the eighth nerve. Tumors arising in a nerve root or the vestibular nerve may be associated with symptoms related to nerve root compression, which includes hearing loss in the case of vestibular schwannomas.

Most schwannomas are sporadic, but about 10% are associated with *familial neurofibromatosis type 2 (NF2)*. NF2 patients are at risk of developing multiple schwannomas, meningiomas, and ependymomas (the latter are described in Chapter 23). The presence of bilateral vestibular schwannomas is a hallmark of NF2; despite the name, neurofibromas (described later) are not found in NF2 patients. Affected patients carry a dominant loss of function mutation of the merlin gene on chromosome 22. Merlin is a cytoskeletal protein that functions as a tumor suppressor by facilitating E-cadherin–mediated contact inhibition (Chapter 6). With loss of merlin function, the tumor cells proliferate because contact inhibition is lost. Of note, merlin expression also is disrupted in sporadic schwannomas, possibly because of somatic mutations.

MORPHOLOGY

Most schwannomas appear as circumscribed masses abutting an adjacent nerve. On microscopic examination, these tumors often show an admixture of dense and loose areas referred to as Antoni A and B, respectively (Fig. 22.7A–B). They are comprised of a uniform proliferation of neoplastic Schwann cells. In the dense **Antoni A** areas, bland spindle cells with buckled nuclei are arranged into intersecting fascicles. These cells often align to produce nuclear palisading, resulting in alternating bands of nuclear and anuclear areas called Verocay bodies. Axons are largely excluded from the tumor. In the loose, hypocellular **Antoni B** areas, the spindle cells are spread apart by a prominent myxoid extracellular matrix. Thick-walled hyalinized vessels often are present. Hemorrhage or cystic changes also are sometimes seen.

Neurofibromas

Neurofibromas are benign peripheral nerve sheath tumors. Three important subtypes are recognized:

- *Localized cutaneous neurofibromas* arise as superficial nodular or polypoid tumors. These occur either as solitary sporadic lesions or often as multiple lesions in the context of neurofibromatosis 1 (NF1).
- *Plexiform neurofibromas* grow diffusely within the confines of a nerve or nerve plexus. Surgical enucleation of such lesions is therefore difficult and is often associated with lasting neurologic deficits. Plexiform neurofibromas are virtually pathognomonic for NF1 (discussed later). Unlike other benign nerve sheath tumors, these tumors are associated with a small but real risk of malignant transformation.
- *Diffuse neurofibromas* are infiltrative proliferations that can take the form of large, disfiguring subcutaneous masses. These also are often associated with NF1.

MORPHOLOGY

Unlike schwannomas, neurofibromas are not encapsulated. They may appear circumscribed, as in **localized cutaneous neurofibromas,** or may exhibit a diffusely infiltrative growth pattern. Also in contrast to schwannomas, the neoplastic Schwann cells in neurofibroma are admixed with other cell types, including mast cells, fibroblast like cells, and perineurial-like cells. The background stroma often contains loose wavy collagen bundles but also can be myxoid or can contain dense collagen (Fig. 22.7D). **Plexiform neurofibromas** involve multiple fascicles of individual affected nerves (Fig. 22.7C). **Diffuse neurofibromas** show an extensive infiltrative pattern of growth within the dermis and subcutis of the skin.

Neurofibromatosis Type 1

NF1 is an autosomal dominant disorder caused by mutations in the tumor suppressor neurofibromin, encoded on the long arm of chromosome 17 (17q). Neurofibromin is a negative regulator of the potent oncoprotein Ras (Chapter 6). Loss of neurofibromin function and the resulting Ras hyperactivity appear to be a cardinal feature of NF1-associated tumors. As would be anticipated for a tumor suppressor gene, the sole normal *NF1* allele is mutated or silenced in tumors arising in the setting of NF1. These include neurofibromas of all three main types, malignant peripheral nerve sheath tumors, "optic gliomas," and other glial tumors. In addition, patients with NF1 exhibit learning disabilities, seizures, skeletal abnormalities, vascular abnormalities with arterial stenoses, pigmented nodules of the iris *(Lisch nodules)*, and pigmented skin lesions (axillary freckling and café-au-lait spots) in various degrees.

Malignant Peripheral Nerve Sheath Tumors

Malignant peripheral nerve sheath tumors are neoplasms seen in adults that typically show evidence of Schwann cell derivation and sometimes a clear origin from a peripheral nerve. They may arise from transformation of a neurofibroma, usually of the plexiform type. About one-half of such tumors arise in patients with NF1, and 3% to 10% of all patients with NF1 develop a malignant peripheral

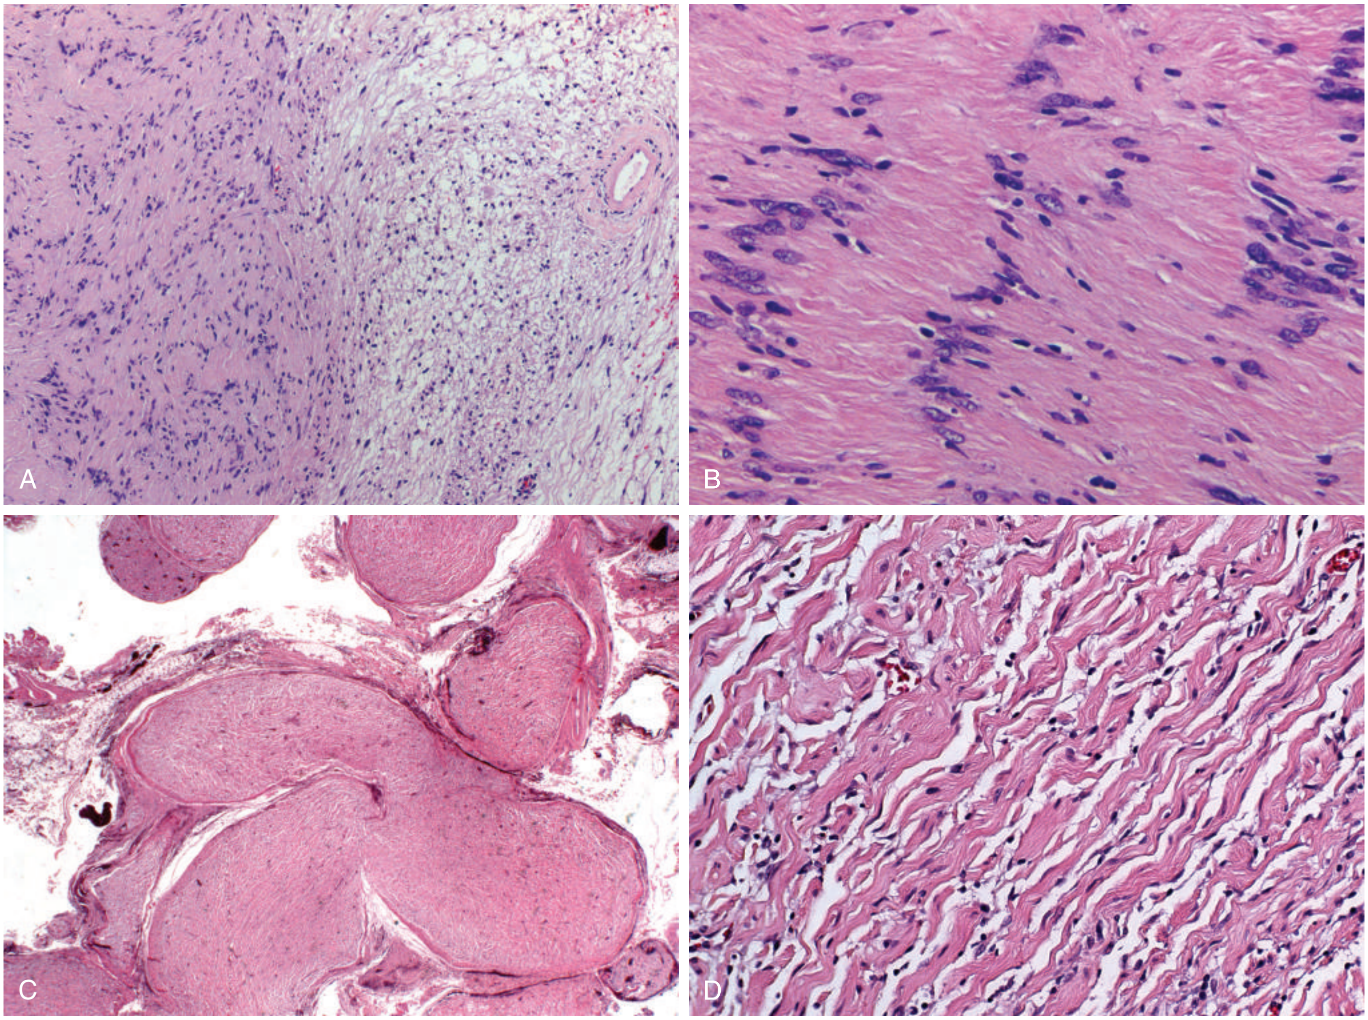

Fig. 22.7 Schwannoma and plexiform neurofibroma. (A–B) Schwannoma. As seen in (A), schwannomas often contain dense pink Antoni A areas *(left)* and loose, pale Antoni B areas *(right)*, as well as hyalinized blood vessels *(right)*. (B) Antoni A area with the nuclei of tumor cells aligned in palisading rows. (C–D) Plexiform neurofibroma. Multiple nerve fascicles are expanded by infiltrating tumor cells (C), which at higher power (D) are seen to consist of bland spindle cells admixed with wavy collagen bundles likened to carrot shavings.

nerve sheath tumor during their lifetimes. Histologically, these tumors are highly cellular and exhibit features of overt malignancy, including anaplasia, necrosis, infiltrative growth pattern, pleomorphism, and high proliferative activity.

Traumatic Neuroma

Traumatic neuroma is a nonneoplastic proliferation associated with a previous injury leading to transection of a peripheral nerve. Such injuries activate a regenerative program (see Fig. 22.1) characterized by sprouting and elongation of processes from the proximal axonal stump. With severe injuries that disrupt the perineurial sheath, these new processes may "miss" their target, the distal end of the transected nerve. The misguided elongating axonal processes can induce a reactive proliferation of Schwann cells, leading to the formation of a painful localized nodule that consists of a haphazard mixture of axons, Schwann cells, and connective tissue.

SUMMARY

PERIPHERAL NERVE SHEATH TUMORS

- In most peripheral nerve sheath tumors, the neoplastic cells show evidence of Schwann cell differentiation.
- Peripheral nerve sheath tumors are important features of the familial tumor syndromes NF1 and NF2.
- Schwannomas and neurofibromas are benign nerve sheath tumors.
- Schwannomas are circumscribed, usually encapsulated tumors that abut the nerve of origin and are a feature of NF2.
- Neurofibromas may manifest as a sporadic subcutaneous nodule, as a large, poorly defined soft tissue lesion, or as a growth within a nerve. Neurofibromas are associated with NF1.
- About 50% of malignant peripheral nerve sheath tumors occur de novo in otherwise normal persons, whereas the remainder arise from the malignant transformation of a preexisting NF1-associated neurofibroma.

CHAPTER

Central Nervous System 23

CHAPTER OUTLINE

Degenerative, inflammatory, infectious, vascular, and neoplastic disorders of the central nervous system (CNS) are some of the most serious diseases of mankind. These diseases have many unique features that reflect the highly specialized structure and functions of the CNS. The principal functional unit of the CNS is the *neuron*. Neurons of different types and in different locations have distinct properties, including functional roles, distribution of their connections, neurotransmitters used, metabolic requirements, and levels of electrical activity at a given moment. A set of neurons, not necessarily clustered together in a region of the brain, may thus show *selective vulnerability* to various insults because it shares one or more of these properties. Since different regions of the brain participate in different functions, the pattern of clinical signs and symptoms that follow injury depend as much on the region of brain involved as on the pathologic process. Mature neurons are incapable of cell division, so destruction of even a small number of neurons essential for a specific function may leave the individual with a neurologic deficit. In addition to neurons the CNS contains other cells, such as *astrocytes* and *oligodendrocytes*, which make up the *glia*. The components of the CNS are affected by a number of unique neurologic disorders and also respond to common insults (e.g., ischemia, infection) in a manner that is distinct from other tissues.

Before delving into specific disorders, we will briefly review the characteristic morphologic changes that are often seen in the CNS in the setting of injury or infection.

MORPHOLOGY

Features of Neuronal Injury. In response to injury, a number of changes occur in neurons and their processes (axons and dendrites). Within 12 hours of an irreversible hypoxic-ischemic insult, **neuronal injury** becomes evident on routine hematoxylin and eosin (H&E) staining (Fig. 23.1A). There is shrinkage of the cell body, pyknosis of the nucleus, disappearance of the nucleolus, loss of Nissl substance, and intense eosinophilia of the cytoplasm ("red neurons"). Axonal injury also leads to cell body enlargement and rounding, peripheral displacement of the nucleus, enlargement of the nucleolus, and peripheral dispersion of Nissl substance **(central chromatolysis).** In addition, acute injuries typically result in breakdown of the blood-brain barrier and variable degrees of cerebral edema (discussed later).

Many neurodegenerative diseases are associated with specific **intracellular inclusions** (e.g., Lewy bodies in Parkinson disease and tangles in Alzheimer disease). Pathogenic viruses may form inclusions in infected neurons, just as in other cells, and such inclusions aid in the diagnosis. In some neurodegenerative diseases, neuronal processes become thickened and tortuous; these are termed **dystrophic neurites.**

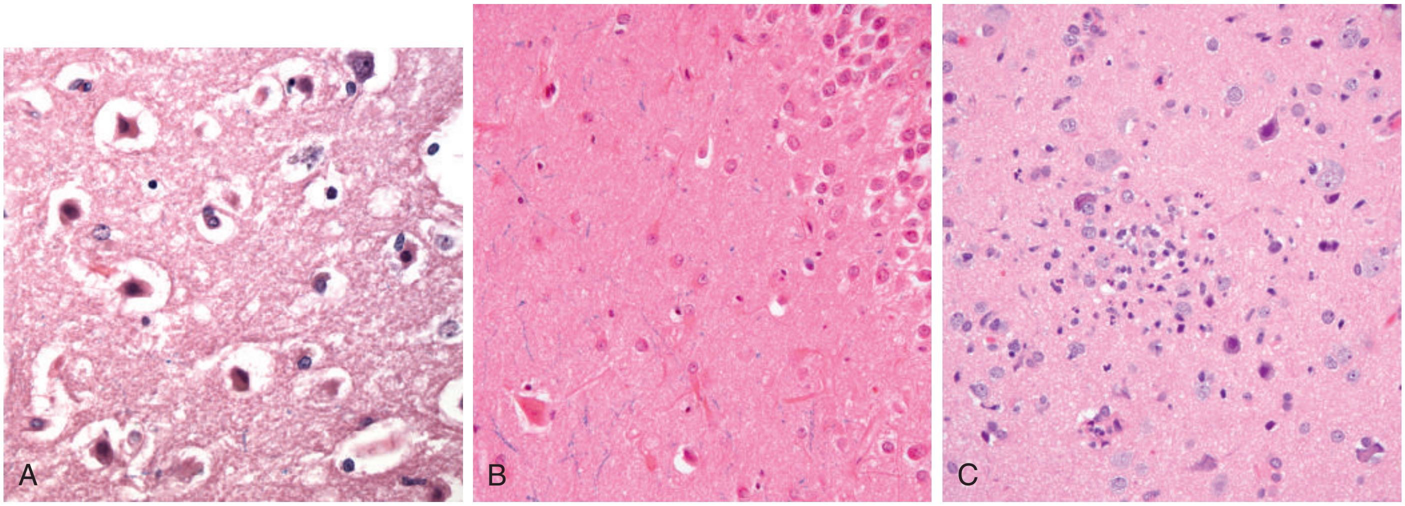

Fig. 23.1 Patterns of neuronal injury. (A) Acute hypoxic-ischemic injury in the cerebral cortex. The cell bodies are shrunken and eosinophilic ("red neurons"), and the nuclei are pyknotic. (B) Reactive astrocytes, with eosinophilic cytoplasm and multiple radiating processes. (C) Collection of microglial cells forming a poorly defined nodule, a common finding in viral infections.

Astrocyte Injury and Repair. Astrocytes are the principal cells responsible for repair and scar formation in the brain, a process termed **gliosis.** In response to injury, astrocytes undergo both hypertrophy and hyperplasia. The nucleus enlarges and becomes vesicular, and the nucleolus becomes prominent. The cytoplasm expands and takes on a bright pink hue, and the cell extends multiple stout, ramifying processes (called **gemistocytic astrocyte;** see Fig. 23.1B). Unlike elsewhere in the body, fibroblasts participate in healing after brain injury to a limited extent except in specific settings (penetrating brain trauma or around abscesses). In long-standing gliosis, the cytoplasm of reactive astrocytes shrinks in size, and the cellular processes become more tightly interwoven **(fibrillary astrocytes). Rosenthal fibers** are thick, elongated, brightly eosinophilic protein aggregates found in astrocytic processes in chronic gliosis and in some low-grade gliomas.

Oligodendrocytes, which produce myelin, exhibit a limited spectrum of specific morphologic changes in response to various injuries. In progressive multifocal leukoencephalopathy, viral inclusions can be seen in oligodendrocytes, with a smudgy, homogeneous-appearing enlarged nucleus.

Microglial cells are long-lived cells derived from the embryonic yolk sac that function as the resident phagocytes of the CNS. When activated by tissue injury, infection, or trauma, they proliferate and become more prominent histologically. Microglial cells take on the appearance of activated macrophages in areas of demyelination, organizing infarct, or hemorrhage; in other settings such as infections, they develop elongated nuclei **(rod cells).** Aggregates of elongated microglial cells at sites of tissue injury are termed **microglial nodules** (see Fig. 23.1C). Similar collections can be found congregating around and phagocytosing injured neurons **(neuronophagia).**

Ependymal cells line the ventricular system and the central canal of the spinal cord. Certain pathogens, particularly cytomegalovirus (CMV), can produce extensive ependymal injury, with typical viral inclusions. **Choroid plexus** is in continuity with the ependyma, and its specialized epithelial covering is responsible for the secretion of cerebrospinal fluid (CSF).

EDEMA, HERNIATION, AND HYDROCEPHALUS

The brain and spinal cord are encased within the skull and spinal canal, with nerves and blood vessels passing through specific foramina. The advantage of housing the delicate CNS within hard, rigid structures is obvious, but this arrangement provides little room for expansion of the brain in disease states. As a result, virtually any increase in the volume of the skull contents brings with it an increase in intracranial pressure. Substantial increases in the intracranial pressure compromise the ability of the cardiovascular system to deliver blood to the brain, resulting in decreased brain perfusion, with serious or fatal consequences. Disorders that may cause dangerous increases in the volume of intracranial contents include generalized cerebral edema, hydrocephalus, hemorrhages, ischemia, and mass lesions such as tumors.

Cerebral Edema

Cerebral edema is the accumulation of excess fluid within the brain parenchyma. There are two types, which often occur together, particularly after generalized injury.

- *Vasogenic edema* occurs when the integrity of the normal blood-brain barrier is disrupted, allowing fluid to shift from the vascular compartment into the extracellular spaces of the brain. Vasogenic edema can be localized (e.g., the result of increased vascular permeability due to inflammation or in tumors) or generalized.
- *Cytotoxic edema* is an increase in intracellular fluid secondary to neuronal and glial cell injury, as might follow generalized hypoxic or ischemic insult or exposure to certain toxins.

The edematous brain is softer than normal and often appears to "overfill" the cranial vault. In generalized

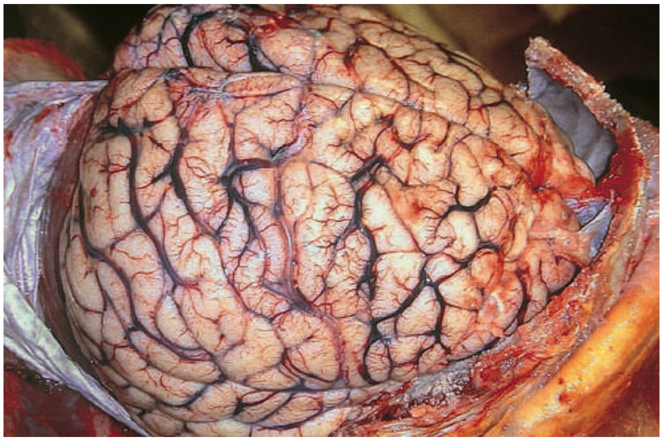

Fig. 23.2 Cerebral edema. The surfaces of the gyri are flattened as a result of compression of the expanding brain by the dura mater and inner surface of the skull. Such changes are associated with a dangerous increase in intracranial pressure.

edema, the gyri are flattened, the intervening sulci are narrowed, and the ventricular cavities are compressed (Fig. 23.2).

Hydrocephalus

After being produced by the choroid plexus within the ventricles, CSF circulates through the ventricular system and flows through the foramina of Luschka and Magendie into the subarachnoid space, where it is absorbed by arachnoid granulations. The balance between rates of generation and resorption regulates CSF volume.

Hydrocephalus refers to an increase in the volume of the CSF within the ventricular system. This disorder most often is a consequence of impaired flow or decreased resorption of CSF. If there is a localized obstacle to CSF flow within the ventricular system, then a portion of the ventricles enlarges while the remainder does not. This pattern is referred to as *noncommunicating hydrocephalus* and most commonly is caused by masses obstructing the foramen of Monro or compressing the cerebral aqueduct. In *communicating hydrocephalus,* the entire ventricular system is enlarged; it is usually caused by reduced CSF resorption.

If hydrocephalus develops in infancy before closure of the cranial sutures, the head enlarges. Once the sutures fuse, hydrocephalus causes ventricular expansion and increased intracranial pressure, but no change in head circumference (Fig. 23.3). In contrast to these disorders, in which increased CSF volume is the primary process, a compensatory increase in CSF volume *(hydrocephalus ex vacuo)* may occur secondary to a loss of brain volume from any underlying cause (e.g., infarction, neurodegenerative disease). In such settings, the hydrocephalus merely reflects the primary disorder and is of no clinical significance.

Herniation

Herniation is the displacement of brain tissue from one compartment to another in response to increased intracranial pressure. The intra-cranial compartment is divided by rigid dural folds (falx and tentorium). If the pressure is sufficiently high, portions of the brain are displaced across these rigid structures. This herniation often leads to compromise of the blood supply to compressed tissue, producing infarction, additional swelling, and further herniation.

There are three main types of herniation (Fig. 23.4):

- *Subfalcine (cingulate) herniation* occurs when unilateral or asymmetric expansion of a cerebral hemisphere displaces the cingulate gyrus under the edge of the falx. This may compress the anterior cerebral artery.
- *Transtentorial (uncinate) herniation* occurs when the medial aspect of the temporal lobe is compressed against the free margin of the tentorium. As the temporal lobe is displaced, the third cranial nerve is compromised, resulting in pupillary dilation and impaired ocular movements on the side of the lesion ("blown pupil"). The posterior cerebral artery may also be compressed, resulting in ischemic injury to tissue supplied by that vessel, including the primary visual cortex. With further displacement of the temporal lobe, pressure on the midbrain may compress the contralateral cerebral peduncle against the tentorium, resulting in hemiparesis ipsilateral to the side of the herniation. The compression of the peduncle creates a deformation known as *Kernohan's notch.* Compression of the midbrain and the ascending reticular activating system with transtentorial herniation leads to depressed consciousness. Progression of transtentorial herniation is often accompanied by linear or flame-shaped hemorrhages in the midbrain and pons, termed *Duret hemorrhages* (Fig. 23.5). These lesions usually occur in the midline and paramedian regions and are believed to be the result of tearing of penetrating veins and arteries supplying the upper brain stem.
- *Tonsillar herniation* refers to displacement of the cerebellar tonsils through the foramen magnum. This type of herniation causes brain stem compression and compromises vital respiratory and cardiac centers in the medulla, and is often fatal.

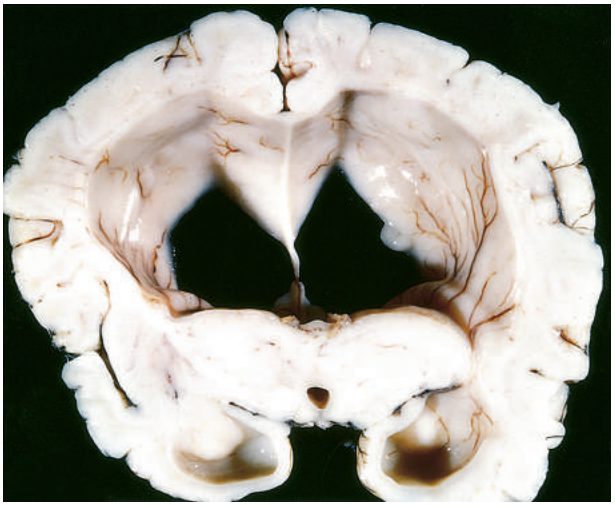

Fig. 23.3 Hydrocephalus. Dilated lateral ventricles seen in a coronal section through the mid-thalamus.

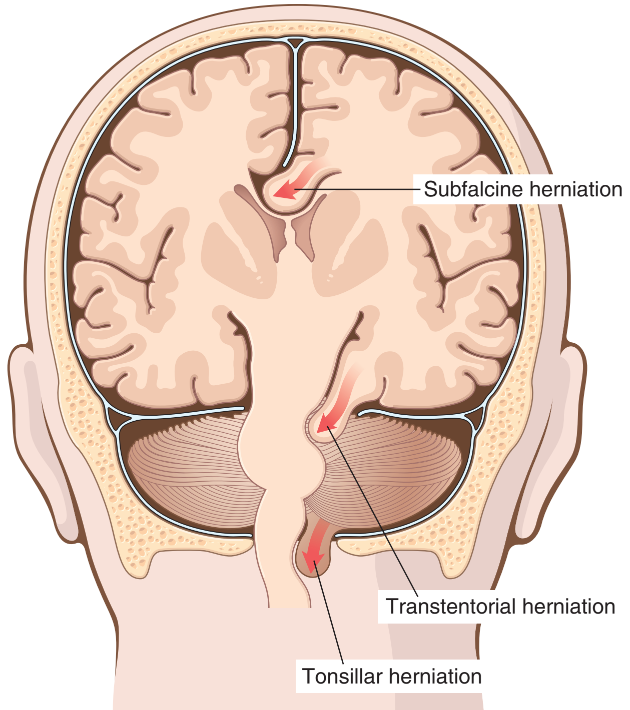

Fig. 23.4 Herniation syndromes. Displacement of brain parenchyma across fixed barriers can be subfalcine, transtentorial, or tonsillar (into the foramen magnum).

SUMMARY

EDEMA, HERNIATION, AND HYDROCEPHALUS

- Cerebral edema is the accumulation of excess fluid within the brain parenchyma. Hydrocephalus is defined as an increase in CSF volume within all or part of the ventricular system.
- Increases in brain volume (as a result of increased CSF volume, edema, hemorrhage, or tumor) raise the pressure inside the fixed capacity of the skull.
- Increases in pressure can damage the brain by decreasing perfusion or by displacing tissue across dural partitions inside the skull or through openings in the skull (herniations).

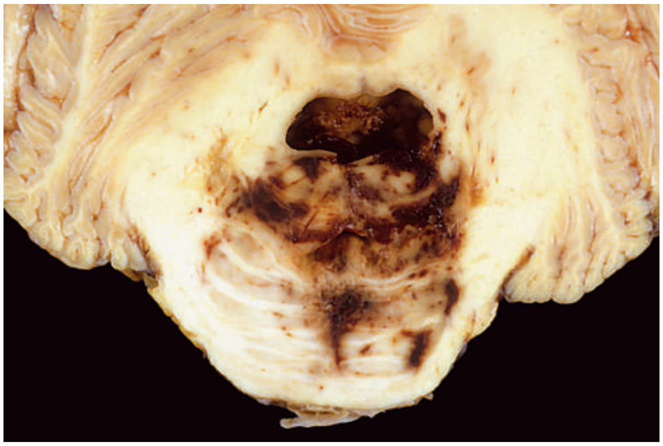

Fig. 23.5 Duret hemorrhage. As mass effect displaces the brain downward, there is disruption of the vessels that enter the pons along the midline, leading to hemorrhage.

CEREBROVASCULAR DISEASES

Cerebrovascular diseases are brain disorders caused by pathologic processes involving blood vessels. They are a major cause of death in the developed world and are the most prevalent cause of neurologic morbidity. The three main pathogenic mechanisms are (1) thrombotic occlusion, (2) embolic occlusion, and (3) vascular rupture. *Stroke* is the clinical designation applied to all of these conditions when symptoms begin acutely. Thrombosis and embolism have similar consequences for the brain: loss of oxygen and metabolic substrates, resulting in infarction or ischemic injury of regions supplied by the affected vessel. Similar injury occurs globally when there is complete loss of perfusion, severe hypoxemia (e.g., hypovolemic shock), or profound hypoglycemia. Hemorrhage accompanies rupture of vessels and leads to direct tissue damage as well as secondary ischemic injury. Traumatic vascular injury is discussed separately in the context of trauma.

Hypoxia, Ischemia, and Infarction

The brain is a highly oxygen-dependent tissue that requires a continual supply of glucose and oxygen from the blood. Although it constitutes no more than 2% of body weight, the brain receives 15% of the resting cardiac output and is responsible for 20% of total body oxygen consumption. Cerebral blood flow normally remains stable over a wide range of blood pressure and intracranial pressure because of autoregulation of vascular resistance. The brain may be deprived of oxygen by two general mechanisms:

- *Functional hypoxia,* caused by a low partial pressure of oxygen (e.g., high altitude), impaired oxygen-carrying capacity (e.g., severe anemia, carbon monoxide poisoning), or toxins that interfere with oxygen use (e.g., cyanide poisoning)
- *Ischemia,* either *transient* or *permanent,* due to tissue hypoperfusion, which can be caused by hypotension, vascular obstruction, or both

Global Cerebral Ischemia

Widespread ischemic-hypoxic injury can occur in the setting of severe systemic hypotension, usually when systolic pressures fall below 50 mm Hg, as in cardiac arrest and shock. The clinical outcome varies with the severity and duration of the insult. When the insult is mild, there may be only a transient postischemic confusional state, with eventual complete recovery. Neurons are more susceptible to hypoxic injury than are glial cells, and the most susceptible neurons are the pyramidal cells of the hippocampus and neocortex and Purkinje cells of the cerebellum. In some individuals, even mild or transient global ischemic insults may cause damage to these vulnerable areas. In severe global cerebral ischemia, widespread neuronal death occurs irrespective of regional vulnerability. Patients who survive often remain severely impaired neurologically and in a persistent vegetative state. Other patients meet the clinical criteria for so-called "brain death," in which all voluntary and reflex brain and brain stem function is absent,

including respiratory drive. When patients with this form of irreversible injury are maintained on mechanical ventilation, the brain gradually undergoes autolysis, resulting in the so-called "respirator brain."

MORPHOLOGY

In the setting of global ischemia, the brain is swollen, with wide gyri and narrowed sulci. The cut surface shows poor demarcation between gray matter and white matter. The histopathologic changes that accompany irreversible ischemic injury (infarction) are grouped into three categories. **Early changes,** occurring 12 to 24 hours after the insult, include acute neuronal cell change (red neurons) (see Fig. 23.1A) characterized initially by microvacuolation, followed by cytoplasmic eosinophilia, and later nuclear pyknosis and karyorrhexis. Similar changes occur somewhat later in astrocytes and oligodendroglia. After this, the reaction to tissue damage begins with infiltration of neutrophils (Fig. 23.6A). **Subacute changes,** occurring at 24 hours to 2 weeks, include necrosis of tissue, influx of macrophages, vascular proliferation, and reactive gliosis (see Fig. 23.6B). **Repair,** seen after 2 weeks, is characterized by removal of necrotic tissue and gliosis (see Fig. 23.6C).

Border zone ("watershed") infarcts occur in regions of the brain and spinal cord that lie at the most distal portions of arterial territories. They are usually seen after hypotensive episodes. In the cerebral hemispheres, the border zone between the anterior and the middle cerebral artery distributions is at greatest risk. Damage to this region produces a wedge-shaped band of necrosis over the cerebral convexity a few centimeters lateral to the interhemispheric fissure.

Focal Cerebral Ischemia

Cerebral arterial occlusion leads first to focal ischemia and then to infarction in the distribution of the compromised vessel. The size, location, and shape of the infarct and the extent of tissue damage that results may be modified by collateral blood flow. Specifically, collateral flow through the circle of Willis or cortical-leptomeningeal anastomoses can limit damage in some regions. By contrast, there is little if any collateral blood flow to structures such as the thalamus, basal ganglia, and deep white matter, which are supplied by deep penetrating vessels.

Embolic infarctions are more common than infarctions due to thrombosis. Cardiac mural thrombi are a frequent source of emboli; myocardial dysfunction, valvular disease, and atrial fibrillation are important predisposing factors. Thromboemboli also arise in arteries, most often from atheromatous plaques in the carotid arteries or aortic arch. Emboli of venous origin may cross over to the arterial circulation through a patent foramen ovale and lodge in the brain (paradoxical embolism; see Chapter 4); these include thromboemboli from deep leg veins and fat emboli, usually following bone trauma. The territory of the middle cerebral artery, a direct extension of the internal carotid artery, is most frequently affected by embolic infarction. Emboli tend to lodge where vessels branch or in areas of stenosis, usually caused by atherosclerosis.

Thrombotic occlusions causing cerebral infarctions usually are superimposed on atherosclerotic plaques; common sites are the carotid bifurcation, the origin of the middle cerebral artery, and either end of the basilar artery. These occlusions may be accompanied by anterograde extension, as well as thrombus fragmentation and distal embolization. Thrombotic occlusions causing small infarcts of only a few millimeters in diameter, so-called "lacunar infarcts," occur when small penetrating arteries occlude due to chronic damage, usually from long-standing hypertension (discussed later).

Infarcts can be divided into two broad groups (Fig. 23.7). *Nonhemorrhagic infarcts* result from acute vascular occlusions and may evolve into *hemorrhagic infarcts* when there is reperfusion of ischemic tissue, either through collaterals or after dissolution of emboli.

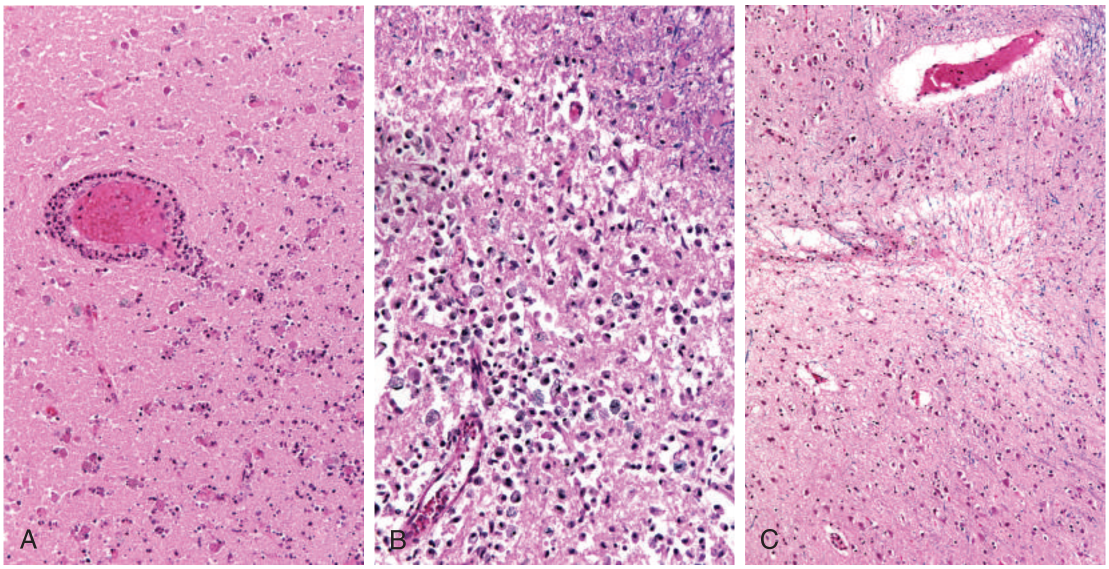

Fig. 23.6 Cerebral infarction. (A) Infiltration of a cerebral infarction by neutrophils begins at the edges of the lesion, where the vascular supply is intact. (B) By day 10, an area of infarction shows the presence of macrophages and surrounding reactive gliosis. (C) Old intracortical infarcts are seen as areas of tissue loss and residual gliosis.

MORPHOLOGY

Hemorrhagic infarcts usually manifest as multiple, sometimes confluent, petechial hemorrhages (Fig. 23.7A and B). The microscopic picture and evolution of hemorrhagic infarction parallel those of ischemic infarction, with the addition of blood extravasation and resorption. In individuals with coagulopathies, hemorrhagic infarcts may be associated with extensive intracerebral hematomas.

The macroscopic appearance of a **nonhemorrhagic infarct** evolves over time. During the first 6 hours, the tissue is unchanged in appearance, but by 48 hours, the tissue becomes pale, soft, and swollen. From days 2 to 10, the injured brain turns gelatinous and friable, and the boundary between normal and abnormal tissue becomes more distinct as edema resolves in the adjacent viable tissue. From day 10 to week 3, the tissue liquefies, eventually leaving a fluid-filled cavity, which gradually expands as dead tissue is resorbed (see Fig. 23.7C).

Microscopically, the tissue reaction follows a characteristic sequence. After the first 12 hours, ischemic neuronal change (red neurons) (see Fig. 23.1A) and cytotoxic and vasogenic edema appear. Endothelial and glial cells, mainly astrocytes, swell, and myelinated fibers begin to disintegrate. During the first several days neutrophils infiltrate the area of injury, but these are replaced over the next 2–3 weeks by macrophages. Macrophages containing myelin or red blood cell breakdown products may persist in the lesion for months to years. As the process of phagocytosis and liquefaction proceeds, astrocytes at the edges of the lesion progressively enlarge, divide, and develop a prominent network of cytoplasmic extensions. After several months, the striking astrocytic nuclear and cytoplasmic enlargement regresses. In the wall of the cavity, astrocyte processes form a dense feltwork of glial fibers admixed with new capillaries and a few perivascular connective tissue fibers.

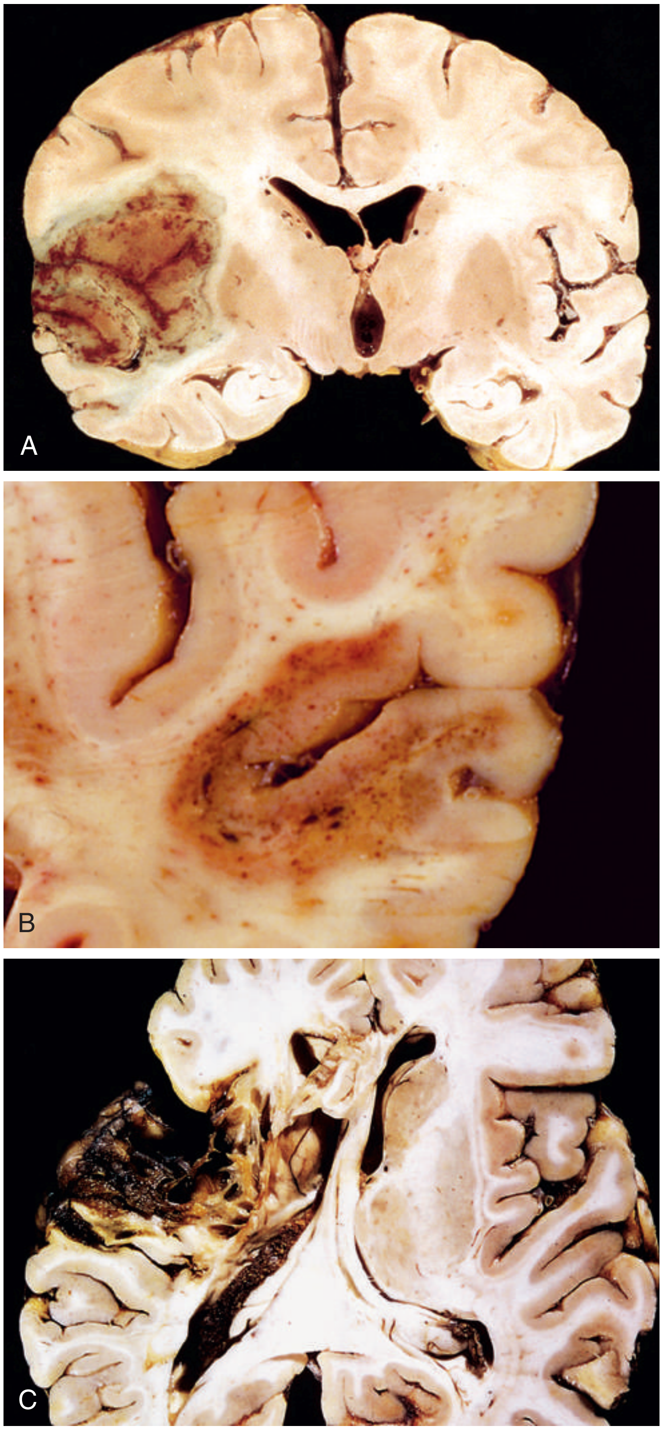

Fig. 23.7 Cerebral infarction. (A) Section of the brain showing a large, discolored, focally hemorrhagic region in the left middle cerebral artery distribution (hemorrhagic, or red, infarction). (B) An infarct with punctate hemorrhages, consistent with ischemia-reperfusion injury, is present in the temporal lobe. (C) Old cystic infarct shows destruction of cortex and surrounding gliosis.

Intracranial Hemorrhage

Hemorrhages within the brain are caused by (1) hypertension and other diseases leading to vascular wall injury, (2) structural lesions such as arteriovenous and cavernous malformations, and (3) tumors. Subarachnoid hemorrhages most commonly are the result of ruptured aneurysms but also occur with other vascular malformations. Subdural or epidural hemorrhages usually are associated with trauma.

Primary Brain Parenchymal Hemorrhage

Spontaneous (nontraumatic) intraparenchymal hemorrhages are most common in mid to late adult life, with a peak incidence at about 60 years of age. Most are due to the rupture of a small intraparenchymal vessel. Hypertension is the leading underlying cause, and brain hemorrhage accounts for roughly 15% of deaths among individuals with chronic hypertension. Intracerebral hemorrhage can be clinically devastating when it affects large portions of the brain or extends into the ventricular system; alternatively, it can affect small regions and be clinically silent. Hypertensive intraparenchymal hemorrhages typically occur in the basal ganglia, thalamus, pons, and cerebellum (Fig. 23.8), with the location and the size of the bleed determining its clinical manifestations. If the individual survives the acute event, gradual resolution of the hematoma ensues, sometimes with considerable clinical improvement.

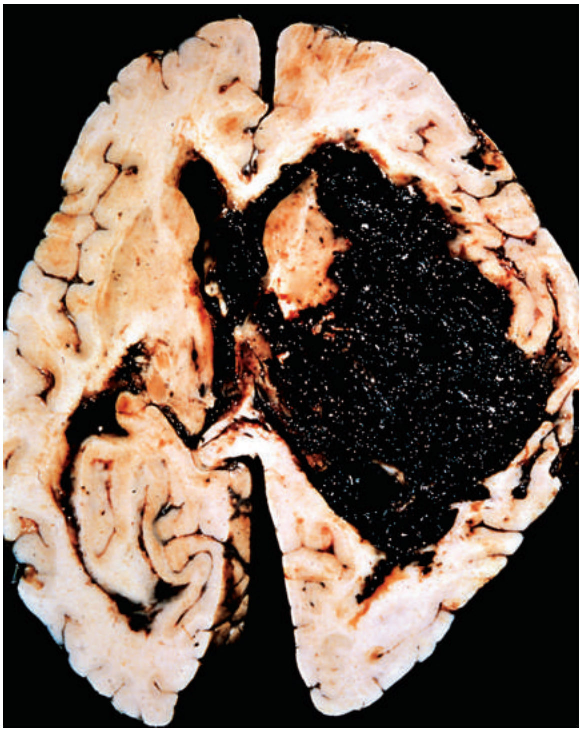

Fig. 23.8 Cerebral hemorrhage. Massive hypertensive hemorrhage rupturing into a lateral ventricle.

MORPHOLOGY

In acute intracerebral hemorrhage, the extravasated blood compresses the adjacent parenchyma. With time, hemorrhages are converted to a cavity with a brown, discolored rim. On microscopic examination, early lesions consist of clotted blood surrounded by edematous brain tissue containing neurons and glia displaying morphologic changes typical of anoxic injury. Eventually the edema resolves, pigment- and lipid-laden macrophages appear, and proliferation of reactive astrocytes becomes visible at the periphery of the lesion. The cellular events then follow the same time course observed after cerebral infarction.

Cerebral Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is a disease in which the same amyloidogenic peptides as those found in Alzheimer disease (discussed later) deposit in the walls of medium- and small-caliber meningeal and cortical vessels. The amyloid confers a rigid, pipe-like appearance and stains with Congo red. Amyloid deposition weakens vessel walls and increases the risk for hemorrhages, which differ in distribution from those associated with hypertension. CAA-associated hemorrhages often occur in the lobes of the cerebral cortex *(lobar hemorrhages)*. In addition to these symptomatic hemorrhages, CAA also results in small (<1 mm) cortical hemorrhages *(microhemorrhages)*.

Subarachnoid Hemorrhage and Saccular Aneurysms

The most frequent cause of clinically significant nontraumatic subarachnoid hemorrhage is rupture of a saccular (berry) aneurysm. Hemorrhage into the subarachnoid space also may result from vascular malformation, trauma, rupture of an intracerebral hemorrhage into the ventricular system, coagulopathies, and tumors.

In about one-third of cases, rupture of a saccular aneurysm occurs at the time of an acute increase in intracranial pressure, such as occurs with straining at stool or sexual orgasm. Blood under arterial pressure is forced into the subarachnoid space, and the patient is stricken with sudden, excruciating headache (known as a *thunderclap headache,* often described as "the worst headache I've ever had") and rapidly loses consciousness. Between 25% and 50% of affected individuals die from the first bleed, and recurrent bleeds are common in survivors. Not surprisingly, the prognosis worsens with each bleeding episode.

About 90% of saccular aneurysms occur in the anterior circulation near major arterial branch points (Fig. 23.9); multiple aneurysms exist in 20% to 30% of cases. The aneurysms are not present at birth but develop over time because of underlying defects in the vessel media. There is an increased risk for aneurysms in patients with autosomal dominant polycystic kidney disease (Chapter 14) and genetic disorders of extracellular matrix proteins (e.g., Ehler-Danlos syndrome). Overall, roughly 1.3% of aneurysms bleed per year, with the probability of rupture increasing with size. For example, aneurysms larger than 1 cm in diameter have a roughly 50% risk for bleeding per year. In the early period after a subarachnoid hemorrhage, there is an additional risk for ischemic injury from vasospasm of other vessels. Healing and the attendant meningeal fibrosis and scarring sometimes obstruct CSF flow or disrupt CSF resorption, leading to hydrocephalus.

MORPHOLOGY

A saccular aneurysm is a thin-walled outpouching of an artery (Fig. 23.10). Beyond the neck of the aneurysm, the muscular wall and intimal elastic lamina are absent, such that the aneurysm sac is lined only by thickened hyalinized intima. The adventitia covering the sac is continuous with that of the parent artery. Rupture usually occurs at the apex of the sac, releasing blood into the subarachnoid space, the substance of the brain, or both.

In addition to saccular aneurysms, atherosclerotic, mycotic, traumatic, and dissecting aneurysms also occur intracranially. The last three types (like saccular aneurysms) most often are found in the anterior circulation, whereas atherosclerotic aneurysms frequently are fusiform and most commonly involve the basilar artery. Nonsaccular aneurysms usually manifest as cerebral infarction due to vascular occlusion instead of subarachnoid hemorrhage.

Vascular Malformations

Vascular malformations of the brain are classified into four principal types based on the nature of the abnormal vessels: arteriovenous malformations (AVMs), cavernous

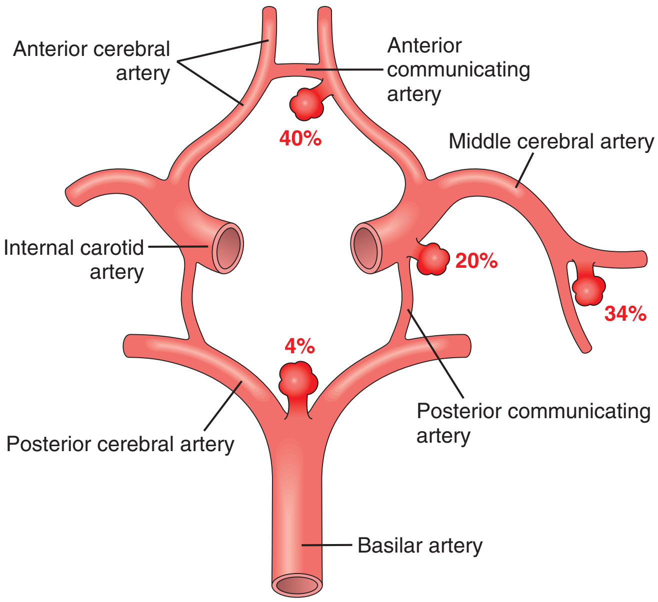

Fig. 23.9 Common sites of saccular aneurysms.

malformations, capillary telangiectasias, and venous angiomas. AVMs, the most common of these, affect males twice as frequently as females and most commonly manifest between 10 and 30 years of age with seizures, an intracerebral hemorrhage, or a subarachnoid hemorrhage. In the newborn period, large AVMs may lead to high-output congestive heart failure because of blood shunting from arteries to veins. *The risk for bleeding makes AVM the most dangerous type of vascular malformation.* Multiple AVMs can be seen in the setting of hereditary hemorrhagic telangiectasia, an autosomal dominant condition often associated with mutations affecting the TGFβ pathway.

MORPHOLOGY

AVMs may involve subarachnoid vessels extending into brain parenchyma or occur exclusively within the brain. On gross inspection, they resemble a tangled network of wormlike vascular channels (Fig. 23.11). Microscopic examination shows enlarged blood vessels separated by gliotic tissue, often with evidence of previous hemorrhage. Some vessels can be recognized as arteries with duplicated and fragmented internal elastic lamina, while others show marked thickening or partial replacement of the media by hyalinized connective tissue.

Cavernous malformations consist of distended, loosely organized vascular channels with thin collagenized walls without intervening nervous tissue. They occur most often in the cerebellum, pons, and subcortical regions, and have a low blood flow without significant arteriovenous shunting. Foci of old hemorrhage, infarction, and calcification frequently surround the abnormal vessels.

Capillary telangiectasias are microscopic foci of dilated thin-walled vascular channels separated by relatively normal brain parenchyma that occur most frequently in the pons. **Venous angiomas** (varices) consist of aggregates of ectatic venous channels. These latter two types of vascular malformation are unlikely to bleed or to cause symptoms, and most are incidental findings.

Other Vascular Diseases

Hypertensive Cerebrovascular Disease

Hypertension causes *hyaline arteriolar sclerosis* of the deep penetrating arteries and arterioles that supply the basal ganglia, the hemispheric white matter, and the brain stem. Affected arteriolar walls are weakened and are more vulnerable to rupture. In some instances, minute aneurysms *(Charcot-Bouchard microaneurysms)* form in vessels less than 300 μm in diameter. In addition to massive intracerebral

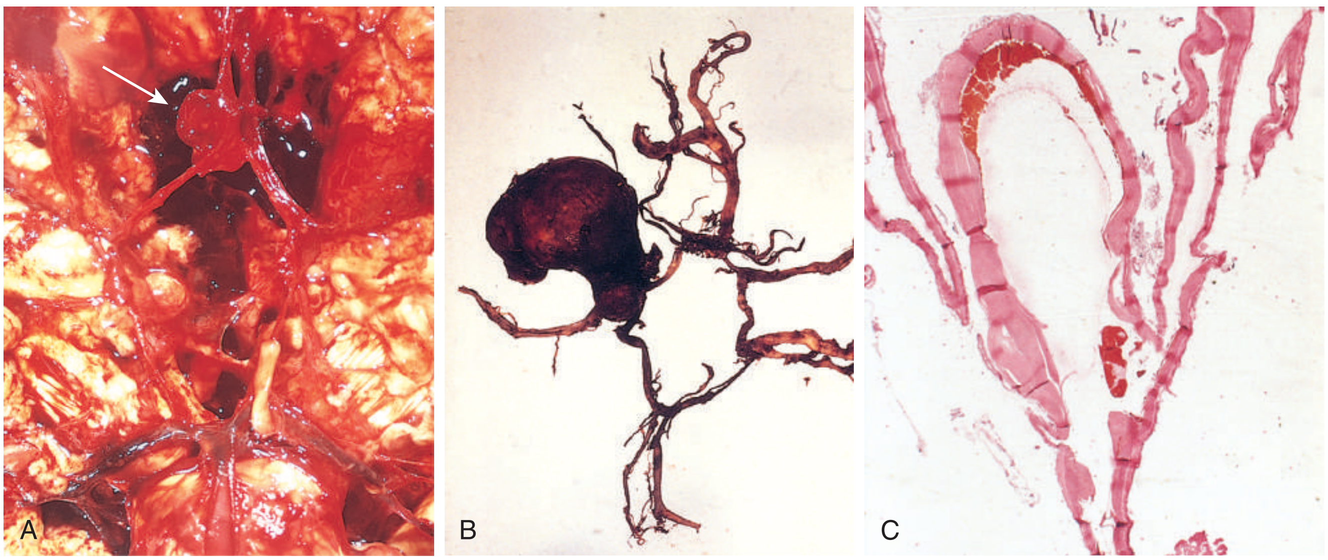

Fig. 23.10 Saccular aneurysms. (A) View of the base of the brain, dissected to show the circle of Willis with an aneurysm of the anterior cerebral artery *(arrow)*. Fig. 23.11 Arteriovenous malformation.

hemorrhage (discussed earlier), several other pathologic outcomes are related to hypertension.

- *Lacunes* or *lacunar infarcts* are small cavitary infarcts, just a few millimeters in size, that are found most commonly in the deep gray matter (basal ganglia and thalamus), the internal capsule, the deep white matter, and the pons. They are caused by occlusion of a single penetrating branch of a large cerebral artery. Depending on their location, lacunes can be silent clinically or cause significant neurologic impairment.
- *Rupture of the small-caliber penetrating vessels* may occur, leading to the development of small hemorrhages. In time, these hemorrhages resorb, leaving behind a slit-like cavity *(slit hemorrhage)* surrounded by brownish discoloration.
- *Acute hypertensive encephalopathy* most often is associated with sudden sustained increases in diastolic blood pressure to greater than 130 mm Hg. It is characterized by increased intracranial pressure and global cerebral dysfunction, manifesting as headaches, confusion, vomiting, convulsions, and sometimes coma. Rapid therapeutic intervention to reduce the blood pressure is essential. Postmortem examination may show brain edema, with or without transtentorial or tonsillar herniation. Petechiae and fibrinoid necrosis of arterioles in the gray matter and white matter may be seen microscopically.

Vasculitis

Inflammatory processes involving blood vessels may compromise blood flow and cause cerebral dysfunction or infarction. Infectious arteritis of small and large vessels was previously seen mainly in association with syphilis and tuberculosis, but is now more often caused by opportunistic infections (such as aspergillosis, herpes zoster, or CMV) in the setting of immunosuppression. Some systemic forms of vasculitis, such as polyarteritis nodosa, may involve cerebral vessels and cause single or multiple infarcts. *Primary angiitis of the CNS* is a form of vasculitis that involves multiple small- to medium-sized parenchymal and subarachnoid vessels and is characterized by chronic inflammation, multinucleate giant cells (with or without granuloma formation), and destruction of vessel walls. Affected individuals present with a diffuse encephalopathy, often with cognitive dysfunction. Treatment consists of immunosuppressive agents.

SUMMARY

CEREBROVASCULAR DISEASES

- *Stroke* is the clinical term for acute-onset neurologic deficits resulting from hemorrhagic or obstructive vascular lesions.
- Cerebral infarction follows loss of blood supply and can be widespread or focal, or affect regions with the least robust vascular supply ("watershed" infarcts).
- Focal cerebral infarcts are most commonly embolic; with subsequent dissolution of the embolus and reperfusion, a nonhemorrhagic infarct can become hemorrhagic.
- Primary intraparenchymal hemorrhages typically are due to either hypertension (most commonly in white matter, deep gray matter, or posterior fossa contents) or cerebral amyloid angiopathy (cerebral cortex).
- Spontaneous subarachnoid hemorrhage usually is caused by a structural vascular abnormality, such as an aneurysm or arteriovenous malformation.

CENTRAL NERVOUS SYSTEM TRAUMA

Trauma to the brain and spinal cord is a significant cause of death and disability. The severity and site of injury affect the outcome: injury of several cubic centimeters of brain parenchyma may be clinically silent (if in the frontal lobe), severely disabling (affecting the spinal cord), or fatal (involving the brain stem).

A blow to the head may be *penetrating* or *blunt;* it may cause an *open* or a *closed* injury. The magnitude and distribution of resulting traumatic brain lesions depend on the shape of the object causing the trauma, the force of impact, and whether the head is in motion at the time of injury. Severe brain damage can occur in the absence of external signs of head injury, and conversely, severe lacerations and even skull fractures do not necessarily indicate damage to the underlying brain. When the brain is damaged, the injuries may involve the parenchyma, the vasculature, or both.

Traumatic Parenchymal Injuries

When an object impacts the head, brain injury may occur at the site of impact—a *coup injury*—or opposite the site of impact on the other side of the brain—a *contrecoup injury.* Both coup and contrecoup lesions are contusions, with comparable gross and microscopic appearances. A *contusion* is caused by rapid tissue displacement, disruption of vascular channels, and subsequent hemorrhage, tissue injury, and edema. Since they are closest to the skull, the crests of the gyri are the parts of the brain that are most susceptible to traumatic injury. Contusions are common in regions of the brain overlying rough and irregular inner skull surfaces, such as the orbitofrontal regions and the temporal lobe tips. Penetration of the brain by a projectile

such as a bullet or a skull fragment from a fracture causes a laceration, with tissue tearing, vascular disruption, and hemorrhage.

MORPHOLOGY

Contusions are wedge-shaped, with the widest aspect closest to the point of impact (Fig. 23.12A). Within a few hours of injury, blood extravasates throughout the involved tissue, across the width of the cerebral cortex, and into the white matter and subarachnoid spaces. Although functional effects are seen earlier, morphologic evidence of neruonal injury (nuclear pyknosis, cytoplasmic eosinophilia, cellular disintegration) takes about 24 hours to appear. The inflammatory response to the injured tissue follows its usual course, with neutrophils preceding the appearance of macrophages. In contrast with ischemic lesions, in which the superficial layer of cortex may be preserved, trauma affects the superficial layers most severely.

Old traumatic lesions characteristically appear as depressed, retracted, yellowish brown patches involving the crests of gyri (see Fig. 23.12B). These lesions show gliosis and residual hemosiderin-laden macrophages.

Although contusions are more easily seen, trauma may also cause more subtle but widespread injury to axons within the brain (called **diffuse axonal injury**), sometimes with devastating consequences. The movement of one region of brain relative to another is thought to disrupt axonal integrity and function. Angular acceleration, even in the absence of impact, may cause axonal injury as well as hemorrhage. As many as 50% of patients who develop coma shortly after trauma are believed to have white matter damage and diffuse axonal injury, usually in the form of axonal swellings that appear within hours of the injury.

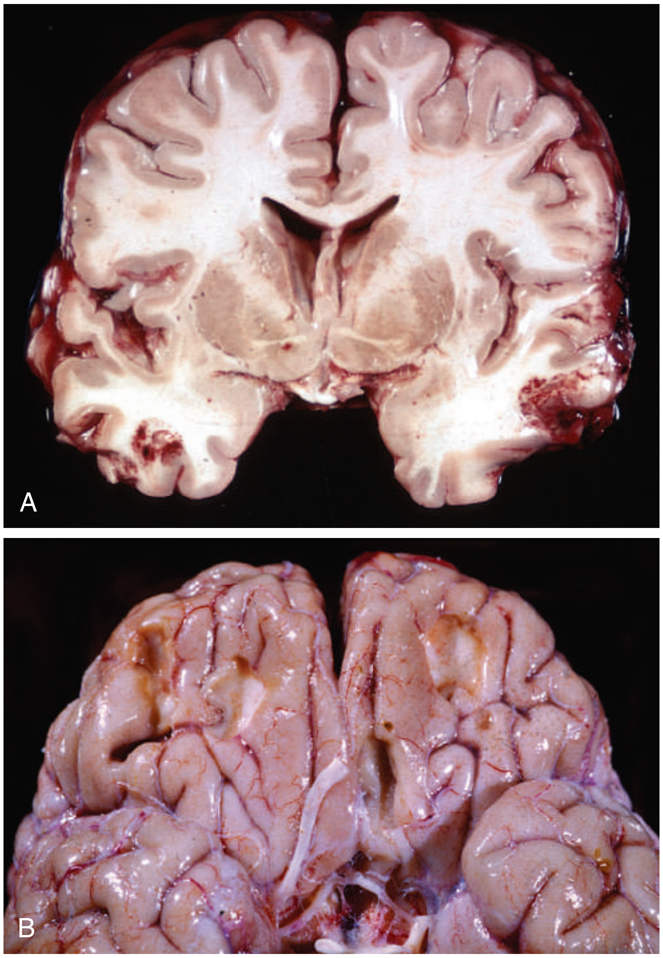

Fig. 23.12 Cerebral trauma. (A) Acute contusions are present in both temporal lobes, with areas of hemorrhage and tissue disruption. (B) Remote contusions, seen as discolored yellow areas, are present on the inferior frontal surface of this brain.

Concussion describes reversible altered brain function, with or without loss of consciousness, from head injury. The characteristic transient neurologic dysfunction includes loss of consciousness, temporary respiratory arrest, and loss of reflexes. Neurologic recovery is the norm, although amnesia for the event persists. The pathogenesis of the sudden disruption of nervous activity is unknown. Repeated episodes of concussion can result in persistent and profound neurologic deficits including cognitive impairment, parkinsonism, and others, and later development of neurodegenerative processes. Initially described in boxers *(dementia pugilistica),* it is now recognized to occur in a wider range of settings, such as in athletes participating in contact sports. This syndrome is termed *chronic traumatic encephalopathy* and is characterized by accumulation of tangles in cerebral cortex and other brain regions (see the "Neurodegenerative Diseases" section later in the chapter).

Traumatic Vascular Injury

CNS trauma often directly disrupts vessel walls, leading to hemorrhage (Table 23.1). Depending on the affected vessel, the hemorrhage may be *epidural, subdural, subarachnoid,* or *intraparenchymal* (Fig. 23.13A), occurring alone or in combination. Subarachnoid and intraparenchymal hemorrhages most often occur at sites of contusions and lacerations.

Epidural Hematoma

Dural vessels—especially the middle meningeal artery—are vulnerable to traumatic injury. In infants, traumatic displacement of the easily deformable skull may tear a vessel, even in the absence of a skull fracture. In children and adults, by contrast, tears involving dural vessels almost always stem from skull fractures. Once a vessel tears, blood accumulates under arterial pressure and dissects the tightly applied dura away from the inner skull surface (see Fig. 23.13B), producing a hematoma that compresses the brain surface. Clinically, patients can be lucid for several hours after the traumatic event before neurologic signs appear. An epidural hematoma may expand rapidly and constitutes a neurosurgical emergency necessitating prompt drainage and repair to prevent death.

Subdural Hematoma

Rapid movement of the brain during trauma can tear the bridging veins that extend from the cerebral hemispheres

Table 23.1 Patterns of Vascular Injury in the Central Nervous System

Location	Etiology	Additional Features
Epidural space	Trauma	Usually associated with a skull fracture (in adults); rapidly evolving neurologic symptoms requiring intervention
Subdural space	Trauma	Level of trauma may be mild; slowly evolving neurologic symptoms, often with a delay from the time of injury
Subarachnoid space	Vascular abnormalities (arteriovenous malformation or aneurysm)	Sudden onset of severe headache, often with rapid neurologic deterioration; secondary injury may emerge due to vasospasm
	Trauma	Typically associated with underlying contusions
Intraparenchymal	Trauma (contusions)	Selective involvement of the crests of gyri where the brain contacts the skull (frontal and temporal tips, orbitofrontal surface)
	Hemorrhagic conversion of an ischemic infarction	Petechial hemorrhages in an area of previously ischemic brain, usually following the cortical ribbon
	Cerebral amyloid angiopathy	"Lobar" hemorrhage, involving cerebral cortex, often with extension into the subarachnoid space
	Hypertension	Centered in the deep white matter, thalamus, basal ganglia, or brain stem; may extend into the ventricular system
	Tumors (primary or metastatic)	Associated with high-grade gliomas or certain metastases (melanoma, choriocarcinoma, renal cell carcinoma)

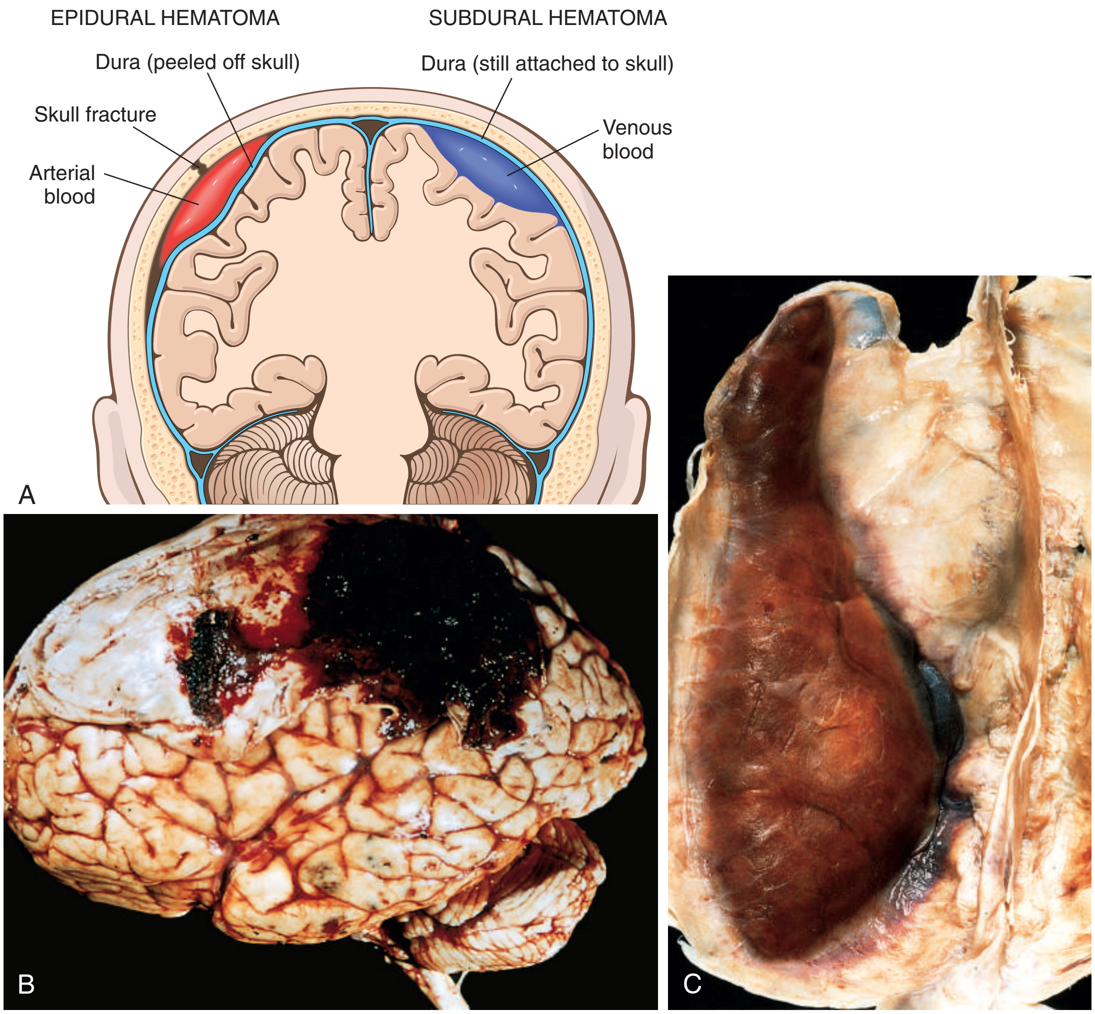

Fig. 23.13 Traumatic intracranial hemorrhages. (A) Epidural hematoma *(left)* in which rupture of a meningeal artery, usually associated with a skull fracture, has led to accumulation of arterial blood between the dura and the skull. In a subdural hematoma *(right),* damage to bridging veins between the brain and the superior sagittal sinus has led to the accumulation of blood between the the two layers of dura. (B) Epidural hematoma covering a portion of the dura. (C) Large organizing subdural hematoma attached to the dura. *(B, Courtesy of the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston, Massachusetts.)*

through the subarachnoid and subdural space to the dural sinuses. Their disruption produces bleeding into the subdural space. Because the inner cell layer of the dura is quite thin and in very close proximity to the arachnoid layer, the blood appears to be between the dura and arachnoid, but in reality it is between the two layers of the dura. In patients with brain atrophy, the bridging veins are stretched out and the brain has additional space within which to move, accounting for the higher rate of subdural hematomas in older adults. Infants also are susceptible to subdural hematomas because their bridging veins are thin walled.

Subdural hematomas typically become manifest within the first 48 hours after injury. They are most common over the lateral aspects of the cerebral hemispheres and may be bilateral. Neurologic signs are attributable to the pressure exerted on the adjacent brain. Symptoms are most often nonlocalizing, taking the form of headache, confusion, and slowly progressive neurologic deterioration.

MORPHOLOGY

Acute subdural hematoma appears as a collection of freshly clotted blood apposed to the contour of the brain surface, without extension into the depths of sulci (see Fig. 23.13C). The underlying brain is flattened, and the subarachnoid space is often clear. Subdural hematomas organize by lysis of the clot (about 1 week), growth of granulation tissue from the dural surface into the hematoma (2 weeks), and fibrosis (1–3 months). Subdural hematomas commonly rebleed, presumably from the thin-walled vessels of the granulation tissue, leading to microscopic findings consistent with hemorrhages of varying ages. Symptomatic subdural hematomas are treated by surgical removal of the blood and associated reactive tissue.

SUMMARY

CENTRAL NERVOUS SYSTEM TRAUMA

- Physical injury to the brain can occur when the inside of the skull comes into forceful contact with the brain.
- In blunt trauma, there may be brain injury both at the original point of contact (coup injury) and on the opposite side of the brain (contrecoup injury) owing to impacts with the skull.
- Rapid displacement of the head and brain can tear axons (diffuse axonal injury), often causing severe, irreversible neurologic deficits.
- Traumatic tearing of blood vessels, depending on the location, leads to epidural, subdural, or intraparenchymal hematoma as well as subarachnoid hemorrhage.

CONGENITAL MALFORMATIONS AND PERINATAL BRAIN INJURY

The incidence of CNS malformations, giving rise to mental retardation, cerebral palsy, or neural tube defects, is estimated at 1% to 2%. Malformations of the brain are more common in the setting of multiple birth defects. Prenatal or perinatal insults may interfere with normal CNS development or cause tissue damage. During gestation, the timing of an injury determines the pattern of malformation, with earlier events typically leading to more severe phenotypes. Mutations affecting genes that regulate the differentiation, maturation, or intercellular communication of neurons or glial cells can cause CNS malformation or dysfunction. Additionally, various chemicals and infectious agents have teratogenic effects.

Some developmental disorders produce profound neuronal dysfunction in the absence of morphologic abnormalities. Genetic underpinnings for various forms of *autism* have emerged recently; many of the implicated genes contribute to the development or maintenance of synaptic connections. *Rett syndrome* is an X-linked dominant disorder associated with mutations in the gene encoding a regulator of epigenetic modifications of chromatin. Development in affected girls initially is normal, but neurologic deficits affecting cognition and movement appear by 1 to 2 years of age.

Malformations

Neural Tube Defects

One of the earliest steps in brain development is the formation of the neural tube, which gives rise to the ventricular system, brain, and spinal cord. **Partial failure or reversal of neural tube closure may lead to several malformations, each characterized by abnormalities involving neural tissue, meninges, and overlying bone or soft tissues**. Collectively, *neural tube defects* are the most frequent type of CNS malformation. Folate deficiency during the first trimester sharply increases risk through uncertain mechanisms and represents an important opportunity for prevention, as administration of folate to women of child-bearing age reduces the incidence of neural tube defects by up to 70%. The combination of imaging studies and maternal screening for elevated α-fetoprotein has increased the early detection of neural tube defects.

Neural tube defects include the following:

- The most common defects involve the posterior end of the neural tube, from which the spinal cord forms. These can range from asymptomatic bony defects *(spina bifida occulta)* to *spina bifida*, a severe malformation consisting of a flat, disorganized segment of spinal cord associated with an overlying meningeal outpouching.
- *Myelomeningocele* is an extension of CNS tissue through a defect in the vertebral column that occurs most commonly in the lumbosacral region (Fig. 23.14). Patients have motor and sensory deficits in the lower extremities and problems with bowel and bladder control. The clinical problems derive from the abnormal spinal cord segment and often are compounded by infections extending from the thin or ulcerated overlying skin.
- *Anencephaly* is a malformation of the anterior end of the neural tube that leads to the absence of the forebrain and the top of the skull. Varying amounts of posterior fossa structures may be present.

Fig. 23.14 Myelomeningocele. Both meninges and spinal cord parenchyma are included in the cystlike structure visible just above the buttocks.

- An *encephalocele* is a diverticulum of malformed CNS tissue extending through a defect in the cranium. It most often involves the occipital region or the posterior fossa. When it occurs anteriorly, brain tissue may extend into the sinuses.

Forebrain Malformations

Microencephaly describes the group of malformations in which the volume of brain is too small; usually it is associated with a small head as well *(microcephaly).* It has a wide range of associations, including chromosome abnormalities, fetal alcohol syndrome, and human immunodeficiency virus (HIV) and Zika virus infection acquired in utero. The unifying feature is decreased generation of neurons destined for the cerebral cortex. During the early stages of brain development, as progenitor cells proliferate in the subependymal ventricular zone, the balance between cells leaving the progenitor population to form the cortex and those remaining in the proliferating pool affects the overall number of neurons and glial cells generated. If too many cells leave the progenitor pool prematurely, there is inadequate generation of mature neurons, leading to a small brain. *Megalencephaly,* excessive brain volume that is always associated with a large head, is far less common and is mostly associated with rare genetic disorders.

Disruption of neuronal migration and differentiation during development can lead to abnormalities of gyration and neocortical architecture, often taking the form of neurons ending up in the wrong location. Mutations in various genes that control migration result in a variety of malformations. A representative example is *holoprosencephaly*, characterized by disruption of normal midline patterning. Mild forms show absence of the olfactory bulbs and related structures *(arrhinencephaly).* In severe forms, the brain is not divided into hemispheres or lobes, and there may be facial midline defects such as cyclopia. The best known genetic causes involve acquired or inherited loss of function mutations in components of the Hedgehog signaling pathway.

Other examples include loss of gyri, which may be complete (lissencephaly) or partial, and increased number of irregularly formed gyri (polymicrogyria).

Posterior Fossa Anomalies

The most common malformations in this region of the brain result in misplacement or absence of portions of the cerebellum.

- *Arnold-Chiari malformation* (Chiari type II malformation) combines a small posterior fossa with a misshapen midline cerebellum and downward extension of the vermis through the foramen magnum; hydrocephalus and a lumbar myelomeningocele typically are also present.
- The far milder *Chiari type I malformation* has low-lying cerebellar tonsils that extend through the foramen magnum. Excess tissue in the foramen magnum results in partial obstruction of CSF flow and compression of the medulla, with symptoms of headache or cranial nerve deficits often manifesting only in adult life. Surgical intervention can alleviate the symptoms.
- *Dandy-Walker malformation* is characterized by an enlarged posterior fossa, absence of the cerebellar vermis, and a large midline cyst.

Perinatal Brain Injury

Brain injury occurring in the perinatal period is an important cause of childhood neurologic disability. *Cerebral palsy* is a term for nonprogressive neurologic motor deficits characterized by spasticity, dystonia, ataxia or athetosis, and paresis attributable to injury occurring during the prenatal and perinatal periods. Signs and symptoms may not be apparent at birth and only declare themselves later, well after the causal event.

The two major types of injury that occur in the perinatal period are hemorrhages and infarcts. These differ from the otherwise similar lesions in adults in terms of their locations and the tissue reactions they engender. In premature infants, there is an increased risk for *intraparenchymal hemorrhage* within the germinal matrix, most often adjacent to the anterior horn of the lateral ventricle. Hemorrhages may extend into the ventricular system and from there to the subarachnoid space, sometimes causing hydrocephalus. Infarcts may occur in the supratentorial periventricular white matter *(periventricular leukomalacia),* especially in premature infants. The residua of these infarcts are chalky yellow plaques consisting of discrete regions of white matter necrosis and dystrophic calcification (Fig. 23.15). When severe enough to involve the gray matter and white matter, large cystic lesions can develop throughout the hemispheres, a condition termed *multicystic encephalopathy.*

Certain infections, which may be acquired transplacentally or during birth, have a propensity to cause destructive

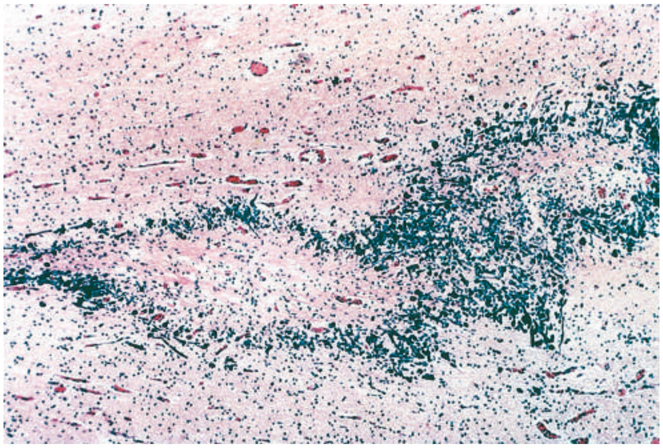

Fig. 23.15 Perinatal brain injury. This specimen from a patient with periventricular leukomalacia contains a central focus of white matter necrosis with a peripheral rim of mineralized axonal processes.

brain lesions. Agents in this group (commonly referred to as *TORCH*) include toxoplasmosis and CMV, which can both result in parenchymal calcifications along with the tissue injury; these are discussed in more detail later.

SUMMARY

CONGENITAL MALFORMATIONS AND PERINATAL BRAIN INJURY

- Malformations of the brain can occur because of genetic factors or external insults.
- The developmental timing and position of the injury determine its pattern and characteristics.
- Various malformations stem from failure of neural tube closure, improper formation of neural structures, and altered neuronal migration.
- Perinatal brain injury mostly takes one of two forms: (1) hemorrhage, often in the region of the germinal matrix with the risk for extension into the ventricular system; and (2) ischemic infarcts, leading to periventricular leukomalacia.
- Certain infections may affect the brain during development with subsequent tissue destruction and neurologic consequences.

INFECTIONS OF THE NERVOUS SYSTEM

The brain and its coverings can be sites of infection. Some infectious agents have a relative or absolute predilection for the nervous system (e.g., rabies), while others affect many other organs as well as the brain (e.g., *Staphylococcus aureus*). Damage to nervous tissue may be the consequence of direct injury of neurons or glial cells by the infectious agent or microbial toxins, or may be a consequence of the host immune response.

Infectious agents may reach the nervous system through several routes:

- *Hematogenous spread* by way of the arterial blood supply is the most common means of entry. There can also be retrograde venous spread through the anastomoses between the veins of the face and the venous sinuses of the skull.
- *Direct implantation* of microorganisms is almost invariably due to open or penetrating trauma; rare cases can be iatrogenic, as when microbes are introduced with a lumbar puncture needle or into a surgical field.
- *Local extension* can occur with infections of the skull or spine. Sources include air sinuses, most often the mastoid or frontal; infected teeth; cranial or spinal osteomyelitis; and congenital malformations, such as meningomyelocele.
- *Peripheral nerves* also may serve as paths of entry for a few pathogens—in particular, viruses such as rabies and herpes zoster.

Basic mechanisms of injury associated with infectious agents are discussed in Chapter 9; in the following sections we discuss infections that are specific to the central nervous system (Table 23.2).

Epidural and Subdural Infections

The epidural and subdural spaces can be involved by bacterial or fungal infections, usually as a consequence of direct local spread. *Epidural abscesses* arise from an adjacent focus of infection, such as sinusitis or osteomyelitis. When abscesses occur in the spinal epidural space, they may cause spinal cord compression and constitute a neurosurgical emergency. Infections of the skull or air sinuses may also spread to the subdural space, producing *subdural empyema.* The underlying arachnoid and subarachnoid spaces usually are unaffected, but a large subdural empyema may produce a mass effect. In addition, thrombophlebitis may develop in the bridging veins that cross the subdural space, resulting in venous occlusion and infarction of the brain. Most patients are febrile, with headache and neck stiffness, and if untreated may develop focal neurologic signs referable to the site of the infection, lethargy, and coma. With treatment, including surgical drainage, resolution of the empyema occurs from the dural side; if resolution is complete, a thickened dura may be the only residual finding. With prompt treatment, complete recovery is usual.

Meningitis

Meningitis* is an inflammatory process involving the leptomeninges within the subarachnoid space; if the infection spreads into the underlying brain, it is termed *meningoencephalitis. These terms are also used in non-infectious settings such as *chemical meningitis*, a response to a nonbacterial irritant such as debris from a ruptured epidermoid cyst, and *carcinomatous meningitis,* the spread of metastatic cancer cells to the subarachnoid space.

Infectious meningitis can be broadly divided into *acute pyogenic* (usually bacterial), *aseptic* (usually viral), and *chronic* (usually tuberculous, spirochetal, or fungal) subtypes. Examination of the CSF is often useful in distinguishing among the various causes of meningitis.

Table 23.2 Common Central Nervous System Infections

Type of Infection	Clinical Syndrome	Common Causative Organisms
Bacterial Infections		
Meningitis	Acute pyogenic meningitis	*Escherichia coli* or group B streptococci (infants) *Neisseria meningitidis* (young adults) *Streptococcus. pneumoniae* or *Listeria monocytogenes* (older adults)
	Chronic meningitis	*Mycobacterium tuberculosis*
Localized infections	Abscess	Streptococci and staphylococci
	Empyema	Polymicrobial (staphylococci, anaerobic gram-negative)
Viral Infections		
Meningitis	Acute aseptic meningitis	Enteroviruses Measles (subacute sclerosing panencephalitis) Influenza species Lymphocytic choriomeningitis virus
Encephalitis	Encephalitic syndromes	Herpes simplex (HSV-1, HSV-2) Cytomegalovirus Human immunodeficiency virus JC polyomavirus (progressive multifocal leukoencephalopathy)
	Arthropod-borne encephalitis	West Nile virus, other arboviruses
Brain stem and spinal cord syndromes	Rhombencephalitis Spinal poliomyelitis	Rabies Polio West Nile virus
Rickettsia, Spirochetes, and Fungi		
Meningitic syndromes	Rocky Mountain spotted fever	*Rickettsia rickettsii*
	Neurosyphilis	*Treponema pallidum*
	Lyme disease (neuroborreliosis)	*Borrelia burgdorferi*
	Fungal meningitis	*Cryptococcus neoformans* *Candida albicans*
Protozoa and Metazoa		
Meningitic syndromes	Cerebral malaria Amebic encephalitis	*Plasmodium falciparum* *Naegleria species*
Localized infections	Toxoplasmosis Cysticercosis	*Toxoplasma gondii* *Taenia solium*

Acute Pyogenic Meningitis (Bacterial Meningitis)

The most likely causes of bacterial meningitis vary with patient age. In neonates, common organisms are *Escherichia coli* and group B streptococci. In adolescents and young adults, *Neisseria meningitidis* is the most common pathogen; in older adults, *Streptococcus pneumoniae* and *Listeria monocytogenes* are more common. Across ages, patients typically show systemic signs of infection along with meningeal irritation and neurologic impairment, including headache, photophobia, irritability, clouding of consciousness, and neck stiffness. Lumbar puncture reveals an increased pressure; examination of the CSF shows abundant neutrophils, elevated protein, and reduced glucose. Untreated pyogenic meningitis is often fatal, but with prompt diagnosis and administration of antibiotics, most patients can be saved.

MORPHOLOGY

In acute meningitis, an exudate is evident within the leptomeninges on the surface of the brain (Fig. 23.16A). The meningeal vessels are engorged and prominent, and tracts of pus may extend along blood vessels. On microscopic examination, neutrophils may fill the entire subarachnoid space or, in less severe cases, may be confined to regions adjacent to leptomeningeal blood vessels. In untreated meningitis, Gram stain reveals varying numbers of the causative organism. Severe involvement of leptomeningeal veins (phlebitis) may lead to venous occlusion and hemorrhagic infarction of the underlying brain. When the meningitis is fulminant, the organisms and the associated inflammatory cells may spread into the substance of the brain (focal cerebritis), sometimes leading to the formation of abscesses, discussed later (see Fig. 23.16B). Extension to the ventricles (ventriculitis) also may occur. If treated early and effectively, resolved meningitis may leave little or no residuum.

Aseptic Meningitis (Viral Meningitis)

Aseptic meningitis is a clinical term for acute illness with meningeal signs and symptoms that is believed to be of viral origin. The clinical course is less fulminant than in pyogenic meningitis and is typically self-limiting. In contrast to pyogenic meningitis, examination of the CSF often shows lymphocytosis, moderate protein elevation, and a normal glucose level, but bacteria cannot be cultured. While an underlying viral agent is suspected, it is often difficult to identify the responsible virus by culture and serologic methods; application of nucleic acid sequencing has the potential to change our understanding of these cases. There are no distinctive macroscopic findings except for brain swelling, which may be seen in only some instances. On microscopic examination, there is either no recognizable abnormality or a mild to moderate leptomeningeal lymphocytic infiltrate.

Chronic Meningitis

Several pathogens, including mycobacteria, some spirochetes, and fungi, cause a chronic meningitis; infections with these organisms also may involve the brain parenchyma.

Tuberculous Meningitis

Tuberculous meningitis usually manifests with generalized signs and symptoms of headache, malaise, mental confusion, and vomiting. There is only a moderate increase in CSF cellularity, with mononuclear cells or a mixture of polymorphonuclear and mononuclear cells; the protein level is elevated, often strikingly so, and the glucose content typically is moderately reduced or normal. Infection with *Mycobacterium tuberculosis* also may result in a well-circumscribed intraparenchymal mass *(tuberculoma),* which may be associated with meningitis. Chronic tuberculous

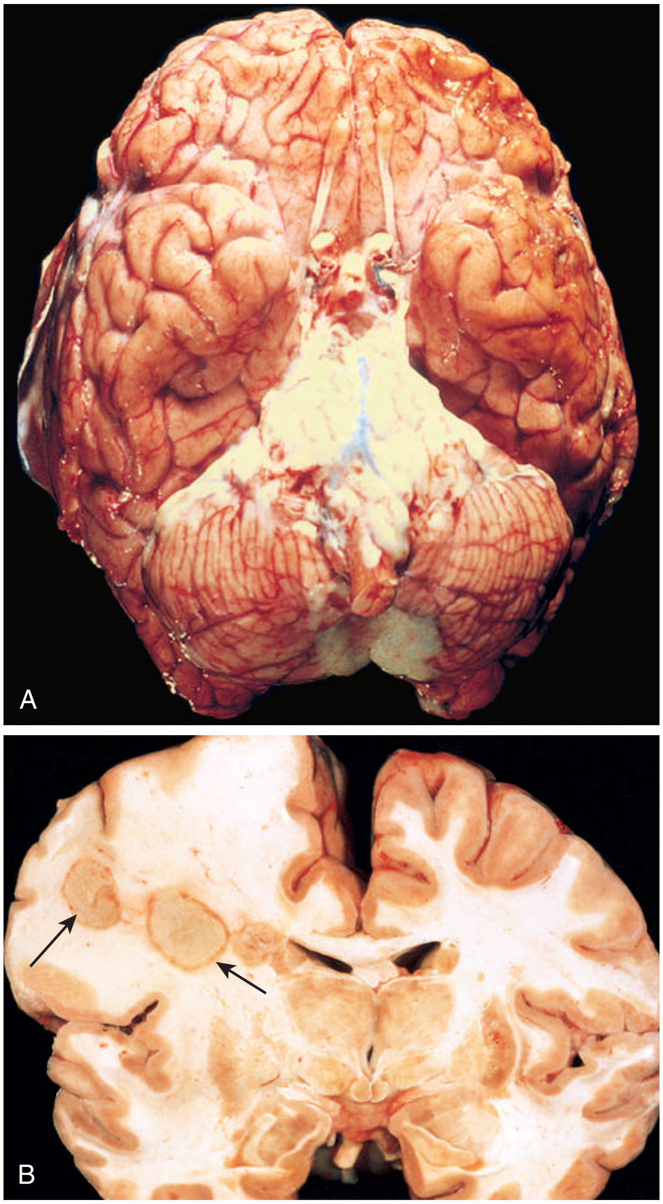

Fig. 23.16 Bacterial infections. (A) Pyogenic meningitis. A thick layer of suppurative exudate covers the brain stem and cerebellum and thickens the leptomeninges. (B) Cerebral abscesses in the frontal lobe white matter (arrows). *(A, From Golden JA, Louis DN: Images in clinical medicine: acute bacterial meningitis.* N Engl J Med *333:364, 1994. Copyright © 1994 Massachusetts Medical Society. All rights reserved.)*

meningitis leads to arachnoid fibrosis and hydrocephalus from interference with resorption of CSF.

Spirochetal Infections

Neurosyphilis, a tertiary stage of syphilis, occurs in about 10% of individuals with untreated *Treponema pallidum* infection. Infection with HIV increases the risk for developing neurosyphilis, and the disease is often more aggressive in this setting. There are several patterns of CNS involvement by syphilis, which may be present alone or in combination.

- *Meningovascular neurosyphilis* is a chronic meningitis, usually involving the base of the brain, often with an obliterative endarteritis rich in plasma cells and lymphocytes.
- *Paretic neurosyphilis* stems from parenchymal involvement by spirochetes and is associated with neuronal loss and marked proliferation of microglial cells. Clinically, this form of the disease causes an insidious progressive loss of mental and physical functions, mood alterations (including delusions of grandeur), and eventually severe dementia.
- *Tabes dorsalis* results from damage to the sensory nerves in the dorsal roots. Consequences include impaired joint position sense and ataxia; loss of pain sensation, leading to skin and joint damage *(Charcot joints);* other sensory disturbances, particularly characteristic "lightning pains"; and the absence of deep tendon reflexes.

Neuroborreliosis refers to involvement of the nervous system by the spirochete *Borrelia burgdorferi,* the causative agent of Lyme disease. Neurologic signs and symptoms are highly variable and include aseptic meningitis, facial nerve palsies, mild encephalopathy, and polyneuropathies.

Fungal Meningitis

Fungal infection of the nervous system can give rise to chronic meningitis and, as with other pathogens, this can be associated at times with parenchymal infection. Immunosuppression increases the risk for these diseases, but it is not a requirement for infection to occur. Several fungal pathogens cause CNS disease:

- *Cryptococcus neoformans* can cause both meningitis and meningoencephalitis, often in the setting of immunosuppression. It may be fulminant and fatal in as little as 2 weeks or may be indolent, evolving over months or years. The CSF may have few cells but elevated protein, and the mucoid encapsulated yeasts can be visualized on India ink preparations. Extension into the brain follows vessels in the Virchow-Robin spaces. As organisms proliferate, these spaces expand, giving rise to a "soap bubble"–like appearance (Fig. 23.17).
- *Histoplasma capsulatum* commonly involves the nervous system in the setting of disseminated infection. There is an increased risk for disease in the setting of HIV infection. Histoplasmosis typically causes a basilar meningitis, with elevated CSF protein, mildly decreased glucose, and mild lymphocytic pleocytosis. Parenchymal lesions can occur, mostly from tracking of organisms along Virchow-Robin spaces.
- *Coccidioides immitis,* a fungus endemic to desert regions of the American Southwest, most commonly causes meningitis in the setting of disseminated infection. Diagnosis can be made by examining the CSF for specific antibody. Without treatment, coccidioidal meningitis has a high fatality.

Parenchymal Infections

The entire gamut of infectious pathogens (viruses to parasites) can infect the brain, often in characteristic patterns. In general, viral infections are diffuse, bacterial infections (when not associated with meningitis) are localized, while

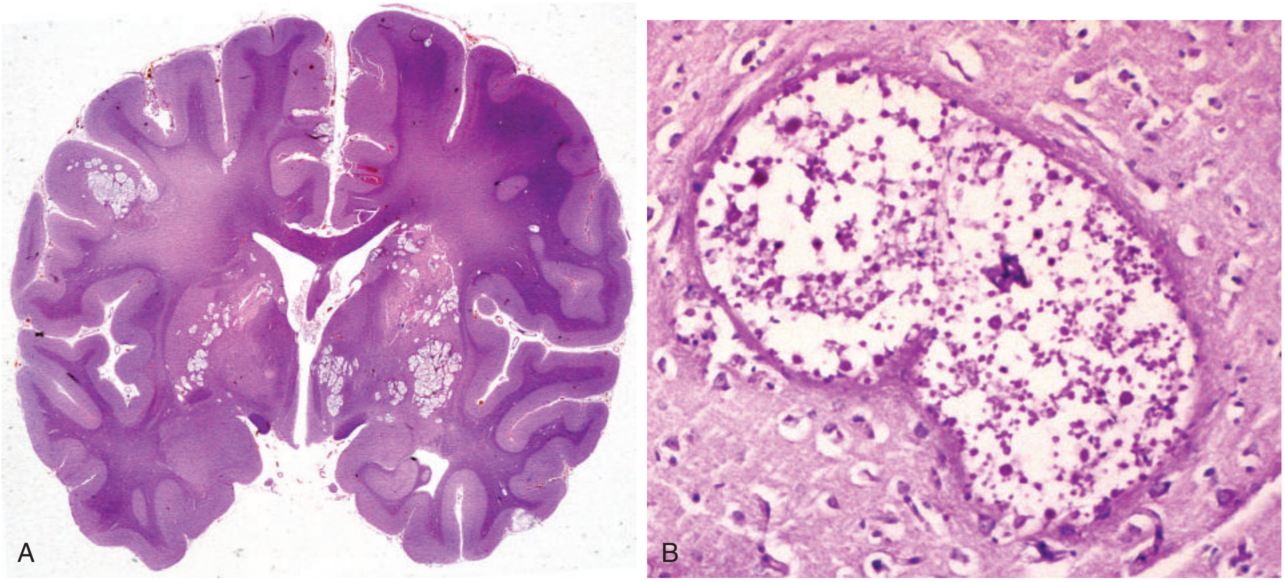

Fig. 23.17 Cryptococcal infection. (A) Whole-brain section showing the numerous areas of tissue destruction associated with the spread of organisms in the perivascular spaces. (B) At higher magnification, it is possible to see the cryptococci in the lesions.

other organisms produce mixed patterns. In immunosuppressed hosts, more widespread involvement with any agent is typical.

Brain Abscesses

Brain abscesses are most often caused by bacterial infections. These can arise by direct implantation of organisms, local extension from adjacent foci (mastoiditis, paranasal sinusitis), or hematogenous spread (usually from a primary site in the heart, lungs, or distal bones, or after tooth extraction). Predisposing conditions include *acute bacterial endocarditis*, from which septic emboli are released that may produce multiple abscesses; *cyanotic congenital heart disease*, associated with a right-to-left shunt and loss of pulmonary filtration of organisms; and *chronic pulmonary infections,* as in bronchiectasis, which provide a source of microbes that spread hematogenously.

Abscesses are discrete destructive lesions with central liquefactive necrosis surrounded by a rim of vascularized granulation and fibrous tissue (see Fig. 23.16B). Outside the fibrous capsule is a zone of reactive gliosis. Patients almost invariably present with progressive focal deficits as well as general signs related to increased intracranial pressure. While CSF white blood cell count and protein may be elevated, lumbar puncture has little role in the diagnosis of brain abscess since organisms are more reliably cultured by draining the abscess directly. In addition, if there is significant mass effect from the abscess, the decrease in lumbar CSF pressure following lumbar puncture can result in downward herniation of cerebral contents and neurologic deterioration. A systemic or local source of infection may or may not be apparent. The increased intracranial pressure may cause fatal brain herniation, and abscess rupture can lead to ventriculitis, meningitis, and venous sinus thrombosis. Surgery and antibiotics reduce the otherwise high mortality rate, with earlier intervention leading to better outcomes.

Viral Encephalitis

Viral encephalitis is a parenchymal infection of the brain that is almost invariably associated with meningeal inflammation (*meningoencephalitis*). While different viruses show varying patterns of injury, the most characteristic histologic features are perivascular and parenchymal mononuclear cell infiltrates, microglial nodules, and neuronophagia (Fig. 23.18A–B). Certain viruses also form characteristic inclusion bodies.

The nervous system is particularly susceptible to certain viruses such as rabies virus and poliovirus. Some viruses infect specific CNS cell types, while others preferentially involve particular brain regions (such as the medial temporal lobes, or the limbic system) that lie along the viral route of entry. Intrauterine viral infection following transplacental spread of rubella and CMV may cause destructive lesions, and Zika virus causes developmental abnormalities of the brain. In addition to direct infection of the nervous system, the CNS also can be injured by immune mechanisms after systemic viral infections.

Arboviruses

Arboviruses (arthropod-borne viruses) are an important cause of epidemic encephalitis, especially in tropical regions of the world, and are capable of causing serious morbidity and high mortality. Among the more commonly encountered types are Eastern and Western equine encephalitis and West Nile virus infection. Patients develop generalized neurologic symptoms, such as seizures, confusion, delirium, and stupor or coma, as well as focal signs, such as reflex asymmetry and ocular palsies. The CSF usually is colorless but with a slightly elevated pressure and an early neutrophilic pleocytosis that rapidly converts to a lymphocytosis; the protein concentration is elevated, but the glucose is normal. Thus, CSF examination helps to distinguish viral from bacterial infections of the CNS.

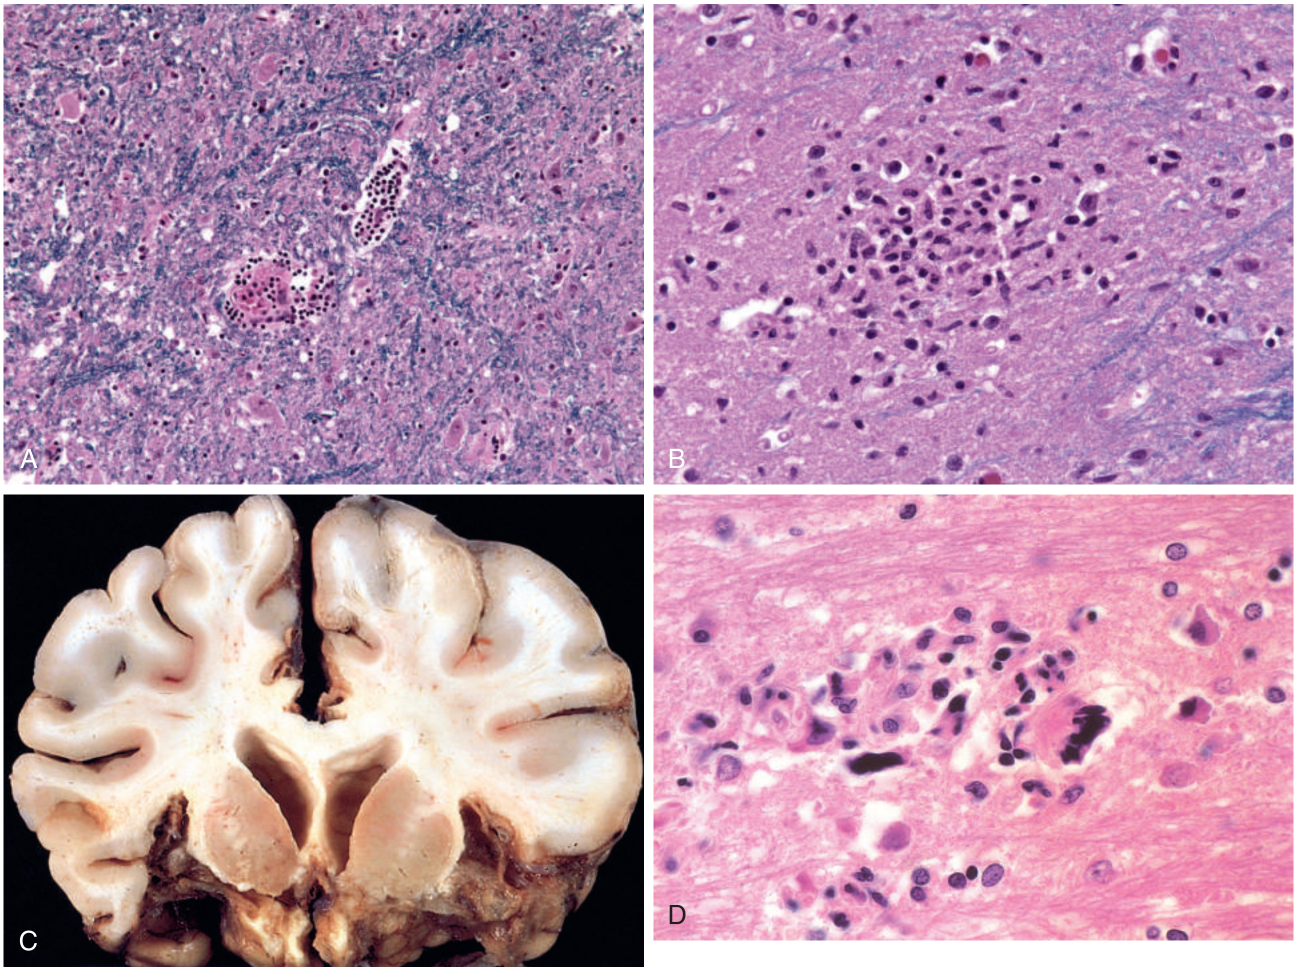

Fig. 23.18 Viral infections. (A and B) Characteristic findings in many forms of viral meningitis include perivascular cuffing of lymphocytes (A) and microglial nodules (B). (C) Herpes encephalitis showing extensive destruction of inferior frontal and anterior temporal lobes. (D) Human immunodeficiency virus (HIV) encephalitis. Note the accumulation of microglia forming a microglial nodule and multinucleate giant cell. *(C, Courtesy of Dr. T.W. Smith, University of Massachusetts Medical School, Worcester, Massachusetts.)*

MORPHOLOGY

Arbovirus encephalitides produce a similar histopathologic picture. Characteristically, there is a perivascular lymphocytic meningoencephalitis (sometimes with neutrophils) (see Fig. 23.18A). Multifocal gray matter and white matter necrosis is seen, often associated with neuronophagia, the phagocytosis of neuronal debris, as well as localized collections of microglia termed **microglial nodules** (see Fig. 23.18B). In severe cases, there may be a necrotizing vasculitis with associated focal hemorrhages.

Herpesviruses

HSV-1 encephalitis may occur in any age group but is most common in children and young adults. It typically manifests with alterations in mood, memory, and behavior, reflecting involvement of the frontal and temporal lobes. Recurrent HSV-1 encephalitis is sometimes associated with inherited mutations that interfere with Toll-like receptor signaling (specifically that of TLR-3), which has an important role in anti-viral defense.

MORPHOLOGY

Herpes encephalitis starts in and most severely involves the inferior and medial regions of the temporal lobes and the orbital gyri of the frontal lobes (see Fig. 23.18C). The infection is necrotizing and often hemorrhagic in severely affected regions. Perivascular inflammatory infiltrates usually are present, and large eosinophilic intranuclear viral inclusions (Cowdry type A bodies) can be found in both neurons and glial cells.

HSV-2 also affects the nervous system, usually in the form of meningitis in adults. Disseminated severe encephalitis occurs in many neonates born by vaginal delivery to women with active primary HSV genital infections.

Varicella-zoster virus (VZV) causes chickenpox during primary infection, usually without any evidence of neurologic involvement. The virus establishes latent infection in neurons of dorsal root ganglia. Reactivation in adults manifests as a painful, vesicular skin eruption in the distribution of one or a few dermatomes *(shingles)*. This usually is a self-limited process, but there may be a persistent pain syndrome in the affected region *(postherpetic neuralgia)*.

VZV also may cause a granulomatous arteritis that can lead to tissue infarcts. In immunosuppressed patients, acute herpes zoster encephalitis can occur. Inclusion bodies can be found in glial cells and neurons.

Cytomegalovirus

CMV infects the nervous system in fetuses and immunosuppressed individuals. All cells within the CNS (neurons, glial cells, ependyma, and endothelium) are susceptible to infection. Intrauterine infection causes periventricular necrosis, followed later by microcephaly with periventricular calcification. When adults are infected, CMV produces a subacute encephalitis, which is also often most severe in the periventricular region. Lesions can be hemorrhagic and contain typical viral inclusion–bearing cells.

Poliovirus

Poliovirus is an enterovirus that most often causes a subclinical or mild gastroenteritis; in a small fraction of cases, it secondarily invades the nervous system and damages motor neurons in the spinal cord and brain stem *(paralytic poliomyelitis)*. The loss of motor neurons results in a flaccid paralysis with muscle wasting and hyporeflexia in the corresponding region of the body. In the acute disease, death can occur from paralysis of respiratory muscles. Long after the infection has resolved, typically 25 to 35 years after the initial illness, a poorly understood *post-polio syndrome* of progressive weakness associated with decreased muscle bulk and pain may appear. The re-emergent weakness has the same distribution as the prior polio infection.

Rabies Virus

Rabies is a fatal encephalitic infection transmitted to humans from rabid animals, usually by a bite. Various mammals are natural reservoirs. Exposure to some bat species, even without evidence of a bite, is also a risk factor. The virus enters the CNS by ascending along the peripheral nerves from the wound site, so the incubation period (usually a few months) depends on the distance between the wound and the brain. The disease manifests initially with nonspecific symptoms of malaise, headache, and fever. As the infection advances, the patient shows extraordinary CNS excitability; the slightest touch is painful, with violent motor responses progressing to convulsions. Contracture of the pharyngeal musculature may create an aversion to swallowing even water *(hydrophobia)*. Periods of mania and stupor progress to coma and eventually death, typically from respiratory failure.

Human Immunodeficiency Virus

In the first 15 years or so after recognition of AIDS, neuropathologic changes were demonstrated at postmortem examination in as many as 80% to 90% of cases, owing to direct effects of the virus on the nervous system *(HIV encephalitis)*, along with opportunistic infections and primary CNS lymphoma. Introduction of highly active antiretroviral therapy (HAART) has decreased the frequency of these secondary effects of HIV infection. However, cognitive dysfunction ranging from mild to full-blown dementia that is lumped under the umbrella term *HIV-associated neurocognitive disorder (HAND)* continues to be a source of morbidity. This syndrome is believed to stem from HIV infection of microglial cells in the brain and activation of innate immune responses. Neuronal injury likely stems from a combination of cytokine-induced inflammation and toxic effects of HIV-derived proteins.

Aseptic meningitis occurs within 1 to 2 weeks of onset of primary HIV infection in about 10% of patients; antibodies to HIV can be demonstrated, and the virus can be isolated from the CSF. The few neuropathologic studies of the early and acute phases of symptomatic or asymptomatic HIV invasion of the nervous system have shown mild lymphocytic meningitis, perivascular inflammation, and some myelin loss in the hemispheres.

When effective anti-HIV therapy is begun in the setting of established infection, there is a risk for neurologic involvement associated with the *immune reconstitution inflammatory syndrome (IRIS)*. Neurologic manifestations include rapidly developing cognitive impairment and cerebral edema. The pathogenesis of IRIS is unclear but it is thought to be due to the activation of a previously suppressed inflammatory response brought about by effective treatment of HIV infection. IRIS is often associated with the presence of a mycobacterial, fungal or viral opportunistic CNS infection, although it can also occur in the absence of any other inciting disease.

MORPHOLOGY

HIV encephalitis is a chronic inflammatory process with widely distributed **microglial nodules,** sometimes with associated foci of tissue necrosis and reactive gliosis (see Fig. 23.18D). The microglial nodules also are found in the vicinity of small blood vessels, which show abnormally prominent endothelial cells and perivascular foamy or pigment-laden macrophages. These changes are especially prominent in the subcortical white matter, diencephalon, and brain stem. An important component of the microglial nodule are macrophage-derived **multinucleate cells.** In some cases, there also is a disorder of white matter characterized by multifocal or diffuse areas of myelin pallor, axonal swellings, and gliosis. HIV is present in CD4+ mononuclear and multinucleate macrophages and microglia.

Unlike HIV encephalitis, the brain lesions of IRIS may be associated with a CD8+ T cell infiltrate, both around blood vessels and diffusely in the parenchyma, in the absence of significant HIV burden or multinucleated cells.

Polyomavirus and Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is caused by JC virus, a polyomavirus, which preferentially infects oligodendrocytes, resulting in demyelination as these cells are injured and then die. Most people show serologic evidence of exposure to JC virus during childhood, and it is believed that PML results from virus reactivation, as the disease is restricted to immunosuppressed individuals. Patients develop focal and relentlessly progressive neurologic signs and symptoms, and imaging studies show extensive, often multifocal lesions in the hemispheric or cerebellar white matter.

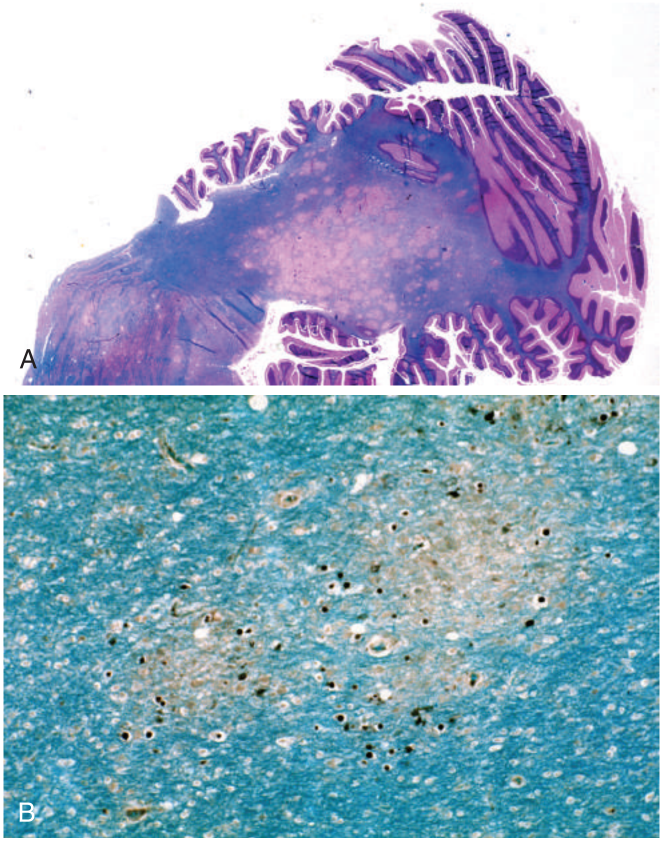

Fig. 23.19 Progressive multifocal leukoencephalopathy. (A) Section stained for myelin showing irregular, poorly defined areas of demyelination, which become confluent in places. (B) Enlarged oligodendrocyte nuclei stained for viral antigens surround an area of early myelin loss.

MORPHOLOGY

The lesions are patchy, irregular, ill-defined areas of white matter destruction that enlarge as the disease progresses (Fig. 23.19). Each lesion is an area of demyelination, in the center of which are scattered lipid-laden macrophages and a reduced number of axons. At the edges of the lesion are greatly enlarged oligodendrocyte nuclei whose chromatin is replaced by glassy-appearing amphophilic viral inclusions. The virus also infects astrocytes, leading to bizarre giant forms with irregular, hyperchromatic, sometimes multiple nuclei that can be mistaken for a tumor.

Fungal Encephalitis

Fungal infections usually produce parenchymal granulomas or abscesses, often associated with meningitis. The most common fungal infections have the following distinctive patterns:

- *Candida albicans* usually produces multiple microabscesses, with or without granuloma formation.
- *Mucormycosis,* caused by several fungi belonging to the order *Mucorales,* typically presents as an infection of the nasal cavity or sinuses in a diabetic patient with ketoacidosis. It may spread to the brain through vascular invasion or by direct extension through the cribriform plate. The proclivity of Mucor to invade the brain directly sets it apart from other fungi, which reach the brain by hematogenous dissemination from distant sites.
- *Aspergillus fumigatus* tends to cause a distinctive pattern of widespread septic hemorrhagic infarctions because of its marked predilection for blood vessel wall invasion with subsequent thrombosis.

Other Meningoencephalitides

While a wide range of other organisms can infect the nervous system and its covering, only three relatively common entities are considered here.

Cerebral Toxoplasmosis

Cerebral infection with the protozoan *Toxoplasma gondii* can occur in immunosuppressed adults or in newborns who acquire the organism transplacentally from a mother with an active infection. The consequences include the triad of *chorioretinitis, hydrocephalus, and intracranial calcifications*. In adults, the clinical symptoms are subacute, evolving over weeks, and may be both focal and diffuse. Due to inflammation and breakdown of the blood-brain barrier at sites of infection, imaging studies often show edema associated with ring-enhancing lesions.

MORPHOLOGY

When the infection is acquired in immunosuppressed adults, the brain shows abscesses, frequently multiple, most often involving the cerebral cortex (near the gray-white junction) and deep gray nuclei. Acute lesions consist of central foci of necrosis surrounded by acute and chronic inflammation, macrophage infiltration, and vascular proliferation. Both free tachyzoites and encysted bradyzoites may be found at the periphery of the necrotic foci (Fig. 23.20).

Cysticercosis

Cysticercosis is the consequence of an end-stage infection by the tapeworm *Tenia solium.* If ingested larval organisms leave the lumen of the gastrointestinal tract, where they would otherwise develop into mature tapeworms, they encyst. Cysts can be found throughout the body and are common within the brain and subarachnoid space. Cysticercosis typically manifests as a mass lesion and can cause seizures. Symptoms can intensify when the encysted organism dies, as occurs after therapy.

The organism is found within a cyst with a smooth lining. The body wall and hooklets from mouth parts are most commonly recognized. Death of the encysted organism may produce an intense inflammatory reaction in the surrounding brain, often including eosinophils, and marked gliosis.

Amebiasis

Amebic meningoencephalitis manifests with different clinical syndromes, depending on the responsible pathogen. *Naegleria fowleri,* associated with swimming in stagnant warm fresh water ponds, causes a rapidly fatal necrotizing encephalitis. By contrast, various species of *Acanthamoeba* cause a chronic granulomatous meningoencephalitis.

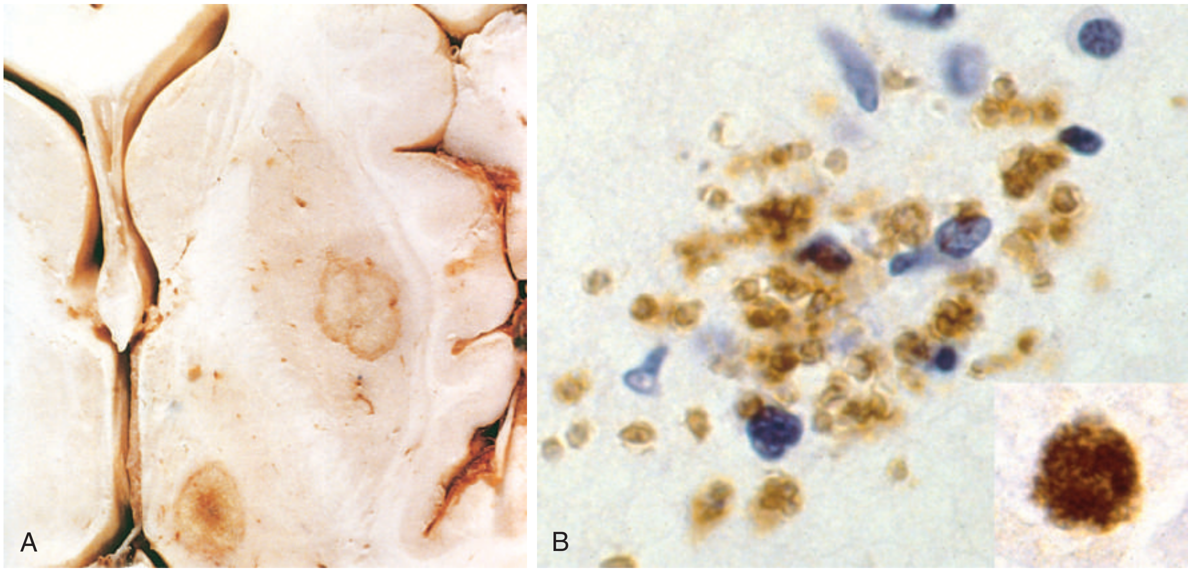

Fig. 23.20 Toxoplasma infection. (A) Abscesses are present in the putamen and thalamus. (B) Free tachyzoites are demonstrated by immunohistochemical staining. *Inset,* Bradyzoites are present as a pseudocyst, again highlighted by immunohistochemical staining.

Prion Diseases

Prion diseases are a group of infectious diseases in which the causative agent is an abnormal form of a cellular protein. These include sporadic, familial, iatrogenic, and variant forms of Creutzfeldt-Jakob disease (CJD), as well as animal diseases such as scrapie in sheep and bovine spongiform encephalopathy in cattle ("mad cow disease"). The causative protein, termed *prion protein (PrP),* may undergo a conformational change from its normal shape (PrP^c) to an abnormal conformation called *PrP^{sc}* (*sc* for *scrapie*). PrP normally is rich in α-helices, but PrP^{sc} has a high content of β-sheets, a characteristic that makes it resistant to proteolysis (hence an alternative term for the pathogenic form, *PrP^{res}*—i.e., protease-resistant). More important, when PrP^{sc} physically interacts with PrP molecules, it induces them to adopt the PrP^{sc} conformation (Fig. 23.21), a property that accounts for the "infectious" nature of PrP^{sc}. Over time, this self-amplifying process leads to the accumulation of a high burden of pathogenic PrP^{sc} molecules in the brain. Certain mutations in the gene encoding PrP^c *(PRNP)* accelerate the rate of spontaneous conformational change; these variants are associated with early-onset familial forms of prion disease (familial Creutzfeldt-Jakob disease [fCJD]). PrP^c also may change its conformation spontaneously (but at an extremely low rate), accounting for sporadic cases of prion disease (sporadic Creutzfeldt-Jakob disease [sCJD]). Accumulation of PrP^{sc} in neural tissue seems to be the cause of cell injury, but the mechanisms underlying the cytopathic changes and eventual neuronal death are still unknown.

Creutzfeldt-Jakob Disease (CJD)

CJD is a rapidly progressive dementing illness, with a typical duration from first onset of subtle changes in memory and behavior to death in only 7 months. It is sporadic in approximately 85% of cases and has a worldwide annual incidence of about 1 per million. While commonly

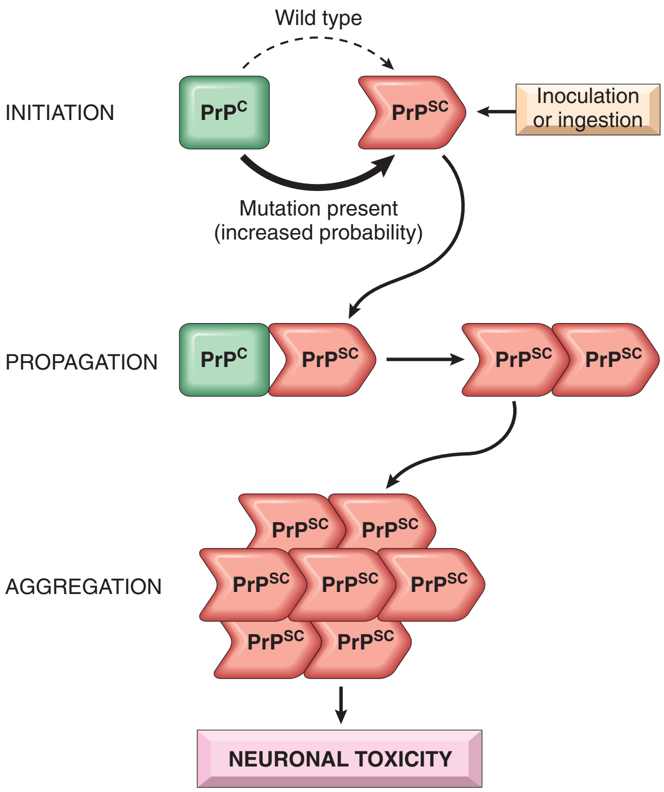

Fig. 23.21 Pathogenesis of prion disease. α-Helical PrP^c may spontaneously shift to the β-sheet PrP^{sc} conformation, an event that occurs at a much higher rate in familial disease associated with germ line PrP mutations. PrP^{sc} may also be from exogenous sources, such as contaminated food, medical instrumentation, or medicines. Once present, PrP^{sc} converts additional molecules of PrP^c into PrP^{sc} through physical interaction, eventually leading to the formation of pathogenic PrP^{sc} aggregates.

affecting individuals older than 70 years of age, familial forms caused by mutations in *PRNP* may present in younger individuals. In keeping with the infectious nature of PrP^{sc}, there are well-established cases of iatrogenic transmission by contaminated deep implantation electrodes and human growth hormone preparations.

MORPHOLOGY

The progression to death in CJD usually is so rapid that there is little, if any, macroscopic evidence of brain atrophy. On microscopic examination, the pathognomonic finding is a **spongiform transformation of the cerebral cortex and deep gray matter structures** (caudate, putamen); this multifocal process results in the uneven formation of small, apparently empty, microscopic vacuoles of varying sizes within the neuropil (the eosinophilic regions in grey matter that contain dendrites, axons, and synapses) and sometimes in the perikaryon of neurons (Fig. 23.22A). In advanced cases, there is severe neuronal loss, reactive gliosis, and sometimes expansion of the vacuolated areas into cystlike spaces ("status spongiosus"). No inflammatory infiltrate is present. Immunohistochemical staining demonstrates the presence of proteinase K–resistant PrP^{sc} in tissue, while western blotting of tissue extracts after partial protease digestion allows detection of diagnostic PrP^{sc}.

Variant Creutzfeldt-Jakob Disease

Starting in 1995, cases of a CJD-like illness appeared in the United Kingdom. The neuropathologic findings and molecular features of these new cases were similar to those of CJD, suggesting a close relationship between the two illnesses, yet this new disorder differed from typical CJD in several important respects: the disease affected young adults; behavioral disorders figured prominently in early disease stages; and the neurologic syndrome progressed somewhat more slowly than typical CJD. Multiple lines of evidence indicate that this new disease, termed *variant Creutzfeldt-Jakob disease (vCJD)* is a consequence of exposure to the prion disease of cattle, called *bovine spongiform encephalopathy.* Also, there is now documentation of transmission by blood transfusion. This variant form has a similar pathologic appearance to that in other types of CJD, with spongiform change and absence of inflammation. In vCJD, however, there are abundant cortical amyloid plaques, surrounded by the spongiform change (see Fig. 23.22B).

SUMMARY

INFECTIONS OF THE NERVOUS SYSTEM

- Pathogens from viruses through parasites can infect the brain; in addition, prion disease is a protein-induced transmissible disease that is unique to the nervous system.
- Different pathogens use distinct routes to reach the brain, and they cause different patterns of disease.
- Bacterial infections may cause meningitis, cerebral abscesses, or a chronic meningoencephalitis.
- Viral infections can cause meningitis or meningoencephalitis.
- HIV can directly cause meningoencephalitis, or indirectly affect the brain by increasing the risk for opportunistic infections (toxoplasmosis, CMV) or CNS lymphoma.
- Prion diseases are transmitted by an altered form of a normal cellular protein. They can be sporadic, transmitted, or inherited.

DISEASES OF MYELIN

Within the CNS, axons are tightly ensheathed by myelin, an electrical insulator that allows rapid propagation of neural impulses. Myelin consists of multiple layers of highly specialized, closely apposed plasma membranes that are assembled by oligodendrocytes. Although myelinated axons are present in all areas of the brain, they are the dominant component in the white matter; therefore, most diseases of myelin are primarily white matter disorders. The myelin in peripheral nerves is similar to the myelin in the CNS, but with several important differences: (1) peripheral myelin is made by Schwann cells, not oligodendrocytes; (2) each Schwann cell in a peripheral nerve

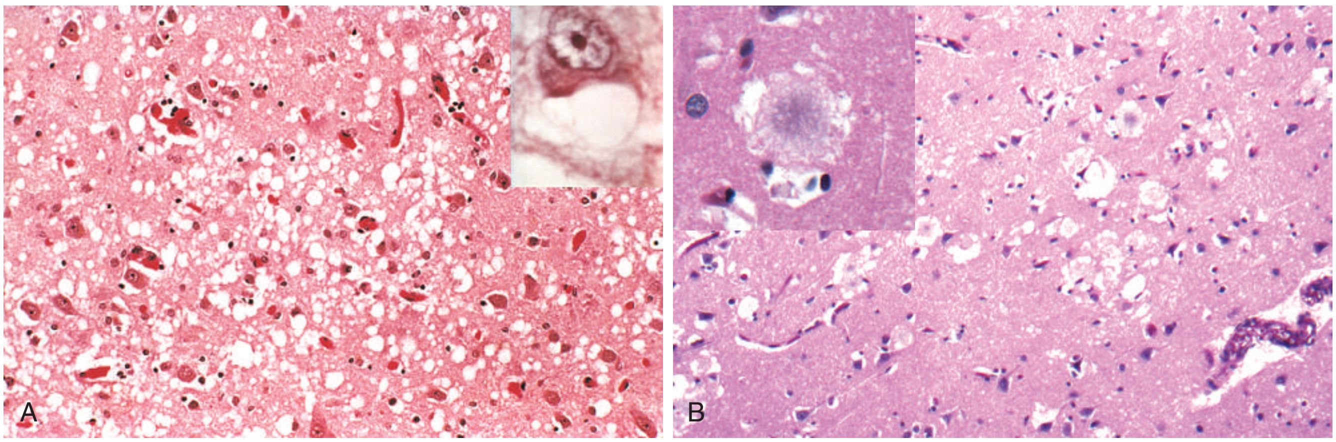

Fig. 23.22 Prion disease. (A) Histologic features of Creutzfeldt-Jakob disease (CJD) include spongiform change in the cerebral cortex. *Inset,* High magnification of a neuron with vacuoles. (B) Variant CJD (vCJD) is characterized by amyloid plaques *(inset)* that sit in the regions of greatest spongiform change.

provides myelin for only one internode, while in the CNS, many internodes are created by processes coming from a single oligodendrocyte; and (3) the specialized proteins and lipids are also different. Most diseases of CNS myelin do not involve the peripheral nerves to any significant extent, and vice versa.

In general, CNS diseases involving myelin are separated into two broad groups.

- Demyelinating diseases of the CNS are acquired conditions characterized by preferential damage to previously normal myelin. The most common diseases in this group result from immune-mediated injury, such as multiple sclerosis (MS) and related disorders. Other processes that can cause this type of disease include viral infection of oligodendrocytes, as in progressive multifocal leukoencephalopathy (see earlier), and injury caused by drugs and other toxic agents.
- By contrast, in other diseases, myelin is not formed properly or has abnormal turnover kinetics. As would be expected, most of these are caused by mutations that disrupt the function of proteins required for the formation of normal myelin sheaths. These diseases are grouped under leukodystrophy or dysmyelinating diseases.

Multiple Sclerosis (MS)

MS is an autoimmune demyelinating disorder characterized by episodes of disease activity, separated in time, that produce white matter lesions that are separated in space. It is the most common demyelinating disorder, having a prevalence of approximately 1 per 1000 individuals in the United States and Europe, and its incidence appears to be increasing. The disease may present at any age, but onset in childhood or after 50 years of age is rare. Women are affected twice as often as men.

Pathogenesis

The lesions of MS are caused by an autoimmune response directed against components of the myelin sheath. As in other autoimmune diseases (Chapter 5), the development of MS is related to genetic susceptibility and largely undefined environmental triggers. The incidence of MS is 15-fold higher when the disease is present in a first-degree relative and roughly 150-fold higher with an affected monozygotic twin. Only a portion of the genetic basis of the disease has been explained, and many of the identified loci are associated with other autoimmune diseases. There is a strong effect of the major histocompatibility complex; each copy of the *HLA-DRB1*1501* allele an individual inherits brings with it a roughly 3-fold increase in the risk for MS. Other genetic loci that are associated with MS include the IL-2 and IL-7 receptor genes and other genes encoding proteins involved in immune responses.

Immune mechanisms that underlie the destruction of myelin are the focus of much investigation. The available evidence indicates that the disease is initiated by T_H1 and T_H17 T cells that react against myelin antigens and secrete cytokines. Experimental autoimmune encephalomyelitis, an animal model of MS in which demyelination and inflammation occur after immunization of animals with myelin proteins, can be passively transferred to unimmunized animals with T_H1 and T_H17 cells that recognize myelin antigens. T_H1 cells secrete IFN-γ, which activates macrophages, and T_H17 cells promote the recruitment of leukocytes. The demyelination is caused by activated leukocytes and their injurious products. The infiltrate in plaques and surrounding regions of the brain consists of T cells (mainly CD4+, some CD8+) and macrophages. B lymphocytes and antibodies also play an important, but poorly defined, role in the disease, as indicated by the surprising success of B cell depleting therapies.

MORPHOLOGY

MS is primarily a multifocal white matter disease. Grossly, the characteristic lesions, termed **plaques**, are discrete, slightly depressed, glassy-appearing, and gray-tan in color (Fig. 23.23A). Plaques are common near the ventricles and also frequently occur in the optic nerves and chiasm, brain stem, ascending and descending fiber tracts, cerebellum, and spinal cord. The lesions have sharply defined borders at the microscopic level (see Fig. 23.23B). **Active plaques** contain abundant macrophages stuffed with myelin debris, evidence of ongoing myelin breakdown. Lymphocytes also are present, mostly as perivascular cuffs. Small active lesions often are centered on small veins. Axons are relatively preserved but may be reduced in number. When plaques become quiescent **(inactive plaques),** the inflammation mostly disappears, leaving behind little to no myelin, astrocytic proliferation, and gliosis.

Clinical Features

The course of MS is variable, but commonly there are multiple *relapses* followed by episodes of *remission;* typically, recovery during remissions is not complete. As a consequence, over time there is usually a gradual, often stepwise, accumulation of neurologic deficits. Imaging studies have demonstrated that there are often more lesions in the brains of patients with MS than might be expected from the clinical examination, and that lesions can come and go much more often than was previously suspected. Changes in cognitive function can be present, but are often much milder than the other deficits. In any individual patient, it is difficult to predict when the next relapse will occur; most current treatments, which are intended to control the immune response, aim at decreasing the rate and severity of relapses rather than recovering lost function.

The CSF in patients with MS shows a mildly elevated protein level with an increased proportion of immunoglobulin; in one-third of cases, there is moderate pleocytosis. When the immunoglobulin is examined further, *oligoclonal bands* usually are identified. These antibodies are directed against a variety of antigenic targets and can be used as markers of disease activity. The contribution of these antibodies to the disease process is unclear.

Other Acquired Demyelinating Diseases

Immune-mediated demyelination can occur after a number of systemic infectious illnesses, including

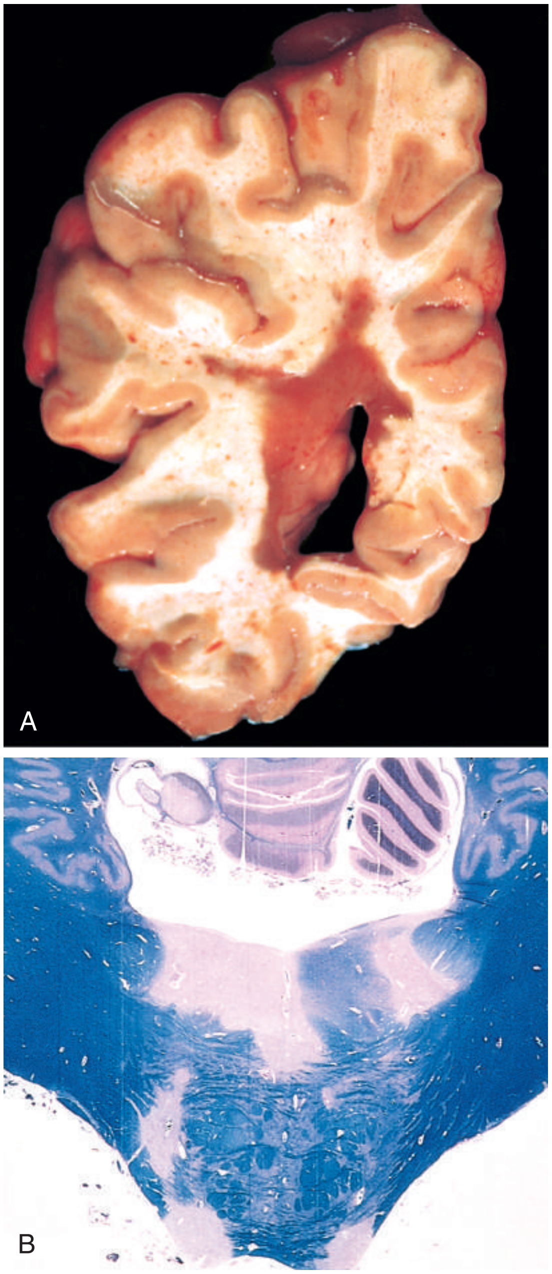

Fig. 23.23 Multiple sclerosis (MS). (A) Section of fresh brain showing a plaque around occipital horn of the lateral ventricle. (B) Unstained regions of demyelination (MS plaques) around the fourth ventricle. Luxol fast blue–periodic acid–Schiff stain for myelin.

relatively mild viral diseases. These are not thought to be related to direct spread of the infectious agents to the nervous system. Rather, it is believed that immune cells responding to pathogen-associated antigens cross-react against myelin antigens, resulting in myelin damage.

There are two general patterns of postinfectious autoimmune reactions to myelin; unlike MS, they both are associated with acute-onset monophasic illnesses. In *acute disseminated encephalomyelitis,* symptoms typically develop 1 or 2 weeks after an antecedent infection and are nonlocalizing (headache, lethargy, and coma), in contrast with the focal findings of MS. Symptoms progress rapidly, and the illness is fatal in as many as 20% of cases; in the remaining patients, there is complete recovery. *Acute necrotizing hemorrhagic encephalomyelitis* is a more devastating related disorder, which typically affects young adults and children.

Other acquired diseases of myelin include *neuromyelitis optica (NMO)*, an antibody-mediated demyelinating disease centered on the optic nerves and spinal cord, and *central pontine myelinolysis*, caused by nonimmune damage to oligodendrocytes typically after sudden correction of hyponatremia, that may result in a rapidly evolving quadriplegia.

As discussed earlier, *progressive multifocal leukoencephalopathy (PML)* is a demyelinating disease that occurs after reactivation of the JC virus in immunosuppressed patients.

Leukodystrophies

Leukodystrophies are inherited dysmyelinating diseases caused by abnormal myelin synthesis or turnover. They are caused by mutations of genes whose products are involved in the generation, turnover, or maintenance of myelin. Some of these mutations affect lysosomal enzymes, while others involve peroxisomal enzymes; a few are associated with mutations in myelin proteins. Most are of autosomal recessive inheritance, although X-linked diseases also occur. There is typically diffuse involvement of white matter leading to deterioration in motor skills, spasticity, hypotonia, or ataxia. Several clinical features separate leukodystrophies from demyelinating diseases. The leukodystrophies typically present with an insidious and progressive loss of function, often begin at younger ages, and are associated with diffuse and symmetric changes on imaging studies.

MORPHOLOGY

Much of the pathologic change of leukodystrophy is found in the white matter, which is diffusely abnormal in color (gray and translucent) and volume (decreased). Early in their course, some diseases may show patchy involvement, while others have a predilection for occipital lobe involvement. In the end, though, nearly all of the white matter usually is affected. With the loss of white matter, the brain becomes atrophic, the ventricles enlarge, and secondary changes can be found in the gray matter. Myelin loss is associated with infiltration of macrophages, which often become stuffed with lipid. Some of these diseases also show specific inclusions created by the accumulation of particular lipids.

SUMMARY

PRIMARY DISEASES OF MYELIN

- Because of the critical role of myelin in nerve conduction, diseases of myelin can lead to widespread and severe neurologic deficits.
- Multiple sclerosis, an autoimmune demyelinating disease, is the most common disorder of myelin, affecting young adults. It often pursues a relapsing-remitting course, with eventual progressive accumulation of neurologic deficits.
- Other, less common forms of immune-mediated demyelination often follow infections and are more acute illnesses.
- Leukodystrophies are genetic disorders in which myelin production or turnover is abnormal.

GENETIC METABOLIC DISEASES

Several genetic diseases disrupt metabolic processes in neurons and glia, resulting in progressive disorders that present early in life. These diseases can be grouped by the cells or compartment affected (neurons vs. white matter), the subcellular organelle affected (e.g., lysosome, peroxisome, or mitochondrion), or the metabolic pathway affected (e.g., sphingolipidoses, very long–chain fatty acid metabolism). The mutations underlying these diseases typically affect synthetic or degradation pathways that are specific to the nervous system.

- *Neuronal storage diseases* are characterized by the accumulation of storage material within neurons, typically leading to neuronal death. Cortical neuronal involvement leads to loss of cognitive function and may also cause seizures. Most commonly, they are autosomal recessive disorders caused by the deficiency of a specific enzyme involved in the catabolism of sphingolipids (including the gangliosides), mucopolysaccharides, or mucolipids; others appear to be caused by defects in protein or lipid trafficking within neurons. Several examples of these diseases, such as Tay-Sachs and Niemann-Pick diseases and mucopolysaccharidoses, are discussed in Chapter 7.
- *Mitochondrial encephalomyopathies* are disorders of oxidative phosphorylation, often affecting multiple tissues including skeletal muscle (Chapter 22). When they involve the brain, gray matter is more severely affected than white matter, as would be expected because of the greater metabolic requirements of neurons. These disorders may be caused by mutations in the mitochondrial or the nuclear genomes.

ACQUIRED METABOLIC AND TOXIC DISTURBANCES

Toxic and acquired metabolic diseases are relatively common causes of neurologic illnesses. **Because of its high metabolic demands, the brain is particularly vulnerable to nutritional diseases and alterations in metabolic state.** Some of these disorders have uneven pathologic lesions and distinct clinical presentations because of unique features or requirements of different anatomic regions of the brain. A few of the more common types of injury are discussed here.

Nutritional Diseases

Thiamine Deficiency

In addition to the systemic effects of thiamine deficiency *(beriberi),* it also may be associated with the abrupt onset of confusion, abnormalities in eye movement and ataxia, syndrome termed *Wernicke encephalopathy.* Treatment with thiamine reverses these deficits, but if treatment is delayed the result is a largely irreversible profound memory disturbance called *Korsakoff syndrome*. Because the two syndromes are closely linked, the term *Wernicke-Korsakoff syndrome* is often used. The syndrome is particularly common in the setting of chronic alcoholism but also may be encountered in patients with thiamine deficiency resulting from gastric disorders, gastric bypass surgery, or persistent vomiting.

MORPHOLOGY

Wernicke encephalopathy is characterized by foci of hemorrhage and necrosis, particularly in the mammillary bodies but also adjacent to the ventricles, especially the third and fourth ventricles. Early lesions show dilated capillaries with prominent endothelial cells and progress to hemorrhage. As the lesions resolve, a cystic space appears along with hemosiderin-laden macrophages. Lesions in the medial dorsal nucleus of the thalamus seem to best correlate with the memory disturbance in Korsakoff syndrome.

Vitamin B_{12} Deficiency

In addition to causing anemia, deficiency of vitamin B_{12} may lead to neurologic deficits associated with changes in the spinal cord, resulting in a syndrome called *subacute combined degeneration of the spinal cord.* As the name implies, both ascending and descending tracts of the spinal cord are affected. Symptoms develop over weeks. Early clinical signs often include mild ataxia and lower-extremity numbness and tingling, which can progress to spastic weakness of the lower extremities; sometimes, complete paraplegia ensues. Prompt vitamin replacement therapy produces clinical improvement; however, if paraplegia has developed, recovery is poor.

Metabolic Disorders

Several systemic metabolic derangements may produce CNS dysfunction; only those associated with abnormal glucose levels and liver dysfunction are considered here.

Hypoglycemia

Since the brain requires glucose as a substrate for energy production, the cellular effects of diminished glucose generally resemble those of global hypoxia. Hippocampal neurons are particularly susceptible to hypoglycemic injury, while cerebellar Purkinje cells are relatively spared. As with anoxia, if the level and duration of hypoglycemia are sufficiently severe, there may be widespread injury to many areas of the brain.

Hyperglycemia

Hyperglycemia is most common in the setting of inadequately controlled diabetes mellitus and can be associated with either ketoacidosis or hyperosmolar coma. Patients develop confusion, stupor, and eventually coma associated with intracellular dehydration caused by the hyperosmolar state. The hyperglycemia must be corrected gradually, because rapid correction can produce severe cerebral edema.

Hepatic Encephalopathy

Decreased hepatic function may be associated with depressed levels of consciousness and sometimes coma. In the early stages, patients exhibit a characteristic "flapping" tremor *(asterixis)* when extending the arms with

palms facing the observer. Elevated levels of ammonia, which the liver normally clears through the urea cycle, in combination with inflammation and hyponatremia, cause the changes in brain function. Because it is only one contributing factor, ammonia levels in symptomatic patients vary widely. Within the CNS, ammonia metabolism occurs only in astrocytes through the action of glutamine synthetase, and in the setting of hyperammonemia, astrocytes in the cortex and basal ganglia develop swollen, pale nuclei (referred to as Alzheimer type II cells).

Toxic Disorders

The list of toxins with effects on the brain is extremely long. Among the major categories of neurotoxic substances are *metals,* including lead, arsenic, and mercury; *industrial chemicals,* including organophosphates (in pesticides) and methanol (causing blindness from retinal damage); and *environmental pollutants* such as carbon monoxide (combining hypoxia with selective injury to the globus pallidus).

Ethanol has a variety of effects on the brain. While acute intoxication is reversible, excessive intake can result in profound metabolic disturbances, including brain swelling and death. Chronic alcohol exposure leads to cerebellar dysfunction in about 1% of cases, with truncal ataxia, unsteady gait, and nystagmus, associated with atrophy in the anterior vermis of the cerebellum.

Ionizing radiation, commonly used to treat intracranial tumors, can cause rapidly evolving signs and symptoms including headache, nausea, vomiting, and papilledema, even months to years after irradiation. Affected brain regions show large areas of coagulative necrosis, edema, and blood vessels with thickened walls containing intramural fibrin like material.

NEURODEGENERATIVE DISEASES

Neurodegenerative diseases are characterized by the progressive loss of neurons, typically affecting groups of neurons with functional interconnections. Different diseases tend to involve particular neural systems and therefore have relatively stereotypic presenting signs and symptoms (Table 23.3):

- Diseases that involve the hippocampus and associated cortices present with cognitive changes, often including disturbances of memory, behavior, and language. With time these progress to dementia, as occurs with Alzheimer disease.
- Diseases that affect the basal ganglia manifest as movement disorders; these may be hypokinetic, as with Parkinson disease, or hyperkinetic, as with Huntington disease.
- Diseases that affect the cerebellum or its input and output circuitry result in ataxia, as seen in the spinocerebellar ataxias.
- When the motor system bears the burden, weakness and difficulty with swallowing and respiration are often seen first, as with amyotrophic lateral sclerosis.

Table 23.3 Features of the Major Neurodegenerative Diseases

Disease	Clinical Pattern	Protein Inclusions
Alzheimer disease (AD)	Dementia	Aβ (plaques) Tau (tangles)
Frontotemporal lobar degeneration (FTLD)	Behavioral changes, language disturbance	Tau TDP43 Others (rare)
Parkinson disease (PD)	Hypokinetic movement disorder	α-synuclein Tau
Huntington disease (HD)	Hyperkinetic movement disorder	Huntingtin (polyglutamine repeat expansions)
Spinocerebellar ataxias	Cerebellar ataxia	Various proteins (polyglutamine repeat expansions)
Amyotrophic lateral sclerosis (ALS)	Weakness with upper and lower motor neurons signs	SOD1 TDP43

A pathologic process shared by most neurodegenerative diseases is the accumulation of protein aggregates, which serve as histologic hallmarks of specific disorders (Table 23.3). Aggregates may arise because of mutations that alter the protein's conformation or that disrupt pathways involved in processing or clearance of the proteins. In other situations, there may be a subtle imbalance between protein synthesis and clearance (due to genetic, environmental, or stochastic factors) that allows gradual accumulation of proteins. The aggregates often are resistant to degradation by normal cellular proteases, accumulate within cells, elicit an inflammatory response, and may be directly toxic to neurons. As is evident from Table 23.3, the same proteins may be present as aggregates in multiple diseases. The clinical phenotype of the neurodegenerative disease is determined more by the distribution of the aggregates than by the nature of the aggregating protein.

Two other features are common to many neurodegenerative diseases:

- There is experimental evidence that many of the protein aggregates that accumulate in neurons affected in these diseases appear to be capable of spreading to healthy neurons. Thus, aggregates can seed the development of more aggregates, and the disease process can spread, like prions. However, there is no evidence for transmission from affected to healthy individuals.
- Activation of the innate immune system is a common feature of neurodegenerative diseases. The importance of this interaction between the brain and the immune system has been further strengthened by the identification of genes that confer risk for diseases (e.g., *TREM2* for Alzheimer disease) that encode components of immune regulatory pathways.

Alzheimer Disease

Alzheimer disease (AD) is the most common cause of dementia in older adults, with an increasing incidence as

a function of age. The incidence is about 3% in individuals 65 to 74 years of age, 19% in those 75 to 84 years of age, and 47% in those older than 84 years of age. Most cases of AD are sporadic, but at least 5% to 10% are familial. Sporadic cases rarely present before 50 years of age, but early onset is seen with some heritable forms.

The disease usually manifests with the insidious onset of impaired higher intellectual function, memory impairment, and altered mood and behavior. Over time, disorientation and aphasia, findings indicative of severe cortical dysfunction, often develop; those in the final phases of AD are profoundly disabled, often mute and immobile. Death usually occurs from intercurrent pneumonia or other infections.

Pathogenesis

The fundamental abnormality in AD is the accumulation of two proteins (Aβ and tau) in specific brain regions, in the forms of plaques and tangles, respectively; these changes result in secondary effects including neuronal dysfunction, neuronal death, and inflammatory reactions. Plaques are deposits of aggregated Aβ peptides in the neuropil, while tangles are aggregates of the microtubule binding protein tau, which develop intracellularly and then persist extracellularly after neuronal death. Both plaques and tangles appear to contribute to neural dysfunction. The details of the interplay between the processes that lead to the accumulation of these abnormal aggregates are a critical aspect of AD pathogenesis that has yet to be unraveled.

Clinical and experimental evidence strongly suggests that **Aβ generation is the critical initiating event for the development of AD.** Notably, mutations or alterations in copy number of the gene encoding the precursor protein for Aβ are associated with an elevated risk of AD, whereas mutations in the gene for tau do not give rise to AD but rather cause frontotemporal lobar degenerations. Overexpression of Aβ can replicate the disease in animal models.

The pathogenesis of AD involves Aβ and Tau deposits, as well as other risk factors and inflammatory reactions.

- *Role of Aβ.* Aβ is created when the transmembrane protein amyloid precursor protein (APP) is sequentially cleaved by the enzymes β-amyloid–converting enzyme (BACE) and γ-secretase (Fig. 23.24). APP also can be cleaved by α-secretase and γ-secretase, liberating a different peptide that is nonpathogenic. Mutations in APP or in components of γ-secretase (encoded by the presenilin-1 or presenilin-2 gene) lead to familial AD by increasing the rate at which Aβ, particularly its most aggregation-prone form, is generated. The *APP* gene is located on chromosome 21, and the risk for AD also is higher in those with an extra copy of the *APP* gene, such as patients with trisomy 21 (Down syndrome) and individuals with small interstitial duplications of *APP,* presumably because this too leads to greater Aβ generation. Once generated, Aβ is highly prone to aggregation; it first forms small oligomers, and these eventually propagate into large aggregates and fibrils. It is these aggregates that deposit in the brain and are visible as plaques. There is evidence that these oligomers decrease the number of synapses present and alter the function of those that remain so that the cellular processes felt to underlie learning and memory are disrupted.
- *Role of tau.* Because neurofibrillary tangles contain the tau protein, there has been much interest in the role of this protein in AD. Tau is a microtubule-associated protein present in axons in association with the microtubular network. With the development of tangles in AD, tau shifts to a somatic-dendritic distribution, becomes hyperphosphorylated, and loses the ability to bind to microtubules. The formation of tangles is an important component of AD, but the mechanism of tangle injury to neurons remains poorly understood. Two pathways have been suggested; 1) aggregates of tau protein elicit a stress response, which persists and eventually leads to cell death; and 2), the microtubule stabilizing function of tau protein is lost, leading to neuronal toxicity and death. It has been shown that tau aggregates can be passed across synapses from one neuron to the next; this may underlie some of the spread of lesions across the brain.
- *Other genetic risk factors.* The genetic locus on chromosome 19 that encodes apolipoprotein E (ApoE) has a strong influence on the risk for developing AD. Three alleles have been identified (ε2, ε3, and ε4) based on two amino acid polymorphisms. The dosage of the ε4 allele increases the risk for AD. This ApoE isoform promotes Aβ generation and deposition, although the mechanisms have not been established. Overall, this locus has been estimated to convey about one fourth of the risk for development of late-onset AD. Genome-wide association studies have identified multiple other loci that contribute to the risk for AD, but the roles of the encoded proteins in disease pathogenesis are not established.
- *Role of inflammation.* Both genetic and histologic studies have indicated that the innate immune system responds to Aβ and tau. Deposits of Aβ elicit an inflammatory response from microglia and astrocytes. This response probably assists in the clearance of the aggregated peptide, but also may stimulate the secretion of mediators that cause neuronal injury over time.
- *Basis for cognitive impairment.* Deposits of Aβ and tangles begin to appear in the brain well in advance of cognitive impairment. While there remains disagreement regarding the best correlate of dementia in individuals with AD, the presence of a large burden of plaques and tangles is strongly associated with severe cognitive dysfunction. The number of neurofibrillary tangles correlates better with the degree of dementia than does the number of neuritic plaques. Biochemical markers that have been correlated with the degree of dementia include amyloid burden.

MORPHOLOGY

Brains involved by AD show a variable degree of cortical atrophy, resulting in a widening of the cerebral sulci that is most pronounced in the frontal, temporal, and parietal lobes. The atrophy produces a compensatory ventricular enlargement (hydrocephalus ex vacuo). At the microscopic level, AD is diagnosed by the presence of **neuritic plaques** (an extracellular lesion) and **neurofibrillary tangles** (an intracellular lesion) (Fig. 23.25).

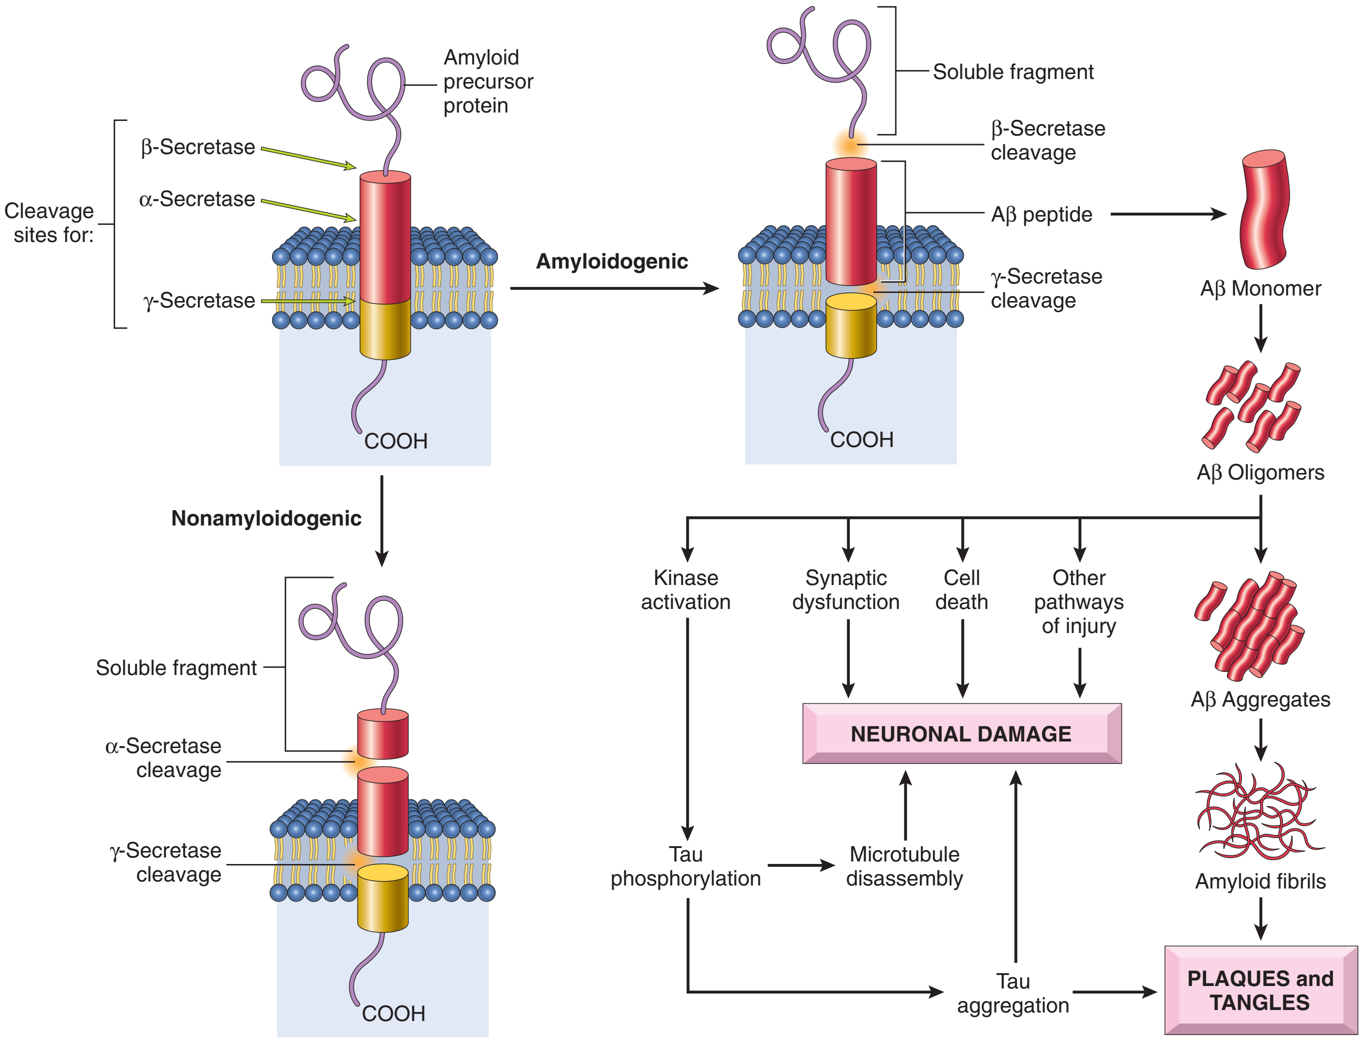

Fig. 23.24 Aβ peptide genesis and consequences in Alzheimer disease. Amyloid precursor protein cleavage by α-secretase and γ-secretase produces a harmless soluble peptide, whereas amyloid precursor protein cleavage by β-amyloid–converting enzyme (BACE) and γ-secretase releases Aβ peptides, which form pathogenic aggregates and contribute to the characteristic plaques and tangles of Alzheimer disease.

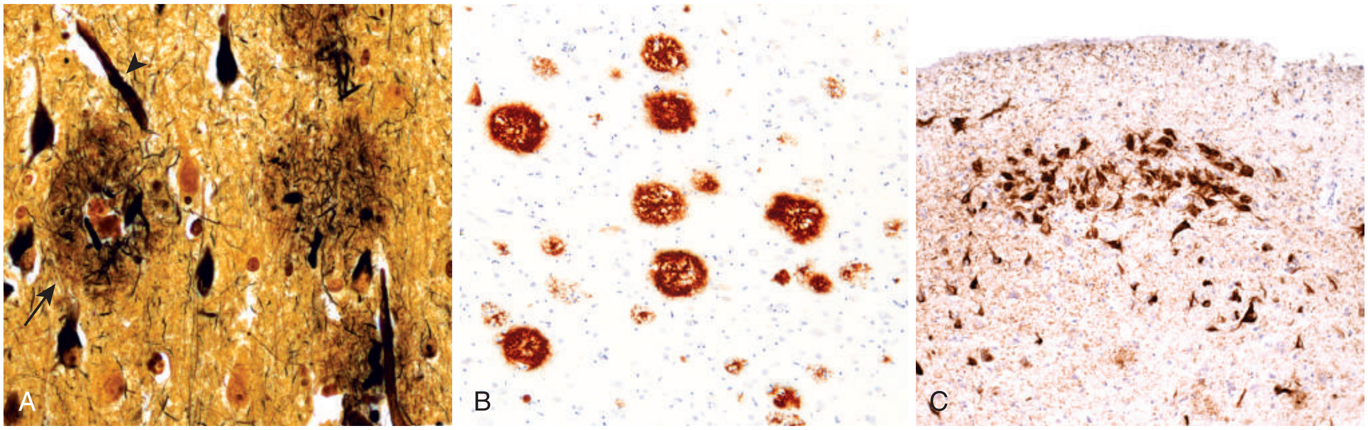

Fig. 23.25 Alzheimer disease. (A) Plaques *(arrow)* contain a central core of amyloid and a surrounding region of dystrophic neurites (Bielschowsky stain). (B) Immunohistochemical stain for Aβ. Peptide is present in the core of the plaques as well as in the surrounding region. (C) Neurons containing tangles stained with an antibody specific for tau.

Neuritic plaques are focal, spherical collections of dilated, tortuous, processes derived from dystrophic neurites, often around a central amyloid core (see Fig. 23.25A). Neuritic plaques range in size from 20 to 200 μm in diameter; microglial cells and reactive astrocytes are present at their periphery. Plaques can be found in the hippocampus and amygdala as well as in the neocortex, although there is relative sparing of primary motor and sensory cortices until late in the disease course. The amyloid core contains Aβ (see Fig. 23.25B). Aβ deposits also can be found that lack the surrounding neuritic reaction, termed **diffuse plaques;** these are found in the superficial cerebral cortex, the basal ganglia, and the cerebellar cortex and may represent an early stage of plaque development.

Neurofibrillary tangles are bundles of paired helical filaments visible as basophilic fibrillary structures in the cytoplasm of the neurons that displace or encircle the nucleus; tangles can persist after neurons die, becoming a form of extracellular pathology. They are commonly found in cortical neurons, especially in the entorhinal cortex, as well as in the pyramidal cells of the hippocampus, the amygdala, the basal forebrain, and the raphe nuclei. A major component of paired helical filaments is **hyperphosphorylated tau** (see Fig. 23.25C).

In individuals harboring autosomal dominant mutations that cause AD, deposition of Aβ and the formation of tangles precede the emergence of cognitive impairment by as much as 15 to 20 years. For this reason, the current diagnostic criteria consider the burden and distribution of amyloid deposits, tangles, and neuritic plaques—a constellation known as **Alzheimer disease neuropathologic changes.** The staging of each of these processes, which has a fairly consistent pattern across individuals, is then used to assess the likelihood that the observed lesions resulted in cognitive impairment.

Frontotemporal Lobar Degeneration

Frontotemporal lobar degeneration (FTLD) encompasses several disorders that preferentially affect the frontal and/or temporal lobes. As a result, these disorders have certain shared clinical features, such as progressive deterioration of language and changes in personality. The term *degeneration* is applied to describe the neuropathologic changes; clinically, these syndromes commonly are referred to as *frontotemporal dementias.* Depending on the disease distribution (frontal or temporal), behavioral changes or language problems may dominate. In general, behavioral and language problems precede memory disturbances, a distinction that assists in the clinical discrimination between FTLD and AD. The onset of symptoms occurs at younger ages for FTLD than for AD.

In addition to the clinical classification, two pathologic subgroups exist that are distinguished based on the composition of characteristic neuronal inclusions, which may contain tau or TDP43. One well-recognized subtype of FTLD-tau is *Pick disease,* which is associated with smooth, round inclusions known as *Pick bodies.* How tau aggregation may lead to neurodegeneration was discussed earlier, in the context of Alzheimer disease. The other major form of FTLD is characterized by aggregates containing the DNA/RNA-binding protein TDP43 (FTLD-TDP43). It is uncertain how this leads to neurodegeneration; both loss of TDP43 activity and a toxic gain-of-function related to the protein aggregates remain possibilities. TDP43 neuronal inclusions also are found in a large proportion of cases of amyotrophic lateral sclerosis (ALS). This overlap is manifest clinically, as many individuals with ALS also show evidence of FTLD.

MORPHOLOGY

The gross appearance is independent of the type of inclusions, with atrophy of frontal and temporal lobes of variable extent and severity, accompanied by neuronal loss and gliosis (Fig. 23.26A–B). In FTLD-tau, the characteristic additional lesion is the presence of tau-containing neurofibrillary tangles, similar to the tangles found in AD (see Fig. 23.26C). In FTLD-TDP, there is loss of nuclear staining for TDP43 associated with the appearance of TDP43-positive inclusions (see Fig. 23.26D).

Parkinson Disease

Parkinson disease (PD) is a neurodegenerative disease marked by a hypokinetic movement disorder that is caused by loss of dopaminergic neurons from the substantia nigra. *Parkinsonism* is a clinical syndrome characterized by tremor, rigidity, bradykinesia, and instability. These types of motor disturbances may be seen in a range of diseases that damage dopaminergic neurons, which project from the substantia nigra to the striatum and are involved in control of motor activity. Parkinsonism can be induced by drugs such as dopamine antagonists or toxins that selectively injure dopaminergic neurons. Among the neurodegenerative diseases, most cases of parkinsonism are caused by PD, which is associated with characteristic neuronal inclusions containing α-synuclein.

Pathogenesis

PD is associated with protein accumulation and aggregation, mitochondrial abnormalities, and neuronal loss in the substantia nigra and elsewhere in the brain. Based on the genetics of PD, it appears that abnormal protein and organelle clearance due to defects in autophagy and lysosomal degradation have a pathogenic role in the disease. One clue and diagnostic feature of the disease is the Lewy body, a characteristic inclusion containing *α-synuclein*, a protein involved in synaptic transmission. While PD in most cases is sporadic, point mutations and duplications of the gene encoding α-synuclein cause autosomal dominant PD. Synuclein aggregates are cleared by autophagy (Chapter 2), and several mutations associated with PD are in genes whose products (LRRK2, Parkin, others) all appear to have roles in endosomal trafficking pathways implicated in autophagy. It also has been demonstrated that heterozygosity for the Gaucher disease–causing mutation in glucocerebrosidase is a risk factor for PD. Glucocerebrosidase is a lysosomal enzyme, yet another clue suggesting that abnormal turnover of cellular constituents somehow sets the stage for the development of PD.

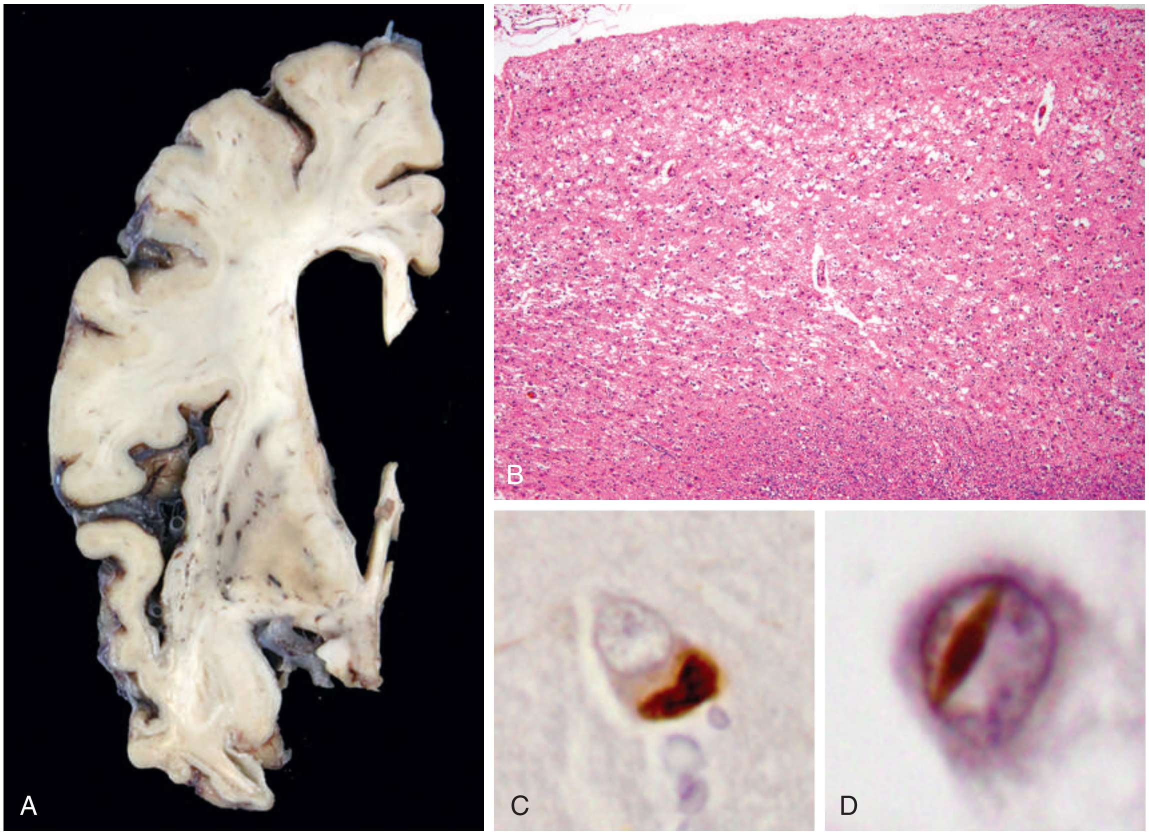

Fig. 23.26 Frontotemporal lobar degeneration (FTLD). (A) Atrophy of the temporal cortex can be seen in comparison to the relative preservation of frontal cortex. (B) Severe neuronal loss and gliosis in the region of atrophy. (C) FTLD-tau. Cytoplasmic inclusions containing TDP43 are seen in association with loss of normal nuclear immunoreactivity. (D) FTLD-TDP. Some forms of FTLD are associated with neuronal intranuclear inclusions containing TDP43.

MORPHOLOGY

A typical gross finding at autopsy is pallor of the substantia nigra (Fig. 23.27A–B) and locus ceruleus. Microscopic features include loss of the pigmented, catecholaminergic neurons in these regions associated with gliosis. **Lewy bodies** (see Fig. 23.27C) may be found in those neurons that remain. These are single or multiple, cytoplasmic, eosinophilic, round to elongated inclusions. On ultrastructural examination, Lewy bodies consist of fine filaments, composed of α-synuclein and other proteins, including neurofilaments and ubiquitin. The other major histologic finding is the presence of **Lewy neurites,** dystrophic neurites that also contain aggregated α-synuclein. Immunohistochemical staining for α-synuclein highlights more subtle Lewy bodies and Lewy neurites in many brain regions outside of the substantia nigra and in non-dopaminergic neurons, including regions of the medulla, the pons, the amygdala, and the cerebral cortex. Eventually they appear in the subcortical areas and the cerebral cortex. With involvement of the cerebral cortex, there is typically dementia present in addition to the movement disorder.

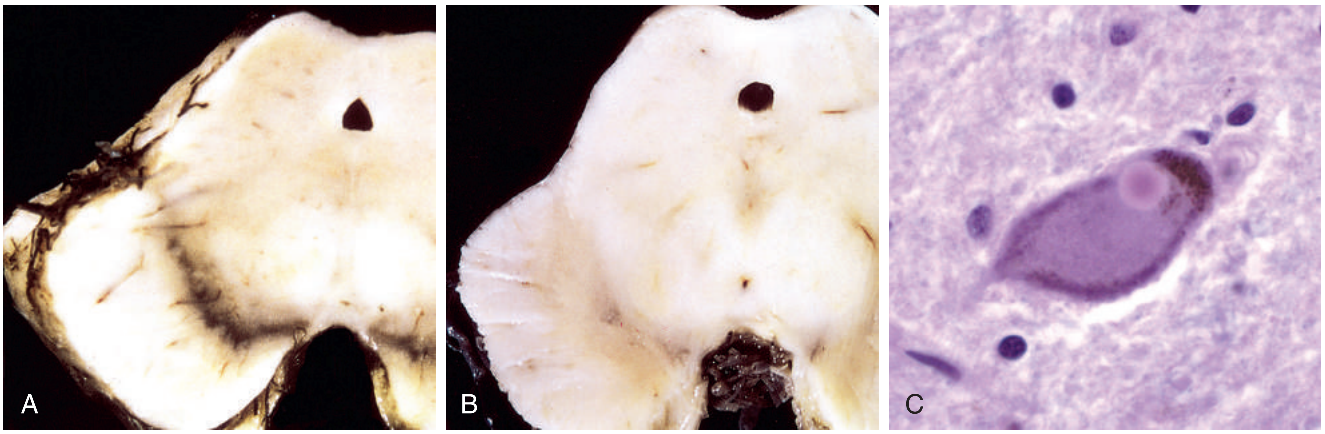

Fig. 23.27 Parkinson disease. (A) Normal substantia nigra. (B) Depigmented substantia nigra in idiopathic Parkinson disease. (C) Lewy body in a neuron from the substantia nigra stains pink.

Clinical Features

PD commonly manifests as a movement disorder in the absence of a toxic exposure or other known underlying etiology. The disease usually progresses over 10 to 15 years, eventually producing severe motor slowing to the point of near immobility. Death usually is the result of aspiration pneumonia or trauma from falls caused by postural instability.

Movement symptoms of PD initially respond to L-dihydroxyphenylalanine (L-DOPA), but this treatment does not slow disease progression. Over time, L-DOPA becomes less effective and begins to cause problematic fluctuations in motor function. Another treatment for the motor symptoms of PD is deep brain stimulation, in which electrodes are implanted in the globus pallidus or subthalamic nucleus to modulate basal ganglia circuitry, often allowing a significant reduction in L-DOPA dose.

While the movement disorder associated with loss of the nigrostriatal dopaminergic pathway is an important feature of PD, it is clear that the disease has more extensive clinical and pathologic manifestations. Lesions in the brain stem (in the dorsal motor nucleus of the vagus and in the reticular formation), in advance of nigral involvement, can give rise to behavioral sleep disorder often before the motor problems. Dementia, typically with a mildly fluctuating course and hallucinations, emerges in many individuals with PD and is attributable to involvement of the cerebral cortex. When dementia arises within 1 year of the onset of motor symptoms, it is referred to *Lewy body dementia (LBD).*

Huntington Disease

Huntington disease (HD) is an autosomal dominant movement disorder associated with degeneration of the striatum (caudate and putamen). The disorder is characterized by involuntary jerky movements of all parts of the body; writhing movements of the extremities are typical. The disease is relentlessly progressive, resulting in death after an average course of about 15 years. Early cognitive symptoms include forgetfulness and thought and affective disorders, and there may be a progression to severe dementia. As a part of these early behavioral changes, HD carries an increased risk for suicide.

Pathogenesis

HD is caused by CAG trinucleotide repeat expansions in a gene located on 4p16.3 that encodes the protein huntingtin. Normal alleles contain 11 to 34 copies of the repeat; in disease-causing alleles, the number of repeats is increased, sometimes into the hundreds. There is a strong genotype-phenotype correlation, with larger numbers of repeats resulting in earlier-onset disease. Once the symptoms appear, however, the course of the illness is not affected by repeat length. Further expansions of the CAG (glutamine-encoding) repeats occur during spermatogenesis, so paternal transmission may be associated with earlier onset in the next generation, a phenomenon referred to as *anticipation* (Chapter 7).

HD appears to be caused by a toxic gain-of-function related to the expanded polyglutamine tract in huntingtin. The mutant protein is subject to ubiquitination and proteolysis, yielding fragments that can form large intranuclear aggregates. As in other degenerative diseases, smaller aggregates of the abnormal protein fragments are suspected to be toxic. These aggregates have been shown to have a range of potentially injurious actions, including sequestration of transcription factors, disruption of protein degradation pathways, and perturbation of mitochondrial function. It is likely that some combination of these aberrations contributes to HD pathogenesis.

MORPHOLOGY

On gross examination, the brain is small and shows striking atrophy of the caudate nucleus and, sometimes less dramatically, the putamen (Fig. 23.28). The globus pallidus may be atrophied secondarily, and the lateral and third ventricles are dilated. Atrophy frequently also is seen in the frontal lobe, less often in the parietal lobe, and occasionally in the entire cortex.

Microscopic examination reveals severe loss of neurons from affected regions of the striatum along with gliosis. The medium-sized, spiny neurons that release the neurotransmitters γ-aminobutyric acid (GABA), enkephalin, dynorphin, and substance P are especially sensitive, disappearing early in the disease. There is a strong correlation between the degree of degeneration in the striatum and the severity of motor symptoms; there is also an association between cortical neuronal loss and dementia. In remaining striatal neurons and in the cortex, there are intranuclear inclusions that contain aggregates of ubiquitinated huntingtin protein (see Fig. 23.28, *inset*).

Spinocerebellar Ataxias

Spinocerebellar ataxias (SCAs) are a heterogeneous group of several dozen diseases with clinical findings that include a combination of cerebellar and sensory ataxia, spasticity, and sensorimotor peripheral neuropathy. They are distinguished from one another based on different

Fig. 23.28 Huntington disease. Normal hemisphere *(left)* compared with a hemisphere with Huntington disease *(right)* showing atrophy of the striatum and ventricular dilation. *Inset,* An intranuclear inclusion in a cortical neuron is strongly immunoreactive for ubiquitin. *(Gross photo courtesy of Dr. Vonsattel, Columbia University, New York, New York.)*

causative mutations, patterns of inheritance, age at onset, and signs and symptoms. This group of diseases affects, to a variable extent, the cerebellar cortex, spinal cord, other brain regions, and peripheral nerves. Degeneration of neurons, often without other distinctive histopathologic changes, occurs in the affected areas and is associated with mild gliosis. The additional clinical symptoms that accompany the ataxia can help distinguish between well-characterized subtypes. Although many distinct genetic types of SCA have been identified, there remain many cases that do not fall into one of the already characterized forms.

As with HD, several forms of SCA are caused by CAG repeat expansions encoding polyglutamine tracts in various genes. In these forms of SCA, as is true for HD, neuronal intranuclear inclusions are present containing the abnormal protein, and there is an inverse correlation between the degree of repeat expansion and age of onset. Other SCAs are caused by repeat expansions in untranslated regions or by other types of mutations.

Friedreich ataxia is an autosomal recessive disorder that generally manifests in the first decade of life with gait ataxia, followed by hand clumsiness and dysarthria. Most patients develop pes cavus and kyphoscoliosis, and there is a high incidence of cardiac disease and diabetes. The disease usually is caused by a GAA trinucleotide repeat expansion in the gene encoding frataxin, a protein that regulates cellular iron levels, particularly in the mitochondria. The repeat expansion results in decreased protein levels through transcriptional silencing; decreased frataxin leads to mitochondrial dysfunction as well as increased oxidative damage.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) results from the death of lower motor neurons in the spinal cord and brain stem as well as upper motor neurons (Betz cells) in the motor cortex. The loss of lower motor neurons results in denervation of muscles, muscular atrophy (the "amyotrophy" of the condition), weakness, and fasciculations, while the loss of upper motor neurons results in paresis, hyperreflexia, and spasticity, along with a Babinski sign. An additional consequence of upper motor neuron loss is degeneration of the corticospinal tracts in the lateral portion of the spinal cord ("lateral sclerosis"). Sensation usually is unaffected, but cognitive impairment is not infrequent.

The disease affects men slightly more frequently than women and becomes clinically manifest in the fifth decade or later. It usually begins with subtle asymmetric distal extremity weakness. As the disease progresses, muscle strength and bulk diminish, and involuntary contractions of individual motor units, termed *fasciculations,* occur. The disease eventually involves the respiratory muscles, leading to recurrent bouts of pulmonary infection, which is the usual cause of death. The balance between upper and lower motor neuron involvement can vary, although most patients exhibit involvement of both. In some patients, degeneration of the lower brain stem cranial motor nuclei occurs early and progresses rapidly, a pattern of disease referred to as *bulbar amyotrophic lateral sclerosis*. With this disease pattern, abnormalities of swallowing and speaking dominate.

Pathogenesis

While most cases are sporadic, about 10% are familial, mostly with autosomal dominant inheritance. Familial disease begins earlier in life than sporadic disease, but once symptoms appear, the clinical course is similar in both forms. Mutations in the superoxide dismutase gene, *SOD1,* on chromosome 21 were the first identified genetic cause of ALS and account for about 20% of the familial forms. These mutations are thought to generate abnormal misfolded forms of the SOD1 protein, which may trigger the unfolded protein response and cause apoptotic death of neurons.

A number of other genetic loci have been identified as associated with ALS. The most common cause of familial ALS is hexanucleotide repeat expansion in a gene with the rather cumbersome name *C9orf72*, which is also frequently expanded in frontotemporal lobar degeneration. The protein encoded by *C9orf72* associates with RNA binding proteins; notably, two other genes that when mutated may cause ALS, TDP43 (also associated with FTLD) and FUS, encode RNA binding proteins. This convergence suggests that an abnormality of RNA processing directly or indirectly contributes to the pathogenesis of ALS, but it is uncertain how mutations in SOD1 fit into this picture, and much remains to be discovered. As expected from the genetic overlap, there is some clinical overlap between ALS and FTLD, such as cognitive impairment.

MORPHOLOGY

The most striking gross changes are found in anterior roots of the spinal cord, which are thin and gray. In especially severe cases, the precentral gyrus (motor cortex) is mildly atrophic due to the death of upper motor neurons. Microscopic examination demonstrates a **reduction in the number of anterior horn cell neurons** throughout the spinal cord associated with reactive gliosis and loss of anterior root myelinated fibers. Similar findings are found with involvement of motor cranial nerve nuclei except those supplying the extraocular muscles, which are spared in all but a few long term survivors. Cytoplasmic inclusions that contain TDP43 may be seen in a subset of cases. With the loss of innervation from the death of anterior horn cells, skeletal muscles show neurogenic atrophy.

SUMMARY

NEURODEGENERATIVE DISEASES

- Neurodegenerative diseases cause symptoms that depend on the pattern of brain involvement. Cortical disease usually manifests as cognitive change, alterations in personality, and memory disturbances; basal ganglia disorders usually manifest as movement disorders.
- Many of the neurodegenerative diseases are associated with various protein aggregates, which serve as pathologic hallmarks. Familial forms of these diseases are associated with mutations in the genes encoding these proteins or controlling their metabolism. Some of these protein aggregates can show prion like properties, facilitating spread from one cell to the next.

- Among dementias, Alzheimer disease (with plaques of Aβ and tangles of tau) is the most common; other predominantly dementing diseases include the various forms of FTLDs (both forms with tau-containing lesions and with other types of inclusions) and dementia with Lewy bodies (with α-synuclein containing lesions).
- Among the hypokinetic movement disorders, Parkinson disease is the most common, with α-synuclein containing inclusions.
- Amyotrophic lateral sclerosis (ALS) is the most common form of motor neuron disease, with diverse genetic causes as well as sporadic forms.

TUMORS

The annual incidence of CNS tumors ranges from 10 to 17 per 100,000 individuals for intracranial tumors and 1 to 2 per 100,000 individuals for intraspinal tumors; about one-half to three-fourths are primary tumors, and the rest are metastatic. Tumors of the CNS make up a larger proportion of childhood cancers, accounting for as many of 20% of all pediatric tumors. Childhood CNS tumors differ from those in adults in both histologic subtype and location. In childhood, tumors are likely to arise in the posterior fossa, whereas tumors in adults are mostly supratentorial.

Tumors of the nervous system have unique characteristics that set them apart from neoplastic processes elsewhere in the body.

- These tumors do not have morphologically evident premalignant or in situ stages comparable to those of carcinomas.
- Even low-grade lesions may infiltrate large regions of the brain, leading to serious clinical deficits, inability to be resected, and poor prognosis.
- The anatomic site of the neoplasm can influence outcome independent of histologic classification due to local effects (e.g., a benign meningioma may cause cardiorespiratory arrest from compression of the medulla).
- Even the most highly malignant gliomas rarely spread outside of the CNS.

Gliomas

Gliomas are tumors of the brain parenchyma that have long been classified as *astrocytomas, oligodendrogliomas,* and *ependymomas* based on their morphologic resemblance to different types of glial cells. With emerging genetic information, it has become clear that the gliomas are a molecularly distinct family of neoplastic lesions, independent of the histologic patterns. Nonetheless, histologic patterns continue to inform diagnosis and guide treatment, with refinement based on molecular characterization. The diffuse gliomas constitute the vast majority of gliomas that occur in adults, and include diffuse astrocytomas and oligodendrogliomas.

Diffuse Astrocytoma

Astrocytomas account for about 80% of adult gliomas. They are most frequent in the fourth through the sixth decades of life. They usually are found in the cerebral hemispheres. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the anatomic site of involvement. **On the basis of histologic features, astrocytomas are stratified into three groups: diffuse astrocytoma (grade II), anaplastic astrocytoma (grade III), and glioblastoma (grade IV), with increasingly grim prognosis as the grade increases.** There is emerging evidence that genetic subtyping provides important additional prognostic information.

Diffuse astrocytomas can be static for several years, but at some point they progress; the mean survival is more than 5 years. Eventually, patients suffer rapid clinical deterioration that is correlated with the appearance of anaplastic features and more rapid tumor growth. Other patients present with glioblastoma from the outset. Once the histologic features of glioblastoma appear, the prognosis is very poor; with treatment (resection, radiotherapy, and chemotherapy), the median survival is only 15 months.

MORPHOLOGY

Grade II and III astrocytomas are poorly defined, gray, infiltrative tumors that expand and distort the invaded brain without forming a discrete mass (Fig. 23.29A). Infiltration beyond the grossly evident margins is always present. The cut surface of the tumor is either firm or soft and gelatinous; cystic degeneration may be seen. In glioblastoma, variation in the gross appearance of the tumor from region to region is characteristic (see Fig. 23.29B). Some areas are firm and white, others are soft and yellow (the result of tissue necrosis), and still others show regions of cystic degeneration and hemorrhage.

Microscopically, low-grade (WHO grade II) astrocytomas are characterized by a mild to moderate increase in the number of glial cell nuclei, somewhat variable nuclear pleomorphism, and an intervening feltwork of fine, glial fibrillary acidic protein (GFAP)-positive astrocytic cell processes that give the background a fibrillary appearance. The transition between neoplastic and normal tissue is indistinct, and tumor cells can be seen infiltrating normal tissue many centimeters from the main lesion. Anaplastic astrocytomas show regions that are more densely cellular and have greater nuclear pleomorphism; mitotic figures are present. Glioblastoma has a histologic appearance similar to that of anaplastic astrocytoma, as well as either necrosis (commonly present as serpiginous bands of necrosis with palisaded tumor cells along the border) or microvascular proliferation (see Fig. 23.29C).

Oligodendroglioma

Oligodendrogliomas account for 5% to 15% of gliomas and most commonly are detected in the fourth and fifth decades of life. Patients may have had several years of antecedent neurologic complaints, often including seizures. The lesions are found mostly in the cerebral hemispheres, mainly in the frontal or temporal lobes. The combination of surgery, chemotherapy, and radiotherapy yields an average survival of 10 to 20 years for well-differentiated (WHO grade II) oligodendrogliomas or 5 to 10 years for anaplastic (WHO grade III) oligodendrogliomas.

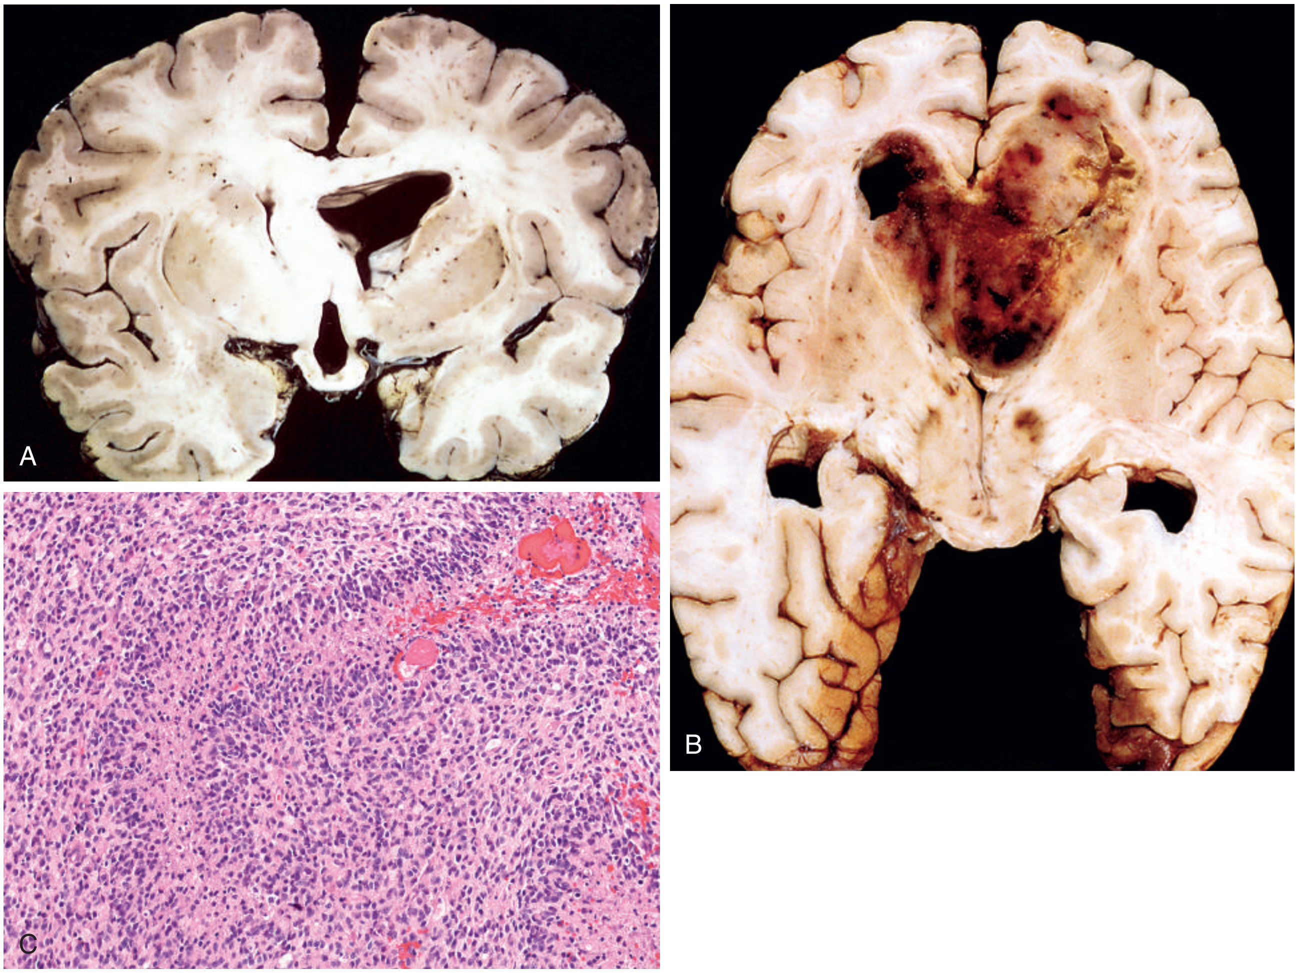

Fig. 23.29 Diffuse astrocytomas. (A) Grade II astrocytoma is seen as expanded white matter of the left cerebral hemisphere and thickened corpus callosum and fornices. (B) Glioblastoma appearing as a necrotic, hemorrhagic, infiltrating mass. (C) Glioblastoma is a densely cellular tumor with necrosis and pseudopalisading of tumor cell nuclei along the edge of the necrotic zone.

MORPHOLOGY

Well-differentiated oligodendrogliomas (WHO grade II) are infiltrative tumors that form gelatinous, gray masses and may show cysts, focal hemorrhage, and calcification. On microscopic examination, the tumor is composed of sheets of regular cells with spherical nuclei containing finely granular chromatin (similar to that in normal oligodendrocytes) surrounded by a clear halo of cytoplasm (Fig. 23.30). The tumor typically contains a delicate network of anastomosing capillaries. Calcification, present in as many as 90% of these tumors, ranges in extent from microscopic foci to massive depositions. Mitotic activity usually is low. Anaplastic oligodendroglioma (WHO grade III) is a more aggressive subtype with higher cell density, nuclear anaplasia, increased mitotic activity, and often microvascular proliferation.

Genetics and Pathogenesis

Several classes of tumor-causing genetic alterations have been described in gliomas.

- Mutations in *isocitrate dehydrogenase (IDH)* genes are commonly observed in grade II astrocytomas and oligodendrogliomas. These mutations may occur in IDH1 or IDH2 and lead to increased production of 2-hydroxyglutarate, which interferes with the activity of several enzymes that regulate gene expression (Chapter 6).
- Mutations in the promoter for *telomerase*, which contribute to the immortalization of tumor cells (Chapter 6), are seen in glioblastomas and other astrocytic tumors. In tumors with IDH mutations, telomerase mutations are uncommon; instead, these tumors often have loss of function mutations in *ATRX*, which normally suppresses recombination events that can preserve telomere length, a mechanism called alternative lengthening of telomeres.
- Co-deletion of 1p and 19q chromosomal segments are present in oligodendrogliomas. The mechanism through which these chromosomal alterations shape tumor morphology and response to treatment is not known.
- Other genetic alterations, which are also common in tumors outside the CNS, include mutations that lead to overexpression of the EGF receptor and other receptor tyrosine kinases or disable p53 or RB (Chapter 6).

Midline Glioma

Midline gliomas arise most commonly in the brain stem (specifically in the pons) and also occur in the spinal cord

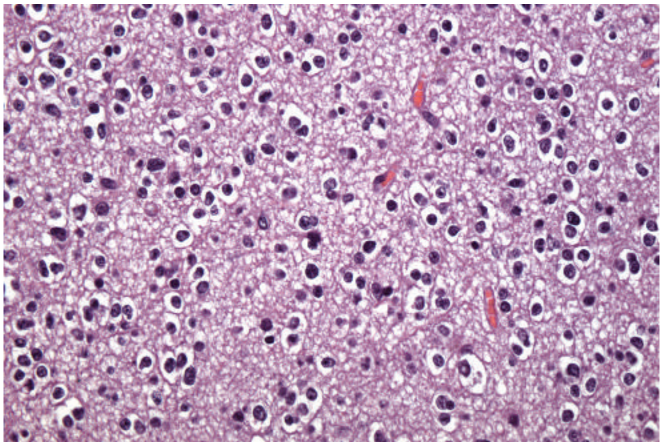

Fig. 23.30 In oligodendroglioma, tumor cells have round nuclei, often with a clear cytoplasmic halo. Blood vessels in the background are thin and can form an interlacing pattern.

and thalamus. They are infiltrative and result in significant neurologic impairment because of the disruption of critical nearby structures. Although they may not show typical high-grade features such as necrosis or vascular proliferation, they often behave aggressively. These lesions typically have acquired point mutations in histone H3, the consequence of which is loss of a lysine residue that is the target of post-translational modifications that regulate gene expression, another example of oncogenesis via alteration of the cancer cell "epigenome". Precisely how this mutation contributes to cellular transformation remains to be determined.

Pilocytic Astrocytoma

Pilocytic astrocytomas are relatively benign tumors that typically affect children and young adults. Most commonly located in the cerebellum, they also may involve the third ventricle, the optic pathways, the spinal cord, and occasionally the cerebral hemispheres. There is often a cyst associated with the tumor, and symptoms appearing after the incomplete resection of the lesions may be associated with cyst enlargement, rather than growth of the solid component. Tumors that involve the hypothalamus are especially problematic because they cannot be resected completely.

A high proportion of pilocytic astrocytomas have activating mutations or translocations involving the gene encoding the serine-threonine kinase BRAF, which result in activation of the MAPK signaling pathway. Pilocytic astrocytomas do not have mutations in *IDH1* and *IDH2*, supporting their distinction from the low-grade diffuse gliomas.

MORPHOLOGY

A pilocytic astrocytoma often is cystic, with a mural nodule in the wall of the cyst; if solid, it is usually well circumscribed. The tumor is composed of bipolar cells with long, thin "hairlike" processes that are GFAP-positive. Rosenthal fibers, eosinophilic granular bodies, and microcysts are often present, while necrosis and mitoses are rare.

Ependymoma

Ependymomas most often arise next to the ependyma-lined ventricular system, including the central canal of the spinal cord. In the first 2 decades of life, they typically occur near the fourth ventricle and constitute 5% to 10% of the primary brain tumors in this age group. In adults, the spinal cord is their most common location; tumors in this site are particularly frequent in the setting of neurofibromatosis type 2 (Chapter 22). The clinical outcome for completely resected supratentorial and spinal ependymomas is better than for those in the posterior fossa.

MORPHOLOGY

In the fourth ventricle, ependymomas typically are solid or papillary masses extending from the ventricular floor. The tumors are composed of cells with regular, round to oval nuclei and abundant granular chromatin. Between the nuclei is a variably dense fibrillary background. Tumor cells may form round or elongated structures **(rosettes, canals)** that resemble the embryologic ependymal canal, with long, delicate processes extending into a lumen (Fig. 23.31); more frequently present are **perivascular pseudorosettes** in which tumor cells are arranged around vessels with an intervening zone containing thin ependymal processes. Anaplastic ependymomas show increased cell density, high mitotic rates, necrosis, microvascular proliferation, and less evident ependymal differentiation.

Neuronal Tumors

Far less frequent than gliomas, tumors composed of cells with neuronal characteristics are typically lower-grade lesions that often present with seizures. While some neuronal differentiation can be observed in many tumors, lesions in this group are primarily composed of cells that express neuronal markers, such as synaptophysin and neurofilaments.

- *Central neurocytoma* is a low-grade neoplasm found within and adjacent to the ventricular system (most commonly the lateral or third ventricle); it is characterized by evenly spaced, round, uniform nuclei and often islands of neuropil.

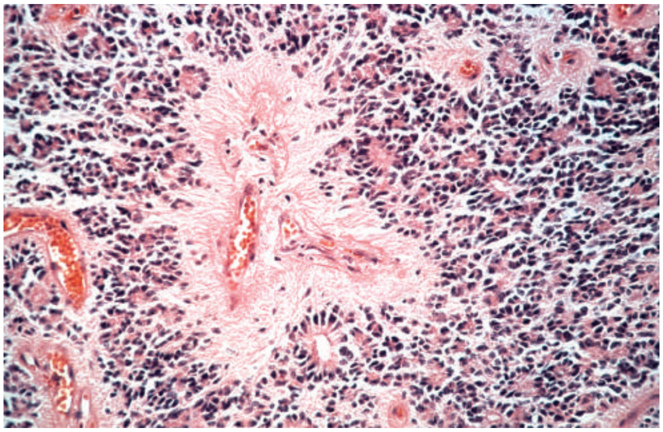

Fig. 23.31 Microscopic appearance of ependymoma.

- *Dysembryoplastic neuroepithelial tumor* is a distinctive, low-grade tumor of children and young adults that grows slowly, often manifests as a seizure disorder, and carries a favorable prognosis after resection. It typically is located in the superficial temporal lobe and consists of small, round neuronal cells arranged in columns and around central cores of processes.
- *Gangliogliomas* are tumors with a mixture of glial elements, usually a low-grade astrocytoma and mature-appearing neurons. Most of these tumors are slow growing, and often manifest with seizures. About 20% to 50% of gangliogliomas harbor point mutations in the *BRAF* gene.

Embryonal (Primitive) Neoplasms

Some tumors of neuroectodermal origin have a primitive "small round cell" appearance that is reminiscent of normal progenitor cells encountered in the developing CNS. Differentiation is often limited, but may progress along multiple lineages. The most common is the *medulloblastoma,* accounting for 20% of pediatric brain tumors.

Medulloblastoma

Medulloblastoma occurs predominantly in children and exclusively in the cerebellum. Neuronal and glial markers are nearly always expressed, at least to a limited extent. It is highly malignant, and the prognosis for untreated patients is dismal; however, medulloblastoma is exquisitely radiosensitive. With total excision, chemotherapy, and irradiation, the 5-year survival rate may be as high as 75%. There are a series of histologic patterns observed in medulloblastoma, which are informative about prognosis and correlate in part with the underlying genetics.

MORPHOLOGY

In children, medulloblastomas are located in the midline of the cerebellum; lateral tumors occur more often in adults. The tumor often is well circumscribed, gray, and friable and may be seen extending to the surface of the cerebellar folia and involving the leptomeninges (Fig. 23.32A). Medulloblastomas are densely cellular, with sheets of anaplastic ("small blue") cells (see Fig. 23.32B). Individual tumor cells are small, with little cytoplasm and hyperchromatic nuclei; mitoses are abundant. Often, focal neuronal differentiation is seen in the form of rosettes, which closely resemble the rosettes encountered in neuroblastomas; they are characterized by primitive tumor cells surrounding central neuropil (delicate pink material formed by neuronal processes).

Pathogenesis

Genetic analysis of medulloblastoma has revealed several subtypes associated with different clinical outcomes. Current approaches separate medulloblastoma into distinct groups with different core pathogenic pathways or driver mutations. Examples of oncogenic pathways in these tumors are the following:

- *Wnt pathway activation,* most commonly associated with gain of function mutations in the gene for β-catenin; these have the most favorable prognosis of all of the genetic subtypes and are commonly classic-type tumors.
- *Hedgehog pathway activation,* most commonly associated with loss of function mutations in *PTCH1,* a negative regulator of the Hedgehog; these tumors have an intermediate prognosis, but the concomitant presence of *TP53* mutation confers a very poor prognosis.
- *MYC overexpression,* due to *MYC* amplification as well as other changes that result in increased expression; these tumors have the poorest prognosis.

Clinical trials are ongoing that seek to tailor therapy targeted to molecular alterations, with the goal of avoiding radiation therapy when possible.

Other Parenchymal Tumors

Primary Central Nervous System Lymphoma

Primary CNS lymphoma, occurring mostly as diffuse large B-cell lymphomas, accounts for 2% of extranodal lymphomas and 1% of intracranial tumors. It is the most common CNS neoplasm in immunosuppressed individuals, in

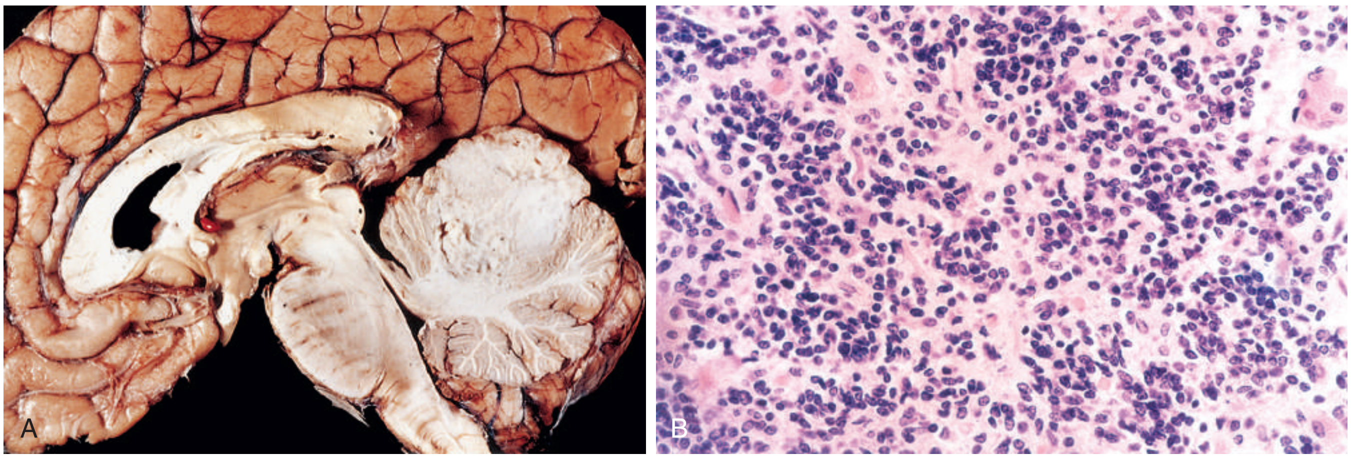

Fig. 23.32 Medulloblastoma. (A) Sagittal section of a brain showing medulloblastoma involving the superior vermis of the cerebellum. (B) Microscopic appearance of medulloblastoma, showing mostly small, blue, primitive-appearing tumor cells.

whom the tumors are nearly always positive for Epstein-Barr virus (EBV). In nonimmunosuppressed populations, the age spectrum is relatively wide, with the incidence increasing after 60 years of age. Regardless of the clinical context, primary brain lymphoma is an aggressive disease with a relatively poor response to chemotherapy as compared with peripheral lymphomas.

Patients with primary brain lymphoma often are found to have multiple tumor nodules within the brain parenchyma, yet involvement of sites outside of the CNS is uncommon. Conversely, lymphoma originating outside the CNS rarely spreads to the brain parenchyma; when this occurs, the tumor usually also involves the CSF or the meninges.

MORPHOLOGY

Lesions often involve deep gray structures, as well as the white matter and the cortex. Periventricular spread is common. The tumors are relatively well defined as compared with glial neoplasms, but they are not as discrete as metastases. EBV-associated tumors often show extensive areas of necrosis. The tumors are nearly always aggressive large B-cell lymphomas, although other histologic types may be encountered. Microscopically, malignant lymphoid cells accumulate around blood vessels and infiltrate the surrounding brain parenchyma. The diagnosis is confirmed by immunohistochemistry for B cell markers such as CD20, which also is a target of therapeutic antibodies.

Germ Cell Tumors

Primary brain *germ cell tumors* occur along the midline, most commonly in the pineal and the suprasellar regions. They account for 0.2% to 1% of brain tumors in individuals of European descent but in as many as 10% of brain tumors in individuals of Japanese ethnicity. They are a tumor of the young, with 90% occurring during the first 2 decades of life. Germ cell tumors in the pineal region show a strong male predominance. The most common primary CNS germ cell tumor is *germinoma,* a tumor that closely resembles testicular seminoma (Chapter 18). Secondary CNS involvement by metastatic gonadal germ cell tumors also occurs.

Meningiomas

Meningiomas are predominantly benign tumors that arise from arachnoid meningothelial cells. They usually occur in adults and are often attached to the dura. Meningiomas may be found along any of the external surfaces of the brain as well as within the ventricular system, where they arise from the stromal arachnoid cells of the choroid plexus. They often come to attention because of vague nonlocalizing symptoms, or with focal findings referable to compression of adjacent brain. Most meningiomas are easily separable from underlying brain, but some tumors are infiltrative, a feature associated with an increased risk for recurrence. The overall prognosis is determined by the lesion size and location, surgical accessibility, and histologic grade.

When an individual has multiple meningiomas, especially in association with eighth-nerve schwannomas or glial tumors, the diagnosis of neurofibromatosis type 2 (NF2) should be considered (Chapter 22). About half of meningiomas not associated with NF2 have somatic loss-of-function mutations in the *NF2* tumor suppressor gene on the long arm of chromosome 22 (22q). These mutations are found in all grades of meningioma, suggesting that they are involved in tumor initiation. Among sporadic tumors that lack mutations in *NF2*, several other driver mutations have been identified including in genes that regulate the Hedgehog pathway as well as in various signaling molecules and transcription factors.

MORPHOLOGY

Meningiomas (WHO grade I) grow as well-defined durabased masses that may compress the brain but do not typically invade it (Fig. 23.33A). Extension into the overlying bone may be present. The varied histologic patterns include: **meningothelial,** named for whorled, tight clusters of cells without visible cell membranes; **fibroblastic,** with elongated cells and abundant collagen deposition; **transitional,** with features of the meningothelial and fibroblastic types; **psammomatous,** with numerous psammoma bodies (see Fig. 23.33B); and **secretory,** with glandlike spaces containing PAS-positive eosinophilic material.

Atypical meningiomas (WHO grade II) are recognized by the presence of either an increased mitotic rate, or prominent nucleoli, increased cellularity, patternless growth, high nucleus-to-cytoplasm ratio, or necrosis. These tumors demonstrate more aggressive local growth and a higher rate of recurrence and may require therapy in addition to surgery. Some histologic patterns—clear cell and chordoid—also correlate with more aggressive behavior, as does the presence of brain invasion.

Anaplastic (malignant) meningiomas (WHO grade III) are highly aggressive tumors that may resemble a high-grade sarcoma or carcinoma morphologically. Mitotic rates are typically much higher than in atypical meningiomas.

Metastatic Tumors

Metastatic lesions, mostly carcinomas, account for approximately one-fourth to one-half of intracranial tumors. The most common primary sites are lung, breast, skin (melanoma), kidney, and gastrointestinal tract, which together account for about 80% of cases. Metastases form sharply demarcated masses, often at the grey-white matter junction, and elicit local edema (Fig. 23.34). The boundary between tumor and brain parenchyma is sharp at the microscopic level as well, with surrounding reactive gliosis.

In addition to the direct and localized effects produced by metastases, *paraneoplastic syndromes* may involve the peripheral and central nervous systems, sometimes even preceding the clinical recognition of the malignant neoplasm. Many patients with paraneoplastic syndromes have antibodies against tumor antigens. Some of the more common patterns include the following:

- *Subacute cerebellar degeneration* resulting in ataxia, with destruction of Purkinje cells, gliosis, and a mild inflammatory infiltrate

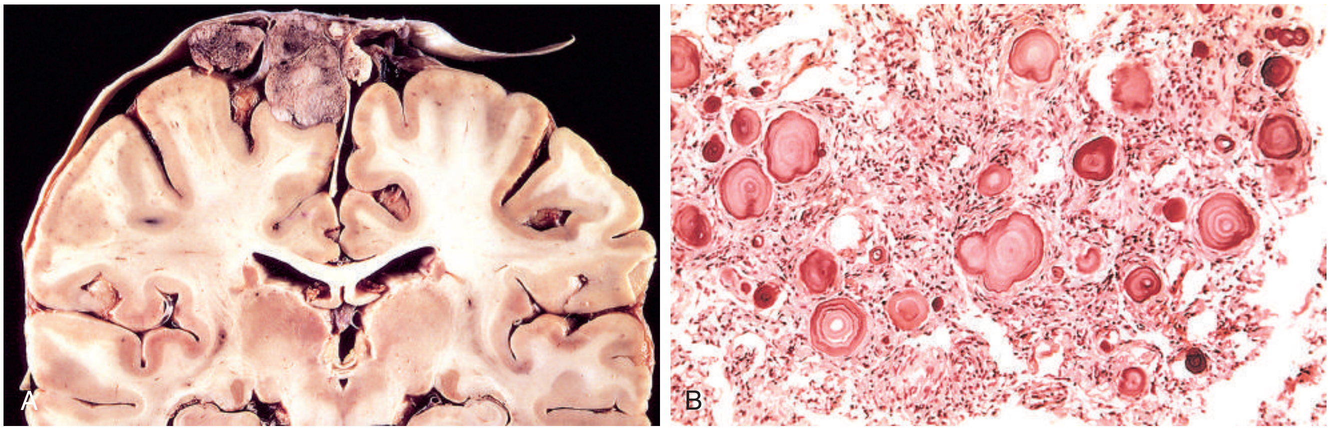

Fig. 23.33 Meningioma. (A) Parasagittal multilobular meningioma attached to the dura with compression of underlying brain. (B) Meningioma with a whorled pattern of cell growth and psammoma bodies.

- *Limbic encephalitis* causing a subacute dementia, with perivascular inflammatory cells, microglial nodules, neuronal loss, and gliosis, all centered in the medial temporal lobe
- *Subacute sensory neuropathy* leading to altered pain sensation, with loss of sensory neurons from dorsal root ganglia, in association with inflammation
- *Syndrome of rapid-onset psychosis, catatonia, epilepsy, and coma* associated with ovarian teratoma and antibodies against the *N*-methyl-D-aspartate (NMDA) receptor.

Familial Tumor Syndromes

Several inherited syndromes caused by mutations in various tumor suppressor genes are associated with an increased risk for particular types of cancers. Those with particular involvement of the CNS are discussed here; familial syndromes associated with tumors of the peripheral nervous system are covered in Chapter 22.

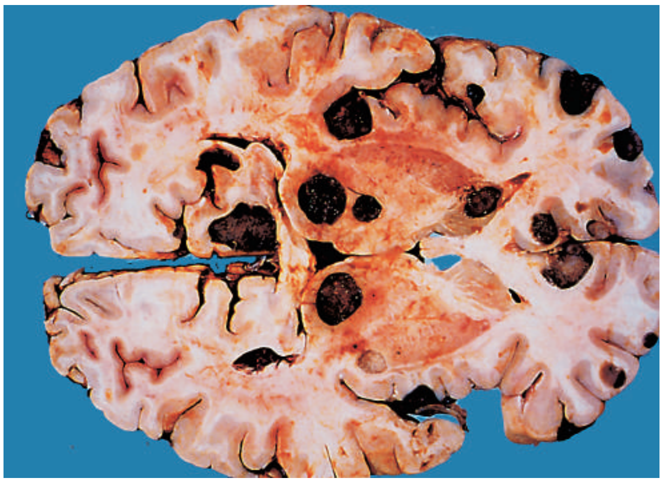

Fig. 23.34 Metastatic melanoma. Metastatic lesions are distinguished grossly from most primary central nervous system tumors by their multicentricity and well-demarcated margins. The dark color of the tumor nodules in this specimen is due to the presence of melanin.

Tuberous Sclerosis

Tuberous sclerosis is an autosomal dominant syndrome characterized by the development of hamartomas and benign neoplasms involving the brain and other tissues. CNS hamartomas variously consist of cortical tubers and subependymal hamartomas, including a larger tumefactive form known as *subependymal giant cell astrocytoma.* Because of their proximity to the foramen of Monro, they often present acutely with obstructive hydrocephalus, which requires surgical intervention and/or therapy with an mTOR inhibitor (see later). Seizures are associated with cortical tubers and can be difficult to control with anti-epileptic drugs. Extracerebral lesions include renal angiomyolipomas, retinal glial hamartomas, pulmonary lymphangiomyomatosis, and cardiac rhabdomyomas. Cysts may be found at various sites, including the liver, kidneys, and pancreas. Cutaneous lesions include angiofibromas, leathery thickenings in localized patches (shagreen patches), hypopigmented areas (ash leaf patches), and subungual fibromas.

Tuberous sclerosis results from disruption of either *TSC1,* which encodes hamartin, or *TSC2,* which encodes tuberin. The two TSC proteins form a dimeric complex that negatively regulates mTOR, a kinase that "senses" the cell's nutrient status and regulates cellular metabolism. Loss of either protein upregulates mTOR activity, which disrupts normal feedback mechanisms that restrict uptake of nutrients and leads to increased cell growth.

MORPHOLOGY

Cortical hamartomas are firmer than normal cortex and have been likened in appearance to potatoes—hence the appellation tubers. They are composed of haphazardly arranged large neurons that lack the normal cortical laminar architecture. These cells may exhibit a mixture of glial and neuronal features, having large vesicular nuclei with nucleoli (like neurons) and abundant eosinophilic cytoplasm. Similar abnormal cells are present in **subependymal nodules,** in which large astrocyte like cells cluster beneath the ventricular surface.

von Hippel–Lindau Disease

In this autosomal dominant disorder, affected individuals develop hemangioblastomas within the cerebellar hemispheres, retina, and, less commonly, the brain stem, spinal cord, and nerve roots. Patients also may have cysts involving the pancreas, liver, and kidneys and have an increased propensity to develop renal cell carcinoma. The disease frequency is 1 in 30,000 to 40,000. Therapy is directed at the symptomatic neoplasms, including surgical resection of cerebellar tumors and laser ablation of retinal tumors.

The affected gene, the tumor suppressor *VHL*, encodes a protein that is part of a ubiquitin-ligase complex that degrades the transcription factor hypoxia-inducible factor (HIF). Tumors arising in patients with von Hippel–Lindau disease generally have lost all VHL protein function. As a result, the tumors express high levels of HIF, which drives the expression of VEGF, various growth factors, and sometimes erythropoietin; the latter effect may produce a paraneoplastic form of polycythemia.

MORPHOLOGY

Hemangioblastoma, the principal neurologic manifestation of the disease, is a highly vascular neoplasm that occurs as a mural nodule associated with a large, fluid-filled cyst. These occur most commonly in the cerebellum, but can be found along the spinal cord and in the retina, and rarely at other sites in the brain. On microscopic examination, the lesion consists of numerous capillary-sized or somewhat larger thin-walled vessels separated by intervening stromal cells with a vacuolated, lightly PAS-positive, lipid-rich cytoplasm. These stromal cells express inhibin, a member of the TGF-β family, which serves as a useful diagnostic marker.

SUMMARY

TUMORS OF THE CENTRAL NERVOUS SYSTEM

- Tumors of the CNS may arise from the cells of the coverings (meningiomas), the brain (gliomas, neuronal tumors, choroid plexus tumors), or other CNS cell populations (primary CNS lymphoma, germ cell tumors), or they may originate elsewhere in the body (metastases).
- Even low-grade or benign tumors can have poor clinical outcomes, depending on where they occur in the brain.
- Distinct types of tumors affect specific brain regions (e.g., cerebellum for medulloblastoma, an intraventricular location for central neurocytoma) and specific age populations (medulloblastoma and pilocytic astrocytomas in pediatric age groups, and glioblastoma and lymphoma in older patients).
- Glial tumors are broadly classified into astrocytomas, oligodendrogliomas, and ependymomas. Increasing tumor malignancy is associated with more cytologic anaplasia, increased cell density, necrosis, and mitotic activity.
- Metastatic spread of brain tumors to other regions of the body is rare, but the brain is not comparably protected against the spread of distant tumors. Carcinomas are the dominant type of systemic tumors that metastasize to the nervous system.

CHAPTER 24

Skin

CHAPTER OUTLINE

Skin diseases are common and diverse, ranging from irritating acne to life-threatening melanoma. Many are intrinsic to the skin, but some are manifestations of diseases involving many tissues, such as systemic lupus erythematosus or genetic syndromes such as neurofibromatosis. In this sense, the skin is a uniquely accessible "window" through which numerous disorders can be recognized.

Skin is not a mere protective mantle but rather a complex organ, actually the largest in the body. It is constantly exposed to microbial and nonmicrobial antigens from the environment. Given this, it is not surprising that the skin is an active participant in immune responses. Environmentally derived antigens are processed by intraepithelial Langerhans cells, which bear their antigenic cargo to regional lymph nodes and initiate immune responses. Squamous cells (keratinocytes) help maintain skin homeostasis by providing a physical barrier to environmental insults and by secreting a plethora of cytokines that influence both the squamous and dermal microenvironments. The dermis contains resident populations of CD4+ helper and CD8+ cytotoxic T lymphocytes, some of which home to the skin by virtue of specialized receptors such as cutaneous lymphocyte antigen, as well as memory T cells, regulatory T cells (T_{regs}) and occasional B cells. The epidermis contains intraepithelial lymphocytes, including γ/δ T cells, while the dermis contains perivascular mast cells and scattered macrophages, all components of the innate immune system. Responses involving these immune cells and locally released cytokines account for the morphologic patterns and clinical expressions of inflammatory and infectious skin disorders.

This chapter focuses on common and pathogenically illustrative skin diseases. In considering these diseases, it is important to appreciate that the practice of dermatopathology relies on close interactions with clinicians, particularly dermatologists, as the clinical history, gross appearance, and distribution of lesions are often as important as the microscopic findings in arriving at a specific diagnosis. Diseases of the skin can be confusing for the student, in part because dermatologists and dermatopathologists communicate using a large, "skin-specific" lexicon that students must become familiar with in order to understand skin diseases. The most important of these terms and definitions are listed in Table 24.1.

The contributions of Dr. George Murphy to this chapter in previous editions are gratefully acknowledged.

ACUTE INFLAMMATORY DERMATOSES

Thousands of inflammatory dermatoses exist, challenging the diagnostic acumen of even experienced clinicians. In general, acute lesions, defined as days to several weeks in duration, are characterized by inflammation, edema, and sometimes epidermal, vascular, or subcutaneous injury. Acute dermatoses are often marked by infiltrates consisting of mononuclear cells rather than neutrophils, unlike acute inflammatory disorders at most other sites. Some acute lesions may persist, transitioning to a chronic phase, while others are self-limited.

Urticaria

Urticaria ("hives") is a common disorder mediated by localized mast cell degranulation, which leads to dermal microvascular hyperpermeability. The resulting erythematous, edematous, and pruritic plaques are termed *wheals.*

Pathogenesis

In most cases, urticaria stems from an immediate (type 1) hypersensitivity reaction (Chapter 5), in which antigens trigger mast cell degranulation by binding to

Table 24.1 Nomenclature of Skin Lesions

Macroscopic Lesions	Definition
Excoriation	Traumatic lesion breaking the epidermis and causing a raw linear area (i.e., deep scratch); often self-inflicted
Lichenification	Thickened, rough skin (similar to a lichen on a rock); usually the result of repeated rubbing
Macule, patch	Circumscribed, flat lesion distinguished from surrounding skin by color. Macules are 5 mm in diameter or less, while patches are greater than 5 mm in size.
Papule, nodule	Elevated dome-shaped or flat-topped lesion. Papules are 5 mm in diameter or less, while nodules are greater than 5 mm in size.
Plaque	Elevated flat-topped lesion, usually greater than 5 mm in diameter (may be formed by coalescence of papules)
Pustule	Discrete, pus-filled, raised lesion
Scale	Dry, horny, platelike excrescence; usually the result of imperfect cornification
Vesicle, bulla, blister	Fluid-filled raised lesion 5 mm or less in diameter (vesicle) or greater than 5 mm in diameter (bulla). *Blister* is the common term for both lesions.
Wheal	Itchy, transient, elevated lesion with variable blanching and erythema formed as the result of dermal edema
Microscopic Lesions	**Definition**
Acanthosis	Diffuse epidermal hyperplasia
Dyskeratosis	Abnormal, premature keratinization within cells below the stratum granulosum
Hyperkeratosis	Thickening of the stratum corneum, often associated with a qualitative abnormality of the keratin
Papillomatosis	Surface elevation caused by hyperplasia and enlargement of contiguous dermal papillae
Parakeratosis	Retention of nuclei in the stratum corneum of a squamous epithelium. On mucous membranes, parakeratosis is normal.
Spongiosis	Intercellular edema of the epidermis

immunoglobulin E (IgE) antibodies attached to the mast cell surface through their Fc receptor. Responsible antigens include viruses, pollens, foods, drugs, and insect venom. IgE-independent urticaria also can result from exposure to substances that directly incite mast cell degranulation, such as opiates and certain antibiotics. In the vast majority of cases, no clinical cause is discovered even with extensive investigation.

MORPHOLOGY

The histologic features of urticaria often are subtle. There is usually a sparse superficial perivenular infiltrate of mononuclear cells, rare neutrophils, and sometimes eosinophils. Superficial dermal edema causes splaying of collagen bundles, making them appear to be more widely spaced than normal. Degranulation of mast cells, which reside around superficial dermal venules, is difficult to appreciate with routine hematoxylin-eosin (H&E) stains but can be highlighted using a Giemsa stain.

Clinical Features

Urticaria typically affects individuals between 20 and 40 years of age, but no age is immune. Individual lesions usually develop and fade within hours, but episodes can persist for days or even months. Lesions range in size and nature from small, pruritic papules to large, edematous, erythematous plaques. They may be localized to a particular part of the body or generalized. In a specific type of urticaria termed *pressure urticaria,* lesions are found only in areas exposed to pressure (such as the feet or buttocks). Although not life-threatening, severe pruritus and the social embarrassment of urticaria can compromise quality of life. Most cases respond to antihistamines, but more severe, refractory disease may require treatment with leukotriene antagonists, monoclonal antibodies that block the action of IgE, or immunosuppressive drugs.

Acute Eczematous Dermatitis

Eczema is a clinical term that embraces a number of conditions with varied underlying etiologies. New lesions take the form of erythematous papules, often with overlying vesicles, which ooze and become crusted. Pruritus is characteristic. With persistence, these lesions coalesce into raised, scaling plaques. The nature and degree of these changes vary among the clinical subtypes, which include the following:

- *Allergic contact dermatitis* – stems from topical exposure to an allergen and is caused by delayed hypersensitivy reactions.
- *Atopic dermatitis* – formerly attributed to allergen exposure, now thought to often stem from defects in keratinocyte barrier function, defined as skin with increased permeability to substances to which it is exposed, such as potential antigens
- *Drug-related eczematous dermatitis* – hypersensitivity reaction to a drug
- *Photoeczematous dermatitis* – appears as an abnormal reaction to UV or visible light
- *Primary irritant dermatitis* – results from exposure to substances that chemically, physically, or mechanically damage the skin

While atopic dermatitis reflects a genetic predisposition and can persist for years or decades, other forms of eczematous dermatitis resolve completely when the offending stimulus is removed or exposure is limited, stressing the importance of investigating the underlying cause. Only the most common form, *contact dermatitis,* is considered here.

Allergic contact dermatitis is triggered by exposure to an environmental contact-sensitizing agent, such as poison ivy, that chemically reacts with self-proteins, creating neoantigens that can be recognized by the T cell

arm of the adaptive immune system. The self-proteins modified by the agent are processed by epidermal Langerhans cells, which migrate to draining lymph nodes and present the antigen to naïve T cells. This sensitization event leads to acquisition of immunologic memory; on reexposure to the antigen, the activated memory CD4+ T lymphocytes migrate to the affected skin sites during the course of normal circulation. There they release cytokines that recruit additional inflammatory cells and also mediate epidermal damage, as in any delayed-type hypersensitivity reaction (Chapter 5).

MORPHOLOGY

As the name implies, skin involvement in contact dermatitis is limited to sites of direct contact with the triggering agent (Fig. 24.1A), whereas in other forms of eczema, lesions may be widely distributed. **Spongiosis,** or epidermal edema, characterizes all forms of acute eczematous dermatitis—hence the synonym **spongiotic dermatitis.** Edema fluid seeps into the epidermis, where it splays apart keratinocytes (Fig. 24.1B). Intercellular bridges are stretched and become more prominent and are easier to visualize. This change is accompanied by a superficial perivascular lymphocytic infiltrate, edema of dermal papillae, and mast cell degranulation. Eosinophils may be present and are especially prominent in spongiotic eruptions provoked by drugs, but in general the histologic features are similar regardless of cause, emphasizing the need for careful clinical correlation.

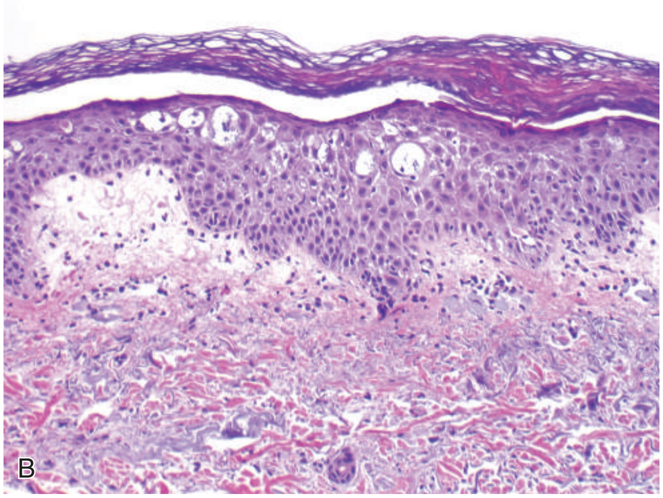

Fig. 24.1 Eczematous dermatitis. (A) Patterned erythema and scale stemming from a nickel-induced contact dermatitis produced by a necklace. (B) Microscopically, there is accumulation of fluid (spongiosis) between epidermal cells, which may progress to frank blister formation.

Clinical Features

Lesions of acute eczematous dermatitis are pruritic, edematous, oozing plaques, often containing vesicles and bullae. With persistent antigen exposure, lesions may become scaly (hyperkeratotic) as the epidermis thickens (acanthosis). Some changes are produced or exacerbated by scratching of the lesion (see "Lichen Simplex Chronicus", discussed later). The clinical causes of eczema are sometimes divided into "inside jobs"—reaction to an internal circulating antigen (such as an ingested food or drug)—and "outside jobs"—disease resulting from contact with an external antigen (such as poison ivy).

Susceptibility to atopic dermatitis is often inherited; the disorder is concordant in 80% of identical twins and 20% of fraternal twins. It usually appears in early childhood and remits spontaneously as patients mature into adults. Children with atopic dermatitis often have asthma and allergic rhinitis, termed the *atopic triad.* Recent genetic studies have identified polymorphisms associated with increased risk in genes that encode proteins involved in keratinocyte barrier function, innate immunity, and T cell function.

Erythema Multiforme

Erythema multiforme is characterized by epithelial injury mediated by skin-homing CD8+ cytotoxic T lymphocytes. It is an uncommon, usually self-limited disorder that appears to be a hypersensitivity response to certain infections and drugs. Antecedent infections include those caused by herpes simplex, mycoplasma, and some fungi, while implicated drugs include sulfonamides, penicillin, salicylates, hydantoins, and anti-malarials. The cytotoxic T cell attack is focused on the basal cells of cutaneous and mucosal epithelia, presumably due to recognition of still unknown antigens. Certain human lymphocyte antigen (HLA) haplotypes are associated with the disease.

MORPHOLOGY

Affected individuals present with a wide array of lesions, which may include macules, papules, vesicles, and bullae (hence the term *multiforme*). Well-developed lesions have a characteristic "targetoid" appearance (Fig. 24.2A). Early lesions show a superficial perivascular lymphocytic infiltrate associated with dermal edema and margination of lymphocytes along the dermoepidermal junction in intimate association with apoptotic keratinocytes (see Fig. 24.2B). With time, discrete, confluent zones of basal

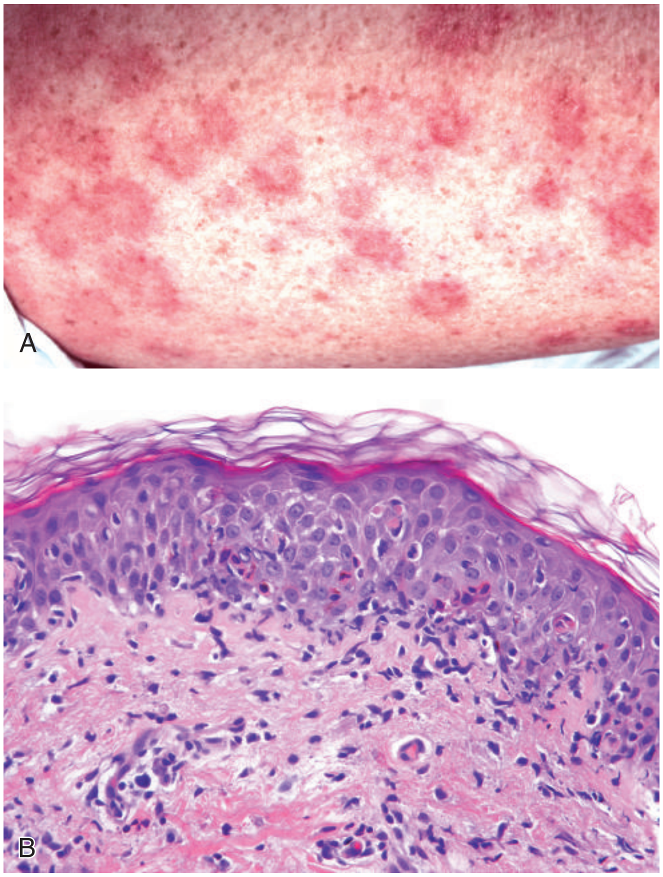

Fig. 24.2 Erythema multiforme. (A) Target like lesions consisting of a pale central blister or zone of epidermal necrosis surrounded by macular erythema. (B) Early lesions show lymphocytes along the dermoepidermal junction (interface dermatitis) associated with scattered apoptotic keratinocytes, marked by dark shrunken nuclei and eosinophilic cytoplasm.

epidermal necrosis appear, with concomitant blister formation. In a rarer and more severe form of this disease, **toxic epidermal necrolysis,** the necrosis extends through the full thickness of the epidermis.

Clinical Features

Erythema multiforme has a broad range of severity. The forms associated with infection (most often herpesvirus) are less severe. Erythema multiforme caused by medications may progress to more serious eruptions, such as Stevens-Johnson syndrome or toxic epidermal necrolysis. These forms can be life-threatening, as they may cause sloughing of large portions of the epidermis, resulting in fluid loss and infections complications similar to those seen in burn-injured patients.

CHRONIC INFLAMMATORY DERMATOSES

Chronic inflammatory dermatoses are persistent skin conditions that exhibit their most characteristic features over many months to years, although they may begin with an acute stage. The skin surface in some chronic inflammatory dermatoses is roughened as a result of excessive or abnormal scale formation and shedding *(desquamation).*

Psoriasis

Psoriasis is a common chronic inflammatory dermatosis, affecting 1% to 2% of individuals residing in the United States. Recent epidemiologic studies have shown that psoriasis is associated with an increased risk for heart attack and stroke, a relationship that may be related to a chronic inflammatory state. Psoriasis also is associated in up to 10% of patients with arthritis, which in some cases may be severe.

Pathogenesis

Psoriasis is a T cell-mediated inflammatory disease, presumed to be autoimmune in origin, although the antigens are not well described. Both genetic (HLA types and other susceptibility loci) and environmental factors contribute to the risk. It is unclear whether the inciting antigens are self-antigens, environmental antigens, or some combination of the two. Sensitized populations of T cells home to the dermis, including CD4+ T_H17 and T_H1 cells and CD8+ T cells, and accumulate in the epidermis. These cells secrete cytokines and growth factors that induce keratinocyte hyperproliferation, resulting in the characteristic lesions. Psoriatic lesions can be induced in susceptible individuals by local trauma *(Koebner phenomenon),* which may induce a local inflammatory response that promotes lesion development. Genome-wide association studies (GWAS) have linked an increased risk for psoriasis to polymorphisms in HLA loci and genes affecting antigen presentation, TNF signaling, and skin barrier function. Several loci also are associated with the development of psoriatic arthritis, a more severe complication of this disease.

MORPHOLOGY

The typical lesion is a **well-demarcated, pink to salmon–colored plaque covered by loosely adherent silver-white scale** (Fig. 24.3A). There is marked epidermal thickening **(acanthosis),** with regular downward elongation of the rete ridges (see Fig. 24.3B). The pattern of this downward growth has been likened to "test tubes in a rack." Increased epidermal cell turnover and lack of maturation results in **loss of the stratum granulosum and extensive parakeratotic scale.** Also seen is thinning of the epidermal cell layer overlying the tips of dermal papillae (suprapapillary plates), and dilated and tortuous blood vessels within the papillae. These vessels bleed readily when the scale is removed, giving rise to multiple punctate bleeding points **(Auspitz sign).** Neutrophils form small aggregates within both the spongiotic superficial epidermis and the parakeratotic stratum corneum. Similar changes can be seen in superficial fungal infections, which need to be excluded with appropriate special stains.

Clinical Features

Psoriasis most frequently affects the skin of the elbows, knees, scalp, lumbosacral areas, intergluteal cleft, glans penis, and vulva. Nail changes on the fingers and toes occur in 30% of cases. In most cases psoriasis is limited in

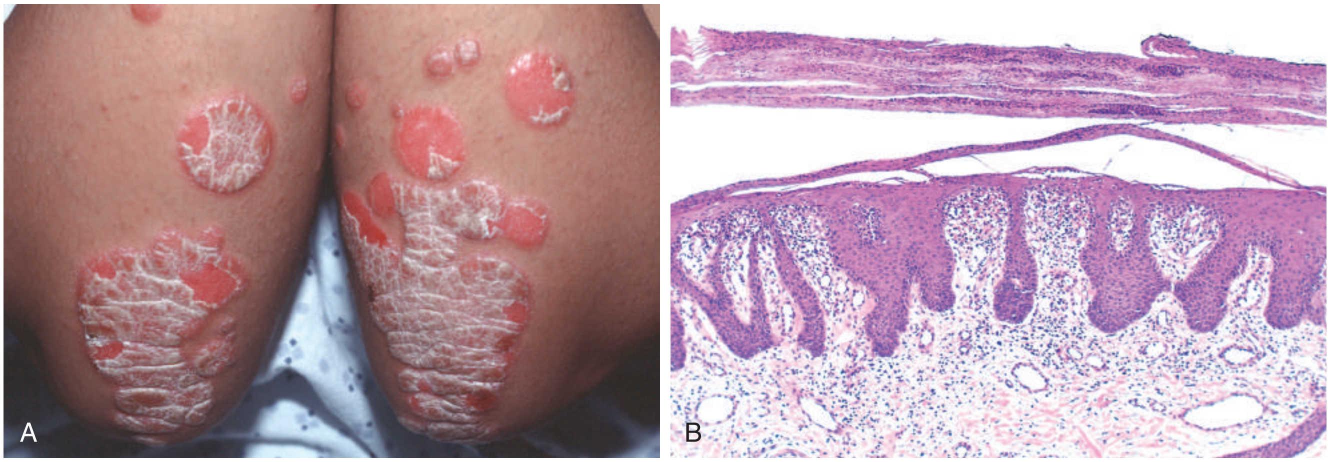

Fig. 24.3 Chronic psoriasis. (A) Erythematous psoriatic plaques covered by silvery-white scale. (B) Microscopic examination shows marked epidermal hyperplasia, downward extension of rete ridges (psoriasiform hyperplasia), and prominent parakeratotic scale with infiltrating neutrophils.

distribution, but it can be widespread and severe. The clinical subtypes are defined by pattern of involvement and severity. Treatment is aimed at preventing the release or actions of inflammatory mediators. Mild disease is treated topically with ointments containing corticosteroids or other immunomodulatory agents, whereas more severe disease is treated with phototherapy (which has immunosuppressive effects) or systemic therapy with immunosuppressive agents such as methotrexate or TNF antagonists.

Lichen Planus

"Pruritic, purple, polygonal, planar papules, and plaques" are the tongue-twisting *P*s that describe this disorder of skin and squamous mucosa. The lesions may result from a CD8+ T cell–mediated cytotoxic response against antigens in the basal cell layer and the dermoepidermal junction that are produced by unknown mechanisms, perhaps as a consequence of a viral infection or drug exposure.

MORPHOLOGY

Cutaneous lesions of lichen planus consist of **pruritic, violaceous, flat-topped papules** that may coalesce focally to form plaques (Fig. 24.4A). These papules are highlighted by white dots or lines termed **Wickham striae.** Hyperpigmentation may result from melanin loss into the dermis from damaged keratinocytes. Microscopically, lichen planus is a prototypical **interface dermatitis,** so called because the inflammation and damage are concentrated at the interface of the squamous epithelium and papillary dermis. There is a dense, continuous infiltrate of lymphocytes along the dermoepidermal junction (see Fig. 24.4B). The lymphocytes are intimately associated with basal keratinocytes, which often atrophy or become necrotic. Perhaps as a response to damage, the basal cells take on the appearance of the more mature cells of the stratum spinosum (squamatization). This pattern of inflammation causes the dermoepidermal interface to assume an angulated, zigzag contour **(sawtoothing).** Anucleate, necrotic basal cells are seen in the inflamed papillary dermis and are referred to as colloid bodies or **Civatte bodies.** Although these changes bear some similarities to those in erythema multiforme (another type of interface dermatitis discussed earlier), lichen planus shows well-developed changes of chronicity, including epidermal hyperplasia, hypergranulosis, and hyperkeratosis.

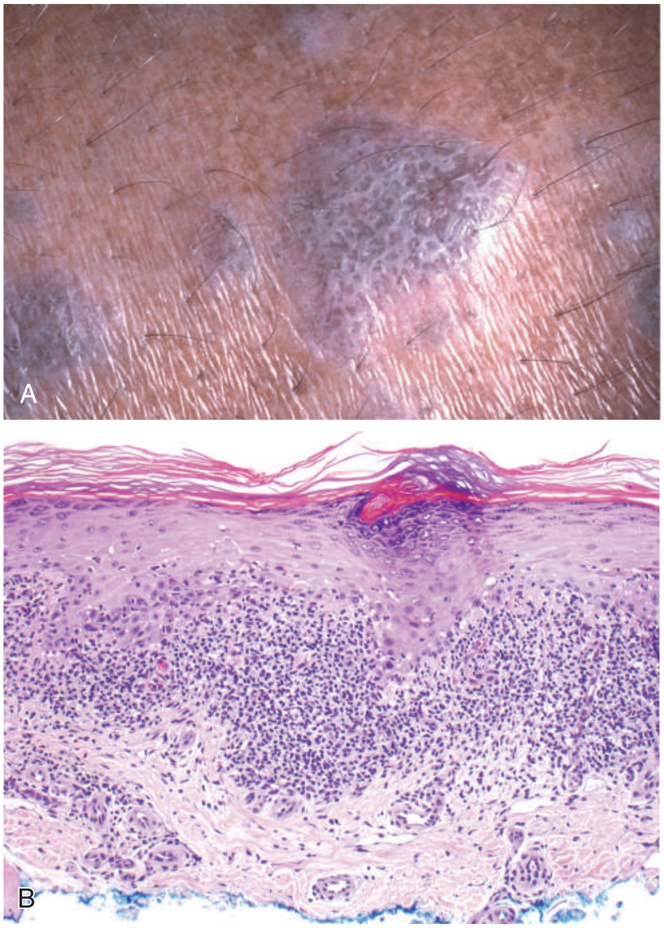

Fig. 24.4 Lichen planus. (A) Flat-topped pink-purple polygonal papule with white lacelike markings referred to as *Wickham striae.* (B) Microscopic examination shows a bandlike infiltrate of lymphocytes along the dermoepidermal junction, hyperkeratosis, hypergranulosis, and pointed rete ridges ("sawtoothing"), which results from chronic injury of the basal cell layer.

Clinical Features

Lichen planus is an uncommon disorder that usually presents in middle-aged adults. The cutaneous lesions are multiple and are usually symmetrically distributed, particularly on the extremities, and often occur around the wrists and elbows and on the vulva and glans penis. Approximately 70% of cases also involve the oral mucosa, where the lesions manifest as white papules with a reticulate or netlike appearance. The cutaneous lesions of lichen planus usually resolve spontaneously within 1 to 2 years, but the oral lesions may persist and be of sufficient severity to interfere with food intake.

Lichen Simplex Chronicus

Lichen simplex chronicus manifests as roughening of the skin, which takes on an appearance reminiscent of lichen on a tree. It is a response to local repetitive trauma, usually from rubbing or scratching. Nodular forms exist that are referred to as *prurigo nodularis.* The pathogenesis of lichen simplex chronicus is not understood, but the trauma probably induces epithelial hyperplasia and eventual dermal scarring.

MORPHOLOGY

Lichen simplex chronicus is characterized by **acanthosis, hyperkeratosis,** and **hypergranulosis.** Also seen are elongation of the rete ridges, fibrosis of the papillary dermis, and a dermal chronic inflammatory infiltrate (Fig. 24.5). Of interest, these lesions are similar in appearance to normal volar (palms and soles) skin, in which skin thickening serves as an adaptation to repetitive mechanical stress.

Clinical Features

The lesions often are raised, erythematous, and scaly and can be mistaken for keratinocytic neoplasms. Lichen simplex chronicus can be superimposed on and mask another (often pruritic) dermatosis. It is therefore important to rule out an underlying cause while recognizing that the lesion may be entirely trauma-related.

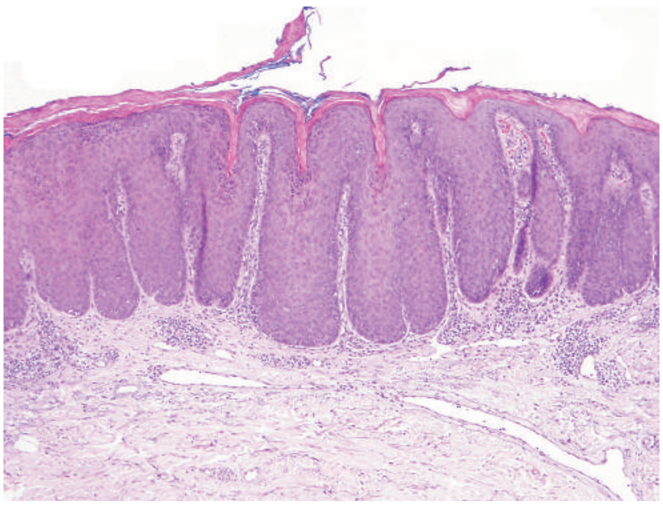

Fig. 24.5 Lichen simplex chronicus. Note the distinctive acanthosis, hyperkeratosis, and hypergranulosis. Superficial dermal fibrosis and vascular ectasia, both common features, also are present.

SUMMARY

INFLAMMATORY DERMATOSES

- Many specific inflammatory dermatoses exist and can be mediated by IgE antibodies (urticaria), antigen-specific T cells (eczema, erythema multiforme, and psoriasis), or trauma (lichen simplex chronicus).
- Underlying genetic susceptibility plays a role in atopic dermatitis and psoriasis.
- These disorders can be grouped based on patterns of inflammation (e.g., interface dermatitis in lichen planus and erythema multiforme).
- Clinical correlation is essential to diagnose specific skin diseases, since many have overlapping, nonspecific histologic features.

INFECTIOUS DERMATOSES

Bacterial Infections

Numerous bacterial infections occur in skin. These range from superficial infections known as *impetigo,* to deeper dermal abscesses associated with puncture wounds that are caused by bacteria such as *Pseudomonas aeruginosa*. The pathogenesis is similar to that for microbial infections elsewhere (Chapter 9). Only impetigo is discussed here.

MORPHOLOGY

Impetigo is characterized by an accumulation of neutrophils beneath the stratum corneum that often produces a subcorneal pustule. Nonspecific reactive epidermal alternation and superficial dermal inflammation accompany these findings. Bacterial cocci in the superficial epidermis can be demonstrated by Gram stain.

Clinical Features

Impetigo, one of the most common bacterial infections of the skin, is seen primarily in children. The causative organism is usually *Staphylococcus aureus* or, less commonly, *Streptococcus pyogenes,* and is typically acquired through direct contact with a source. Impetigo often begins as a single small macule, usually on the extremities or the face near the nose or the mouth, which rapidly evolves into a larger lesion (Fig. 24.6), often with a honey-colored crust of dried serum. Individuals who are colonized by *S. aureus* or *S. pyogenes* (usually nasal or anal) are more likely to be affected. A less common bullous form of childhood impetigo may mimic an autoimmune blistering disorder.

Fungal Infections

Fungal infections are varied, ranging from superficial infections with *Tinea* or *Candida* spp. to life-threatening

Fig. 24.6 Impetigo. A child's arm involved by a superficial bacterial infection showing the characteristic erythematous scablike lesions crusted with dried serum. *(Courtesy of Dr. Angela Wyatt, Bellaire, Texas.)*

Aspergillus spp. infections in immunosuppressed individuals. Fungal infections can be superficial (stratum corneum, hair, and nails), deep (dermis or subcutis), or systemic, the last type arising through hematogenous spread, often in an immunocompromised patient.

MORPHOLOGY

The histologic appearance varies depending on the organism, host response, and degree of superinfection. Superficial infections are often associated with a neutrophilic infiltrate in the epidermis. Deep fungal infections produce greater tissue damage and often elicit a granulomatous response. *Aspergillus* can be angioinvasive. Periodic acid–Schiff (PAS) and Gomori methenamine silver stains are helpful in identifying the fungal organisms.

Clinical Features

Superficial infections usually produce erythematous macules with superficial scale that can be pruritic, while deeper infections such as those seen with *Aspergillus* spp. are erythematous and often nodular and sometimes associated with local hemorrhage. Superficial fungal infections may have an annular appearance. However, they also may induce lesions that mimic other psoriasiform or eczematous dermatoses, so it is important to consider the possibility of fungal infection when these conditions are in the differential diagnosis.

Verrucae (Warts)

Verrucae are proliferative lesions of squamous epithelial cells that are caused by human papillomavirus (HPV). They are most common in children and adolescents, but may be encountered in any age group. HPV infection usually stems from direct contact with an infected individual or autoinoculation. Verrucae generally are self-limited, most often regressing spontaneously within 6 months to 2 years.

Pathogenesis

While some members of the HPV family are associated with preneoplastic and invasive cancers of the anogenital region (Chapters 6 and 18), cutaneous warts are mainly caused by low-risk HPV subtypes that lack transforming potential. Like high-risk HPV, low-risk viruses express viral E6 and E7 oncoproteins that lead to dysregulated epidermal cell growth and increased survival. Why low-risk viruses cause warts instead of cancer is likely due to structural variation in E6 and E7 proteins that affect their interactions with host proteins. Because the growth of warts is normally halted by the immune response, immunodeficiency is associated with more numerous and larger verrucae.

MORPHOLOGY

Different kinds of warts are identified on the basis of their gross appearance and location and generally are caused by distinct HPV subtypes. **Verruca vulgaris** (Fig. 24.7A), the most common type of wart, can occur anywhere but is found most frequently on the hands, particularly on the dorsal surfaces and periungual areas, where it appears as a gray-white to tan, flat to convex, 0.1- to 1-cm papule with a rough, pebble like surface. **Verruca plana,** or **flat wart,** is common on the face or dorsal surfaces of the hands. These warts are flat, smooth, tan macules. **Verruca plantaris** and **verruca palmaris** occur on the soles and palms, respectively. These rough, scaly lesions can reach 1 to 2 cm in diameter and may coalesce to form a surface that can be confused with ordinary calluses. **Condyloma acuminatum (venereal wart)** occurs on the penis, female genitalia, urethra, and perianal areas (Chapters 18 and 19). Histologic features common to verrucae include **epidermal hyperplasia,** which is often undulant in character (so-called **verrucous** or **papillomatous epidermal hyperplasia**) (Fig. 24.7B, *top panel*), and cytoplasmic vacuolization **(koilocytosis),** which preferentially involves the more superficial epidermal layers, producing halos of pallor surrounding infected nuclei. Infected cells also may demonstrate prominent keratohyalin granules and jagged eosinophilic intracytoplasmic protein aggregates as a result of impaired maturation (Fig. 24.7B, *bottom panel*).

BLISTERING (BULLOUS) DISORDERS

Although vesicles and bullae (blisters) occur as secondary phenomena in several unrelated conditions (e.g., herpesvirus infection, spongiotic dermatitis), there is a group of disorders in which blisters are the primary and most distinctive feature. Blistering in these diseases tends to occur at specific levels within the skin, a morphologic distinction that is critical for diagnosis (Fig. 24.8).

Pemphigus (Vulgaris and Foliaceus)

Pemphigus is an uncommon autoimmune blistering disorder resulting from loss of normal intercellular attachments within the epidermis and the squamous mucosal epithelium. There are three major variants:

- Pemphigus vulgaris (the most common type)
- Pemphigus foliaceus
- Paraneoplastic pemphigus

The last entity is associated with internal malignancy and is not discussed here.

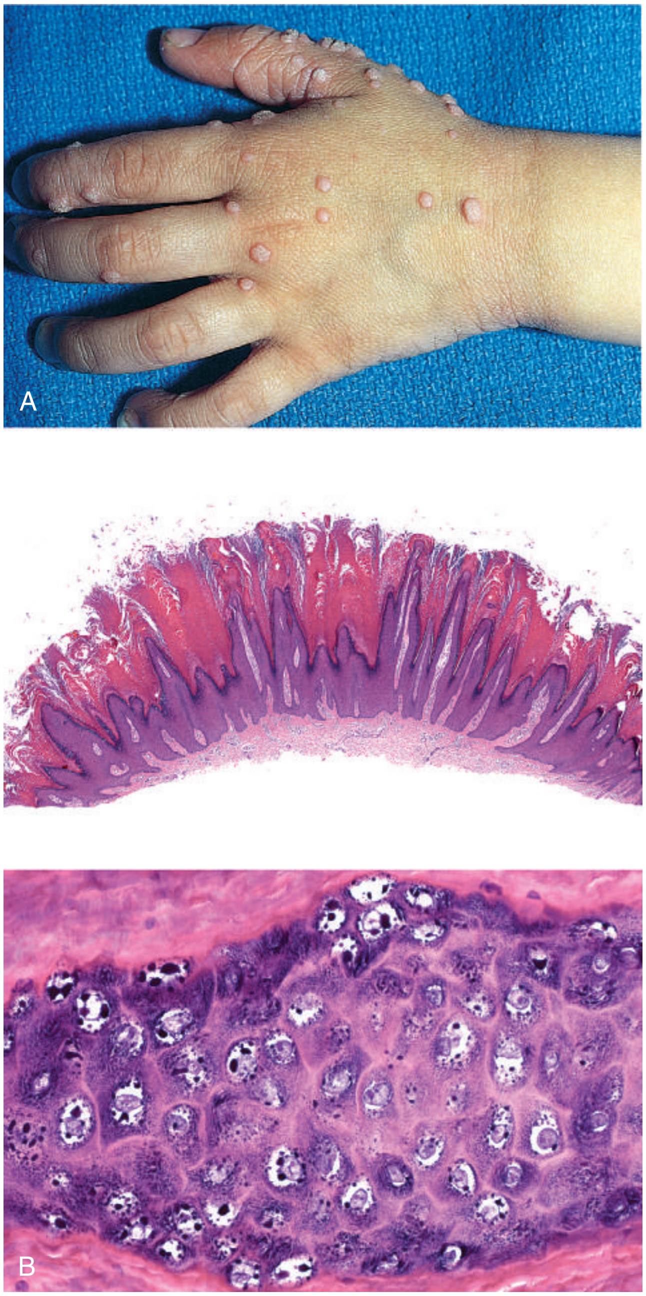

Fig. 24.7 Verruca vulgaris. (A) Multiple warts, with characteristic rough, pebble like surfaces. (B) Microscopically, common warts contain zones of papillary epidermal proliferation that often radiate symmetrically like the points of a crown *(top)*. Pallor or halos around nuclei, prominent keratohyalin granules, and related cytopathic changes are seen at higher magnification *(bottom)*.

Pathogenesis

Pemphigus vulgaris and pemphigus foliaceus are autoimmune diseases caused by antibody-mediated (type II) hypersensitivity reactions (Chapter 5). The pathogenic antibodies are IgG autoantibodies that bind to intercellular desmosomal proteins (desmoglein types 1 and 3) found in the skin and mucous membranes. The antibodies disrupt the intercellular adhesive function of desmosomes and may activate intercellular proteases as well. The distribution of desmoglein proteins within the epidermis determines the location of the lesions. By direct immunofluorescence study, lesional sites show a characteristic fishnet-like pattern of intercellular IgG deposits (Fig. 24.9). As with many other autoimmune diseases, pemphigus is associated with particular HLA alleles.

MORPHOLOGY

Pemphigus vulgaris involves both mucosa and skin, especially on the scalp, face, axillae, groin, trunk, and points of pressure. The lesions are superficial flaccid vesicles and bullae that rupture easily, leaving deep and often extensive erosions covered with a serum crust (Fig. 24.10A). **Pemphigus foliaceus,** a rare, milder form of pemphigus, results in bullae that are mainly confined to the skin, with only infrequent involvement of mucous membranes. The blisters in this disorder are superficial, such that more limited zones of erythema and crusting of ruptured blisters are seen (Fig. 24.11A).

The common histologic denominator in all forms of pemphigus is **acantholysis,** lysis of the intercellular adhesive junctions between neighboring squamous epithelial cells that results in the rounding up of detached cells. In pemphigus vulgaris, acantholysis selectively involves the layer of cells immediately above the basal cell layer, giving rise to a **suprabasal acantholytic blister** (Fig. 24.10B). In pemphigus foliaceus, acantholysis selectively involves the superficial epidermis at the level of the stratum granulosum (Fig. 24.11B). Variable superficial dermal infiltrates composed of lymphocytes, macrophages, and eosinophils accompany all forms of pemphigus.

Clinical Features

Pemphigus vulgaris is a rare disorder that occurs most commonly in older adults and more often in women than in men. Lesions are painful, particularly when ruptured, and frequently develop secondary infections. Most affected patients have oropharyngeal involvement at some point in their course. The mainstay of treatment is immunosuppressive therapy, sometimes for life. Medications can induce pemphigus, more often pemphigus foliaceus than pemphigus vulgaris. There is also an unusual endemic form of pemphigus foliaceus in South America *(fogo selvagem)* that is putatively associated with the bite of a black fly.

Bullous Pemphigoid

Bullous pemphigoid is another distinctive acquired blistering disorder with an autoimmune basis.

Pathogenesis

Blistering in bullous pemphigoid is triggered by the linear deposition of autoreactive IgG antibodies and complement in the epidermal basement membrane (Fig. 24.12A). Reactivity also occurs in the basement membrane attachment plaques (hemidesmosomes), where most bullous pemphigoid antigen (most commonly type XVII collagen) is located. The proteins that are recognized by the autoantibodies have structural roles in dermoepidermal adhesion. IgG autoantibodies to hemidesmosome components fix complement and cause tissue injury by recruiting neutrophils and eosinophils. Bullous pemphigoid and pemphigus vulgaris are thus caused by similar pathogenic

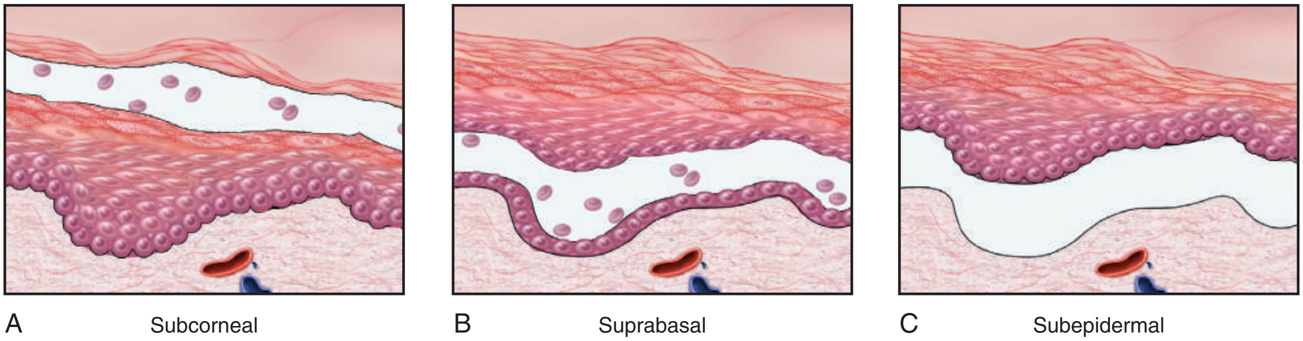

Fig. 24.8 Levels of blister formation. (A) Subcorneal (as in pemphigus foliaceus). (B) Suprabasal (as in pemphigus vulgaris). (C) Subepidermal (as in bullous pemphigoid or dermatitis herpetiformis).

mechanisms, but differ in their clinical presentation and course due to variation in the location of the target antigen (hemidesmosomes in bullous pemphigoid, desmosomes in pemphigus).

MORPHOLOGY

Bullous pemphigoid is associated with tense **subepidermal bullae** filled with clear fluid (Fig. 24.12B). The overlying epidermis characteristically lacks acantholysis. Early lesions show variable numbers of eosinophils at the dermal-epidermal junction, occasional neutrophils, superficial dermal edema, and associated basal cell layer vacuolization. The vacuolated basal cell layer eventually gives rise to a fluid-filled blister (Fig. 24.12C). The blister roof consists of full-thickness epidermis with intact intercellular junctions, a key distinction from the blisters seen in pemphigus.

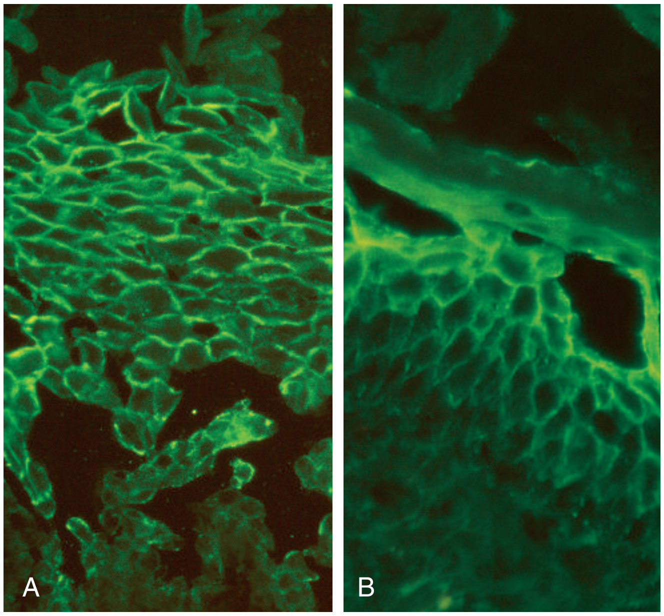

Fig. 24.9 Direct immunofluorescence findings in pemphigus. (A) Pemphigus vulgaris. Note the uniform deposition of immunoglobulin *(green)* along keratinocyte cell membranes in a characteristic "fishnet" pattern. (B) Pemphigus foliaceus. Immunoglobulin deposits are confined to superficial layers of the epidermis.

Clinical Features

The lesions of bullous pemphigoid do not rupture as readily as in pemphigus and, if uncomplicated by infection, heal without scarring. The disease tends to follow a remitting and relapsing course and responds to topical or systemic immunosuppressive agents. Gestational pemphigoid (also known as *herpes gestationis*, a misnomer since there is no

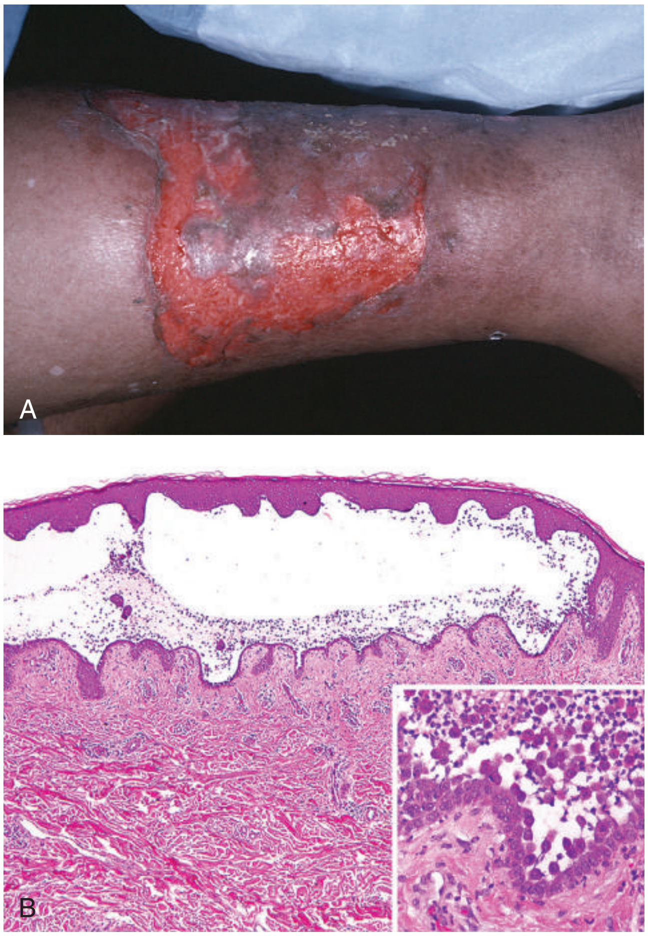

Fig. 24.10 Pemphigus vulgaris. (A) An erosion on the leg arising from coalescence of a group of "unroofed" blisters. (B) Suprabasal intraepidermal blister in which rounded, dissociated (acantholytic) keratinocytes are plentiful *(inset)*.

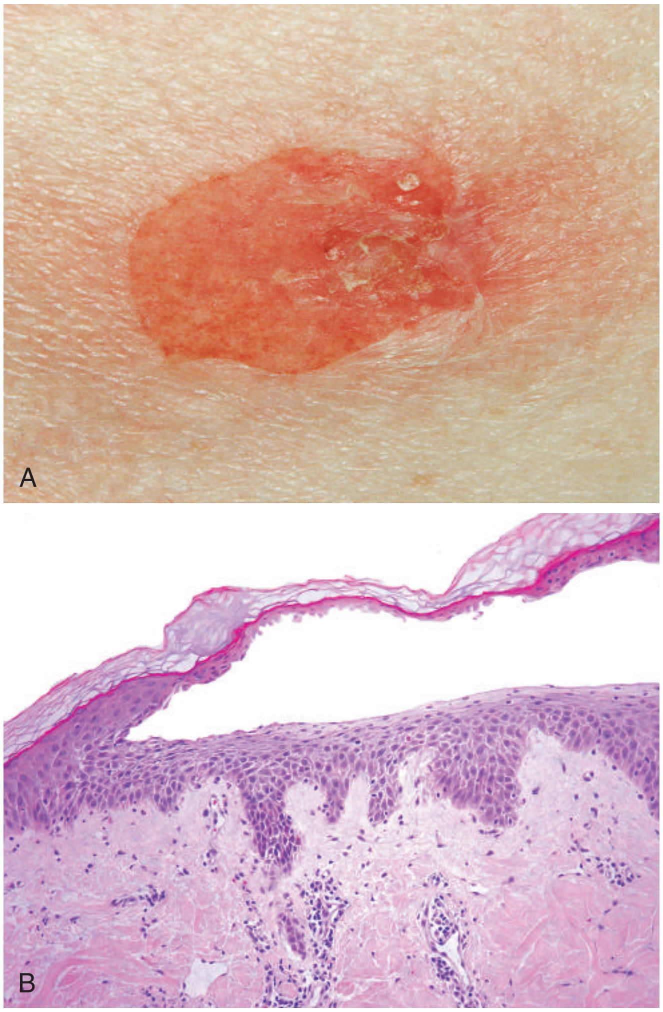

Fig. 24.11 Pemphigus foliaceus. (A) A typical blister, which is more superficial than those seen in pemphigus vulgaris. (B) Microscopic appearance of a characteristic subcorneal blister.

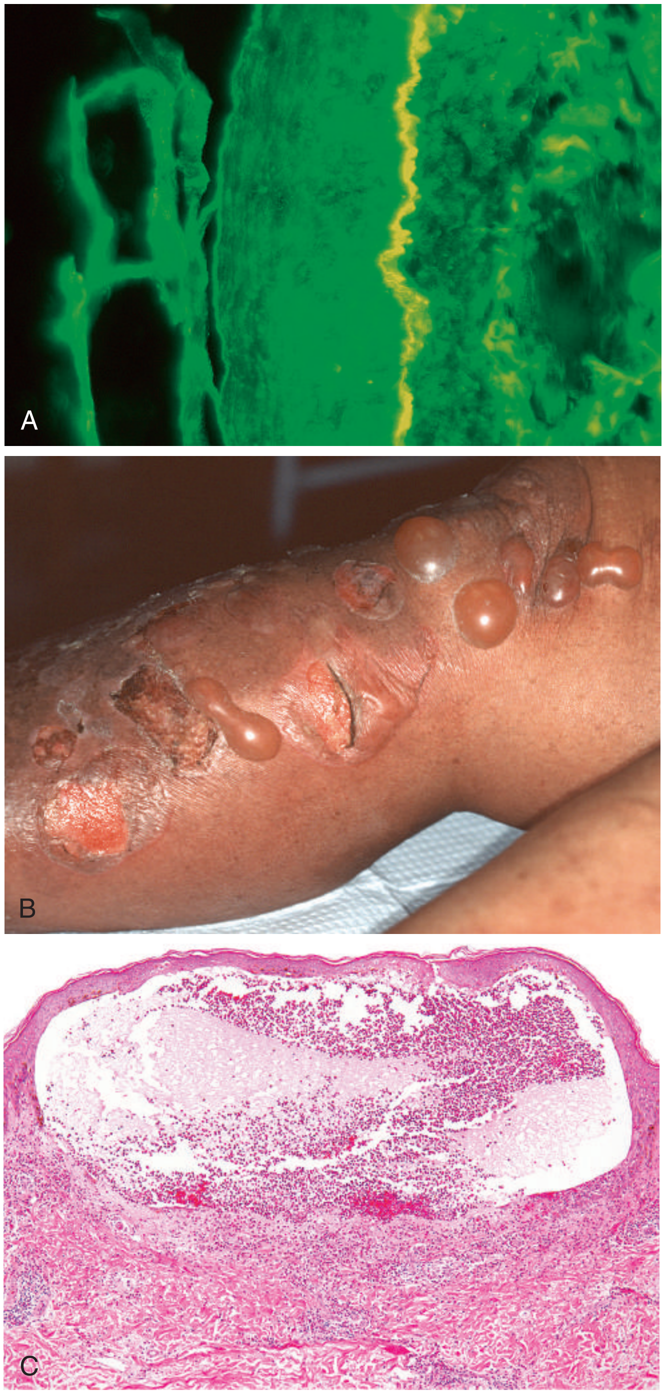

Fig. 24.12 Bullous pemphigoid. (A) Deposition of IgG antibody (detected by direct immunofluorescence) in the subepidermal basement membrane (epidermis is on the left side of the fluorescent band). (B) Gross appearance of characteristic tense, fluid-filled blisters. (C) Subepidermal vesicle with an eosinophil-rich inflammatory infiltrate. *(C, Courtesy of Dr. Victor G. Prieto, Houston, Texas.)*

viral etiology) is a clinically distinct subtype that appears suddenly during the second or third trimester of pregnancy. It also is caused by autoantibodies against bullous pemphigoid antigen. Gestational pemphigoid typically resolves after childbirth, but may recur with subsequent pregnancies.

Dermatitis Herpetiformis

Dermatitis herpetiformis is an autoimmune blistering disorder associated with gluten sensitivity that is characterized by extremely pruritic grouped vesicles and papules. The disease affects predominantly males, often in the third and fourth decades of life. Up to 80% of cases are associated with celiac disease; conversely, only a small fraction of patients with celiac disease develop dermatitis herpetiformis. Like celiac disease, dermatitis herpetiformis responds to a gluten-free diet.

Pathogenesis

The strong association of dermatitis herpetiformis with celiac disease provides a clue to its pathogenesis. Genetically predisposed individuals develop IgA antibodies to dietary gluten (derived from the wheat protein gliadin) as well as IgA autoantibodies that cross-react with endomysium and tissue transglutaminases, including epidermal transglutaminase expressed by keratinocytes. By direct immunofluorescence, the skin shows discontinuous,

granular deposits of IgA selectively localized in the tips of dermal papillae (Fig. 24.13A). The resultant injury and inflammation produce a subepidermal blister.

MORPHOLOGY

The lesions of dermatitis herpetiformis are bilateral, symmetric, and grouped and preferentially involve the extensor surfaces, elbows, knees, upper back, and buttocks (Fig. 24.13B). Initially, neutrophils accumulate selectively at the **tips of dermal papillae,** forming small microabscesses (Fig. 24.13C). The basal cells overlying these microabscesses show vacuolization and focal dermoepidermal separation that ultimately coalesce to form a true **subepidermal blister.**

SUMMARY

BLISTERING DISORDERS

- Blistering disorders are classified based on the level of the epidermis that is affected.
- These disorders often are caused by autoantibodies specific for epithelial or basement membrane proteins that lead to unmooring of keratinocytes (acantholysis).
- Pemphigus is associated with IgG autoantibodies to various intercellular desmogleins (part of the desmosome), resulting in bullae that are either subcorneal (pemphigus foliaceus) or suprabasilar (pemphigus vulgaris).
- Bullous pemphigoid is associated with IgG autoantibodies to basement membrane proteins (part of the hemidesmosome) and produces a subepidermal blister.
- Dermatitis herpetiformis is associated with IgA autoantibodies to transglutaminase, and also is characterized by subepidermal blisters.

TUMORS OF THE SKIN

Benign and Premalignant Epithelial Lesions

Benign epithelial neoplasms are common and probably arise from stem cells residing in the epidermis and hair follicles. These tumors grow to a limited size and generally do not undergo malignant transformation.

Seborrheic Keratosis

These common pigmented epidermal tumors occur most frequently in middle-age or older individuals. They arise spontaneously and are particularly numerous on the trunk, although the extremities, head, and neck also may be sites of involvement.

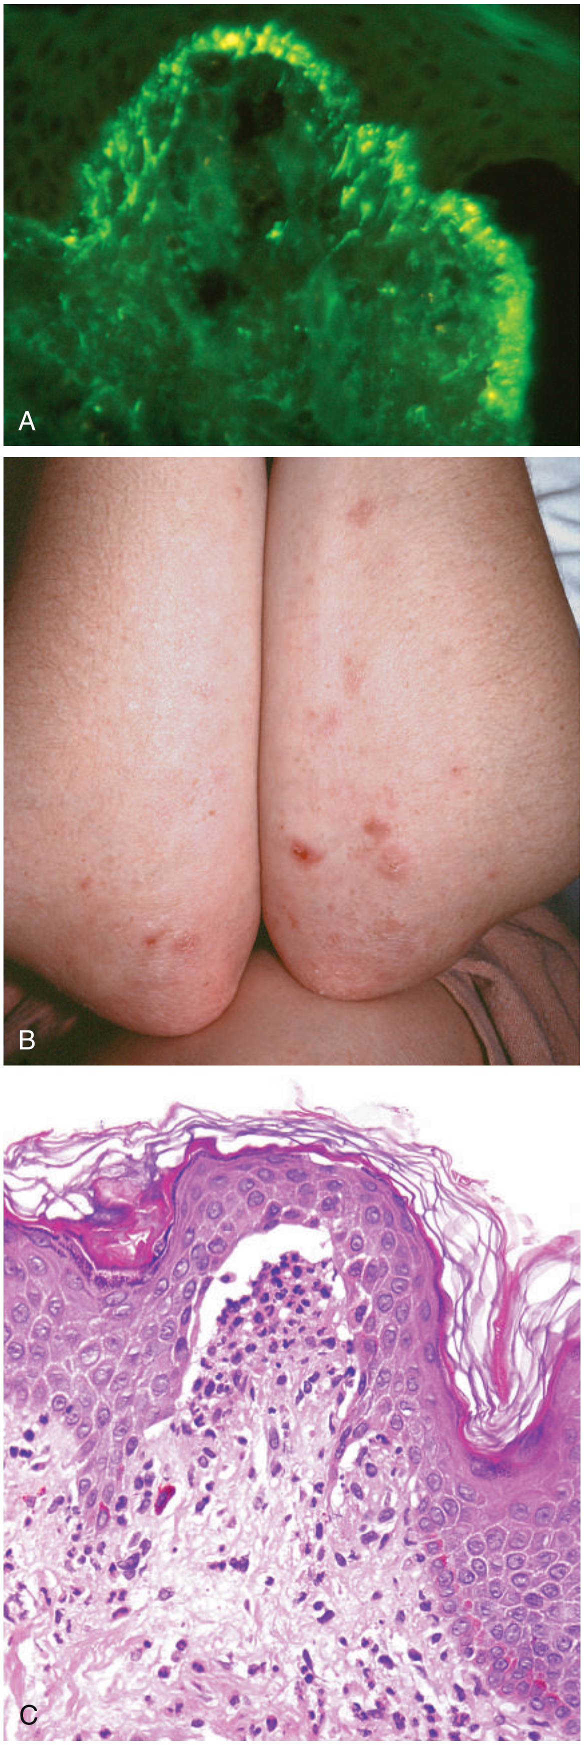

Fig. 24.13 Dermatitis herpetiformis. (A) Characteristic selective deposition of IgA autoantibody at the tips of the dermal papillae. (B) Lesions consist of intact and eroded (usually scratched) erythematous blisters, often grouped (seen here on elbows and arms). (C) Blisters associated with basal cell layer injury, initially caused by accumulation of neutrophils (microabscesses) at the tips of the dermal papillae. *(A, Courtesy of Dr. Victor G. Prieto, Houston, Texas.)*

Seborrheic keratoses are caused by acquired activating mutations in growth factor signaling pathways. A significant fraction of these tumors harbor activating mutations in fibroblast growth factor receptor 3 (FGFR3), which possesses a tyrosine kinase activity that stimulates RAS and the PI3K/AKT pathway, while others have activating mutations in downstream pathway components such as RAS and PI3K. Except for cosmetic concerns, seborrheic keratoses are usually of little clinical importance. However, in rare patients hundreds of lesions may appear suddenly as a paraneoplastic syndrome *(sign of Leser-Trelat).* Patients with this presentation may harbor internal malignancies, most commonly gastrointestinal tract carcinomas, which produce growth factors that stimulate epidermal proliferation.

MORPHOLOGY

Seborrheic keratoses are **round, exophytic, coinlike plaques** that vary in diameter from millimeters to centimeters and have a **"stuck-on"** appearance (Fig. 24.14, *inset*). They are tan to dark brown and have a velvety- to granular-appearing surface. Occasionally, their dark color is suggestive of melanoma, leading to surgical removal.

Microscopically, seborrheic keratoses are composed of monotonous sheets of small cells that resemble the basal cells of the normal epidermis (see Fig. 24.14). Variable melanin pigmentation is present within these basaloid cells, accounting for the brown coloration seen grossly. Hyperkeratosis occurs at the surface, and the presence of small keratin-filled cysts (horn cysts) and downgrowth of keratin into the main tumor mass (pseudo–horn cysts) are characteristic features.

Actinic Keratosis

Actinic keratosis is a premalignant lesion caused by UV-induced DNA damage that is associated with mutations in *TP53* and other genes that also are frequently mutated in squamous cell carcinoma of the skin. Because such lesions usually are the result of chronic exposure to sunlight and are associated with hyperkeratosis, they are called *actinic* (sun-related) *keratoses*. The rate of progression to squamous cell carcinoma is small, varying from 0.1% to 2.6% per year. Most regress or remain stable.

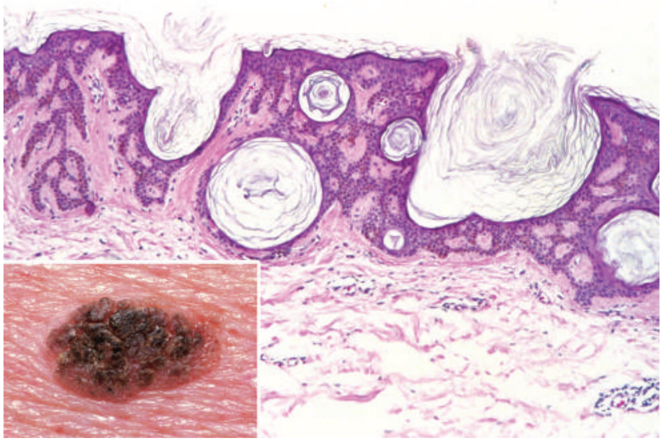

Fig. 24.14 Seborrheic keratosis. A characteristic roughened, brown, waxy lesion that appears to be "stuck on" the skin *(inset).* Microscopic examination shows an orderly proliferation of uniform, basaloid keratinocytes that tend to form keratin microcysts (horn cysts).

MORPHOLOGY

Actinic keratoses usually are less than 1 cm in diameter, tan-brown or red, and rough (sandpaper-like) to the touch (Fig. 24.15A). Microscopically, lower portions of the epidermis show **cytologic atypia,** often associated with hyperplasia of basal cells (see Fig. 24.15B) or with atrophy and diffuse thinning of the epidermal surface. The dermis contains thickened, blue-gray elastic fibers (solar elastosis), the result of chronic sun damage. The stratum corneum is thickened and shows abnormal retention of nuclei (parakeratosis). Uncommonly, full-thickness epidermal atypia is seen; such lesions are considered squamous cell carcinoma in situ (Fig. 24.15C).

Clinical Features

Actinic keratoses are very common in fair-skinned individuals and increase in incidence with age and sun exposure. As would be expected, there is a predilection for sun-exposed areas (face, arms, dorsum of the hands). Despite the low risk for malignant progression, actinic keratoses are often treated, either to prevent progression or for cosmetic reasons. Local eradication with cryotherapy (superficial freezing) or topical agents is effective and safe.

SUMMARY

BENIGN AND PREMALIGNANT EPITHELIAL LESIONS

- *Seborrheic keratosis:* Round, flat plaques made up of proliferating monotonous epidermal basal cells, which sometimes contain melanin. Hyperkeratosis and keratin-filled cysts are characteristic.
- *Actinic keratosis:* Present on sun-exposed skin, these lesions show cytologic atypia in lower parts of the epidermis and infrequently progress to carcinoma in situ.
- Although both of these lesions are associated with oncogenic mutations, malignant transformation is exceedingly rare in seborrheic keratoses and occurs in only a small subset of actinic keratoses.

Malignant Epidermal Tumors

Squamous Cell Carcinoma

Squamous cell carcinoma is a common tumor that typically arises on sun-exposed sites in older adults. These tumors have a higher incidence in men than in women.

Pathogenesis

Cutaneous squamous cell carcinoma is mainly caused by UV light exposure, which leads to widespread DNA damage and extremely high mutational loads (Chapter 6). As one might imagine, patients with the rare disorder *xeroderma pigmentosum,* which disrupts repair of UV-induced DNA damage, are at an exceptionally high risk. *TP53*

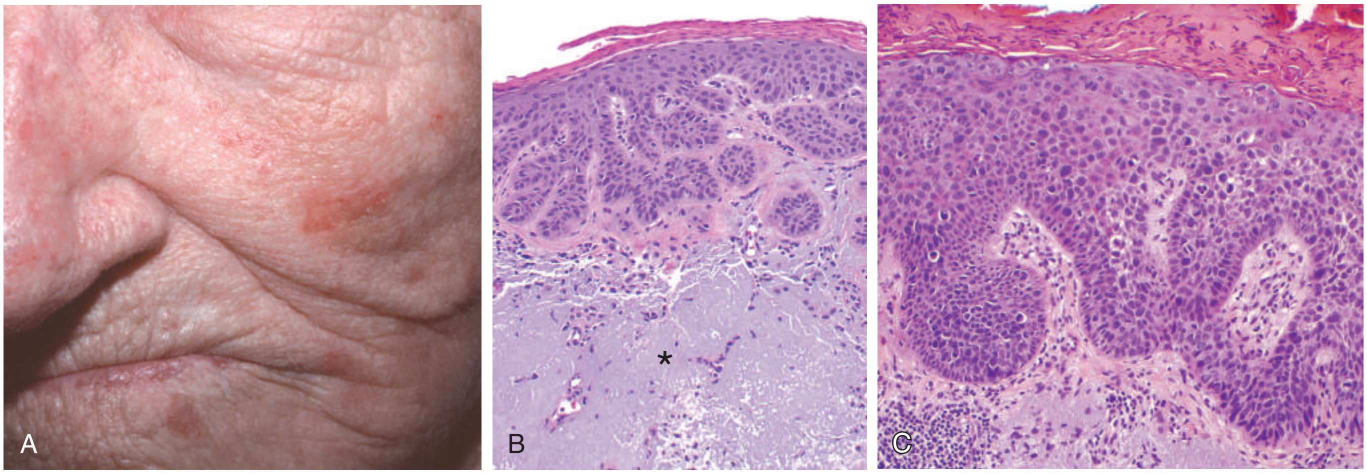

Fig. 24.15 Actinic keratosis. (A) Red, rough (sandpaper-like) lesions owing to excessive scale are present on the cheek and nose. (B) Basal cell layer atypia (dysplasia) with epithelial buds associated with marked hyperkeratosis, parakeratosis, and dermal solar elastosis *(asterisk)*. (C) Squamous cell carcinoma in situ lesion showing full-thickness epithelial atypia.

mutations are common, as are activating mutations in *RAS* and loss-of-function mutations in Notch receptors, which transmit signals that regulate the orderly differentiation of normal squamous epithelia.

Immunosuppression, particularly in organ transplant recipients, is associated with an increased incidence of cutaneous squamous cell carcinomas that are likely to be associated with HPV infection. Other predisposing factors include industrial carcinogens (tars and oils), chronic non-healing ulcers, old burn scars, ingestion of arsenicals, and ionizing radiation.

MORPHOLOGY

Squamous cell carcinomas in situ appear as sharply defined, red, scaling plaques; some appear to arise in association with prior actinic keratoses. Microscopically, squamous cell carcinoma in situ is characterized by highly atypical cells at all levels of the epidermis, with nuclear crowding and disorganization. More advanced, invasive squamous cell carcinomas are nodular, often scaly lesions that may undergo ulceration (Fig. 24.16A). Such tumors show variable degrees of differentiation, ranging from tumors with cells arranged in orderly lobules that exhibit extensive keratinization to neoplasms consisting of highly anaplastic cells with foci of necrosis and only abortive, single-cell keratinization (dyskeratosis) (Fig. 24.16B).

Clinical Features

Invasive squamous cell carcinomas of the skin often are discovered while small and resectable. Less than 1% will have metastasized to regional lymph nodes at diagnosis. The likelihood of metastasis is related to the thickness of the lesion and degree of invasion into the subcutis. Tumors arising from actinic keratoses may be locally aggressive but generally metastasize only after long periods of time, while those arising in burn scars, ulcers, and non–sun-exposed skin often behave more aggressively. Squamous cell carcinomas arising at internal sites (oropharynx, lung, esophagus, anus) are generally invasive and aggressive, possibly because (unlike in the skin) early lesions go unrecognized.

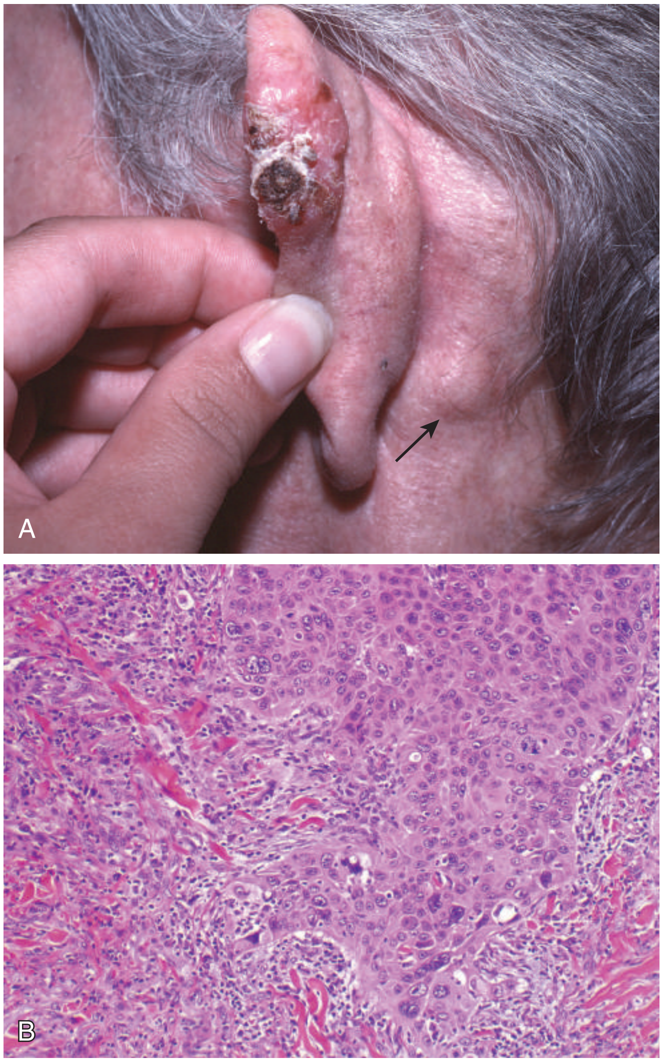

Fig. 24.16 Invasive squamous cell carcinoma. (A) A nodular, hyperkeratotic lesion occurring on the ear, associated with metastasis to a prominent postauricular lymph node *(arrow)*. (B) Tumor invades the dermal soft tissue as irregular projections of atypical squamous cells exhibiting acantholysis.

Basal Cell Carcinoma

Basal cell carcinoma is a common slow-growing cancer that rarely metastasizes. It tends to occur at sites subject to chronic sun exposure and in lightly pigmented individuals.

Pathogenesis

The molecular hallmark of basal cell carcinoma is loss-of-function mutations in *PTCH1*, a tumor suppressor gene that negatively regulates Hedgehog signaling; hence, tumors exhibit constitutive Hedgehog pathway activation. Excessive activation of Hedgehog in turn activates a host of downstream genes implicated in cell growth and survival and other phenotypes linked to malignant transformation. In sporadic basal cell carcinoma, *PTCH1* mutations bear the telltale signs of UV light–induced DNA damage. The central role of increased Hedgehog signaling in basal cell carcinoma is further emphasized by *Gorlin syndrome,* an autosomal dominant disorder caused by inherited defects in *PTCH1* that is associated with familial basal cell carcinoma. The Hedgehog pathway is an important regulator of embryonic development, and patients with Gorlin syndrome also often manifest subtle developmental anomalies. Mutations in *TP53* caused by UV light–induced damage also are common in both familial and sporadic tumors.

MORPHOLOGY

Basal cell carcinomas manifest as **pearly papules**, often with prominent, dilated subepidermal blood vessels **(telangiectasia)** (Fig. 24.17A). Some tumors contain melanin pigment and can have an appearance similar to melanocytic nevi or melanomas. Microscopically, the tumor cells resemble the normal epidermal basal cell layer or follicular germinative elements. Because they arise from either the epidermis or the follicular epithelium, they are not encountered on mucosal surfaces. Two common patterns are seen: **multifocal superficial growths,** originating from the epidermis, and **nodular lesions** growing downward into the dermis as cords and islands of variably basophilic cells with hyperchromatic nuclei, embedded in a fibrotic or mucinous stromal matrix (Fig. 24.17B). Peripheral tumor cell nuclei align in the outermost layer (a pattern termed *palisading*), which often separates from the stroma, creating a characteristic cleft (Fig. 24.17C).

Clinical Features

It is estimated that more than 1 million basal cell carcinomas are treated in the United States annually. By far the most important risk factor is cumulative sun exposure; basal cell carcinoma is more common in warm southern regions of the United States, and its incidence is 40-fold higher in sunny climates near the equator, such as Australia, than it is in Northern European locales. Individual tumors usually are cured by local excision, but approximately 40% of patients develop another basal cell carcinoma within 5 years. Advanced lesions may ulcerate, and extensive local invasion of bone or facial sinuses may occur if the lesions are neglected. Metastasis is exceedingly rare. Hedgehog pathway inhibitors are used to treat locally advanced or metastatic tumors.

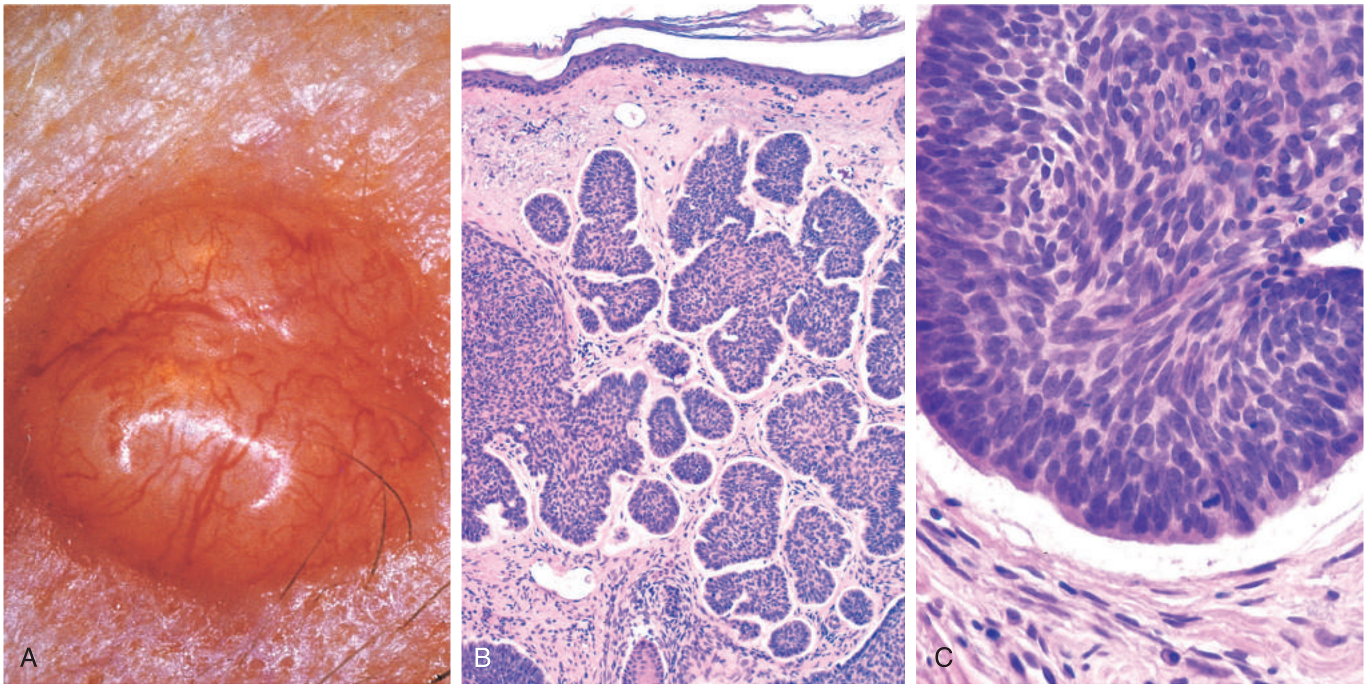

Fig. 24.17 Basal cell carcinoma. (A) A prototypical pearly, smooth-surfaced papule with telangiectatic vessels. (B) Tumor is composed of nests of basaloid cells infiltrating a fibrotic stroma. (C) Tumor cells with scant cytoplasm and small hyperchromatic nuclei that palisade on the outside of the nest. The cleft between the tumor cells and the stroma is a highly characteristic artifact of sectioning.

SUMMARY

MALIGNANT EPIDERMAL TUMORS

- The incidence of both basal cell and squamous cell carcinoma is strongly correlated with increasing lifetime sun exposure.
- Risk factors for cutaneous squamous cell carcinoma include fair skin, UV light exposure, exposure to carcinogenic chemicals, chronic skin inflammation and scarring, and HPV infection (in the setting of immunosuppression).
- Cutaneous squamous cell carcinoma has the potential for metastasis but usually is recognized and excised before it does so.
- Basal cell carcinoma, the most common malignancy worldwide, is a locally aggressive tumor associated with mutations in the Hedgehog pathway. Metastasis is very rare.

Melanocytic Proliferations

Melanocytic Nevi

Strictly speaking, the term *nevus* denotes any congenital lesion of the skin. *Melanocytic* nevus, however, refers to any benign congenital or acquired neoplasm of melanocytes.

Pathogenesis

Melanocytic nevi are benign neoplasms caused by somatic gain-of-function mutations in *BRAF* or *RAS*. Nevi are derived from melanocytes, pigment-producing cells with dendritic projections that are normally interspersed among basal keratinocytes. You will recall that *BRAF* encodes a serine/threonine kinase that lies downstream of RAS in the extracellular regulated kinase (ERK) pathway. Experimental evidence suggests that unbridled BRAF/RAS signaling initially induces melanocytic proliferation followed by senescence. How these opposing effects are coordinated is unclear, but it is believed that the "brake" on proliferation provided by induced senescence explains why very few nevi transform into malignant melanomas. Indeed, the growth and migration of nevus cells from the dermoepidermal junction into the underlying dermis is accompanied by morphologic changes that are taken as evidence of cellular senescence (Fig. 24.18). Superficial nevus cells are larger and tend to produce melanin pigment and grow in nests; deeper nevus cells are smaller, produce little or no pigment, and grow in cords or single cells. The deepest nevus cells have fusiform contours and grow in fascicles. This sequence of morphologic changes is of diagnostic importance, since they are absent from melanomas.

MORPHOLOGY

Common melanocytic nevi are tan-to-brown, uniformly pigmented, small papules (5 mm or less across) with well-defined, rounded borders (Fig. 24.19A). Early lesions are composed of round to oval cells that grow in "nests" along the dermoepidermal junction. Nuclei are uniform and round, and contain inconspicuous nucleoli with little or no mitotic activity. Such early-stage lesions are called **junctional nevi.** Eventually, most junctional nevi grow into the underlying dermis as nests or cords of cells **(compound nevi),** and in older lesions the epidermal nests may be lost entirely, creating **intradermal nevi** (Fig. 24.19B).

Clinical Features

There are numerous types of melanocytic nevi, with varied appearances. Although these lesions usually are of only cosmetic concern, they may cause irritation or mimic melanoma, requiring their surgical removal. Compound and intradermal nevi often are more elevated than junctional nevi.

Dysplastic Nevus

Dysplastic nevi may be sporadic or familial. The latter are important clinically because they identify individuals who

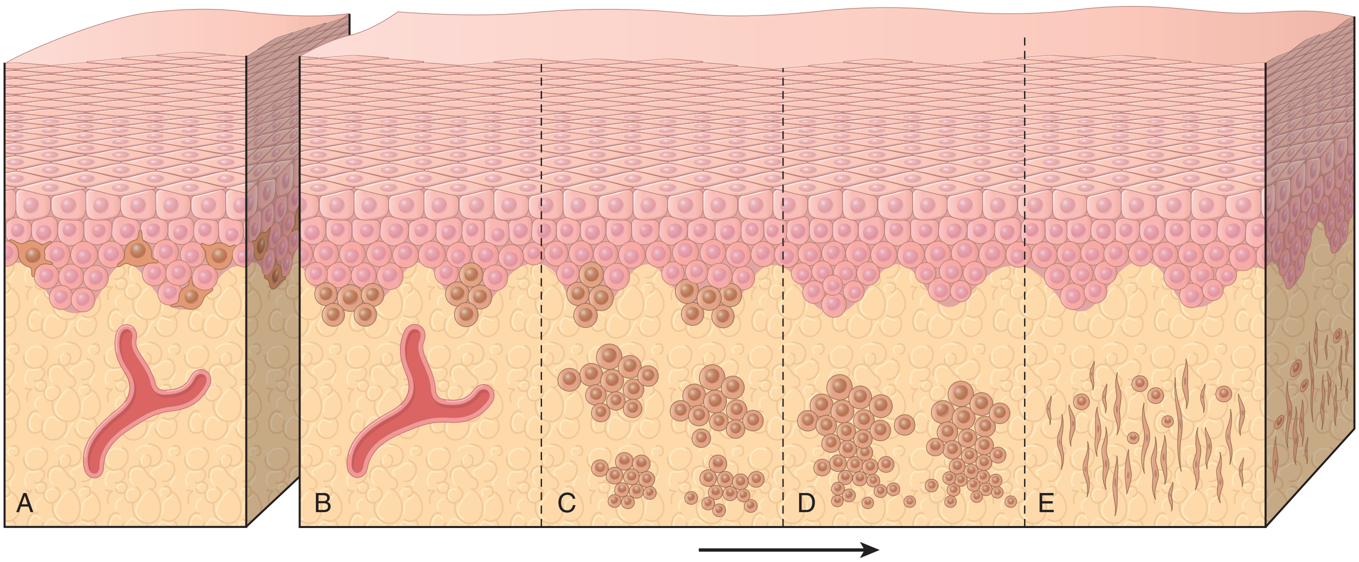

Fig. 24.18 Possible steps in the development of melanocytic nevi. (A) Normal skin shows only scattered melanocytes. (B) Junctional nevus. (C) Compound nevus. (D) Intradermal nevus. (E) Intradermal nevus with extensive cellular senescence.

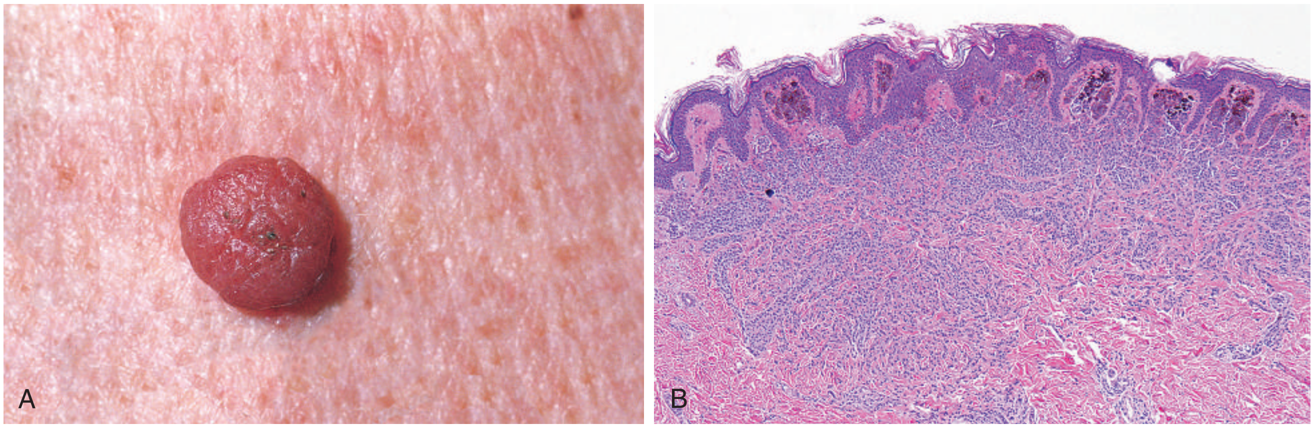

Fig. 24.19 Melanocytic nevus. (A) Melanocytic nevi are relatively small, symmetric, and uniformly pigmented. (B) A nevus composed of melanocytes that lose pigmentation and become smaller and more dispersed as they extend into the dermis—all signs that speak to the benign nature of the proliferation.

have an increased risk of developing melanoma. As with conventional melanocytic nevi, activating *RAS* or *BRAF* mutations are commonly found in dysplastic nevi and are believed to have a pathogenic role.

MORPHOLOGY

Dysplastic nevi are larger than most acquired nevi (often more than 5 mm across) and **may number in the hundreds** (Fig. 24.20A). They are flat macules to slightly raised plaques, with a "pebbly" surface. They usually have variable pigmentation (variegation) and irregular borders (Fig. 24.20A, *inset*).

Microscopically, dysplastic nevi are mostly compound nevi that exhibit both architectural and cytologic evidence of abnormal growth. Nevus cell nests within the epidermis may be enlarged and exhibit abnormal fusion or coalescence with adjacent nests (bridging). As part of this process, single nevus cells begin to replace the normal basal cell layer along the dermoepidermal junction, producing so-called "**lentiginous hyperplasia**" (Fig. 24.20B). Cytologic atypia consisting of irregular, often angulated, nuclear contours and hyperchromasia is frequently observed (Fig. 24.20B-C). Associated alterations also occur in the superficial dermis. These consist of a sparse lymphocytic infiltrate, release of melanin pigment that is phagocytosed by dermal macrophages (melanin incontinence), and linear fibrosis surrounding epidermal nests of melanocytes. These dermal changes are elements of the host response to these lesions.

Clinical Features

Unlike ordinary nevi, dysplastic nevi have a tendency to occur on body surfaces not exposed to the sun as well as on sun-exposed sites. *Familial dysplastic nevus syndrome* is strongly associated with melanoma, as the lifetime risk for the development of melanoma in affected individuals is close to 100%. In sporadic cases, only individuals with 10 or more dysplastic nevi appear to be at an increased

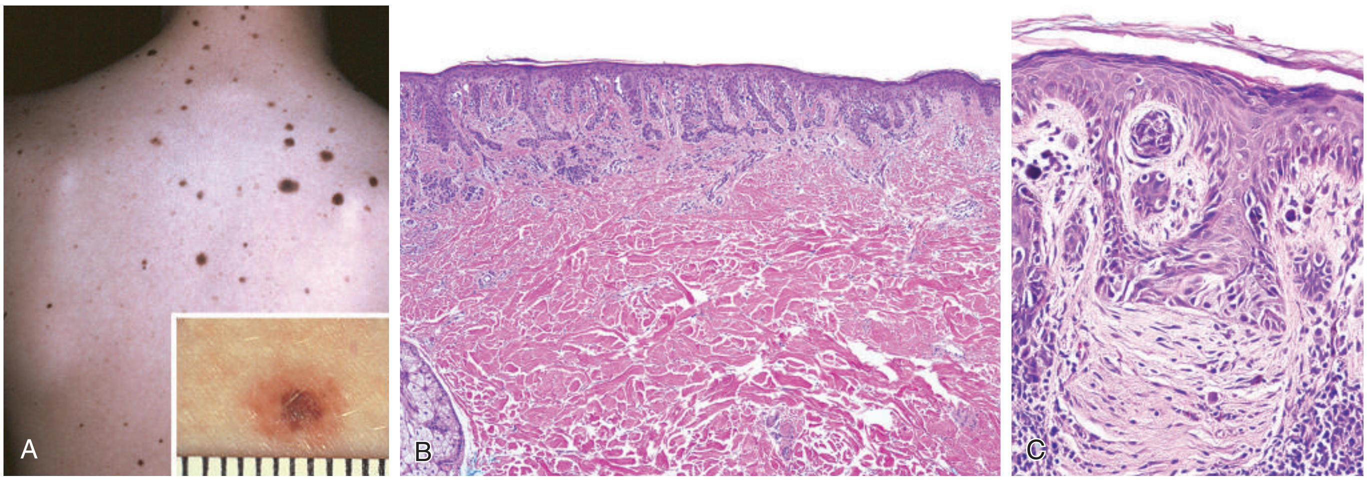

Fig. 24.20 Dysplastic nevus. (A) Numerous irregular nevi on the back of a patient with dysplastic nevus syndrome. The lesions usually are greater than 5 mm in diameter and have irregular borders and variable pigmentation *(inset).* (B) Compound dysplastic nevus featuring a central dermal component and an asymmetric "shoulder" of exclusively junctional melanocytes (lentiginous hyperplasia). The former corresponds to the raised, more pigmented central zone seen in *A (inset)*, and the latter corresponds to the less pigmented flat peripheral rim. (C) Other important features are cytologic atypia (irregular, dark-staining nuclei) and characteristic parallel bands of fibrosis.

risk for melanoma. Transformation of dysplastic nevus to melanoma has been documented, both clinically and histologically. However, such cases are the exception, as most melanomas appear to arise *de novo* and not from a preexisting nevus. Thus, the likelihood that any particular nevus, dysplastic or otherwise, will develop into melanoma is low, and these lesions are best viewed as markers of melanoma risk.

Melanoma

Melanoma is less common but much more deadly than basal or squamous cell carcinoma. Today, as a result of increased public awareness of the earliest signs of skin melanomas, most melanomas are cured surgically. Nonetheless, the incidence of these lesions has increased dramatically over the past several decades, at least in part as a result of increasing sun exposure and/or higher detection rates resulting from vigorous surveillance.

Pathogenesis

As with other cutaneous malignancies, melanoma is mainly caused by UV light–induced DNA damage that leads to the stepwise acquisition of driver mutations. The incidence is highest in sun-exposed skin and in geographic locales such as Australia, where sun exposure is high and much of the population is fair-skinned. Intense intermittent exposure at an early age is particularly harmful. Hereditary predisposition also plays a role in an estimated 5% to 10% of cases, as already discussed under familial dysplastic nevus syndrome. For example, germ-line mutations in the *CDKN2A* locus (located on 9p21) are found in as many as 40% of the rare individuals who suffer from familial melanoma. This complex locus encodes two tumor suppressors: p16, a cyclin-dependent kinase inhibitor that regulates the G_1-S transition of the cell cycle by maintaining the retinoblastoma (RB) tumor suppressor protein in its active state; and p14, which augments the activity of the p53 tumor suppressor by preventing its degradation.

Key phases of melanoma development are marked by radial and vertical growth. The earliest recognizable phase of melanoma development is proposed to consist of lateral expansion of melanocytes along the dermoepidermal junction (lentiginous hyperplasia and lentiginous compound nevus; Fig. 24.21A-C). This then progresses to the phase of melanoma in situ, which is marked by *radial growth* within the epidermis, often for a prolonged period (Fig. 24.21D). During this stage, melanoma cells do not have the capacity to invade and metastasize. With time, a *vertical growth phase* supervenes, in which the tumor grows downward into the deeper dermal layers as an expansile mass lacking cellular maturation (Fig. 24.21E). This event often is heralded by the development of a nodule in a previously flat lesion and correlates with the emergence of metastatic potential.

DNA sequencing of familial and sporadic cases, including cases that appear to have arisen from benign nevi, has provided important insights into the molecular pathogenesis of melanoma (Fig. 24.22). The initiating event appears to be an activating mutation in *BRAF* or (less commonly) *RAS*. In the vast majority of cases, this produces only a benign nevus unless other mutations are superimposed. Sequencing of nevi with "atypical" morphologic features suggestive of melanoma as well as melanomas in the radial phase of growth (melanoma in situ) has shown that they commonly harbor mutations that activate the expression of telomerase, which is proposed to serve as an antidote to senescence (the usual fate of benign nevi). With additional mutations or epigenetic aberrations that lead to loss of

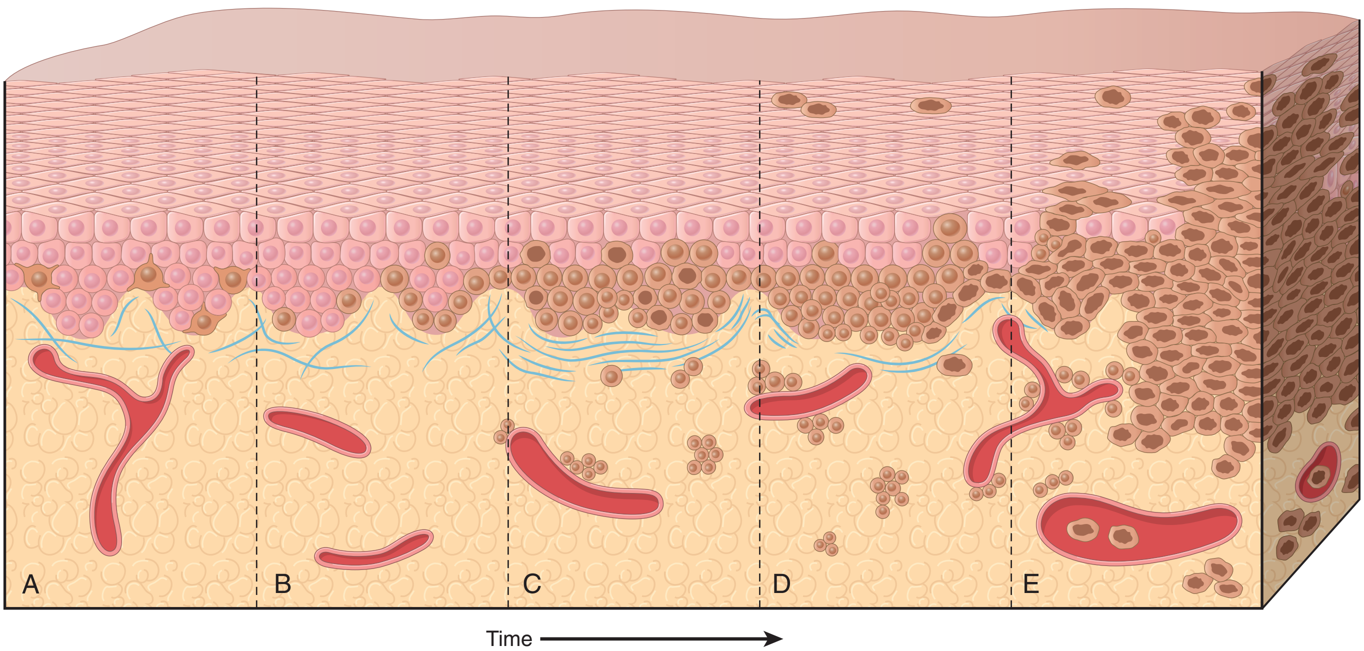

Fig. 24.21 Possible steps in the development of melanoma. (A) Normal skin shows only scattered melanocytes. (B) Lentiginous melanocytic hyperplasia. (C) Lentiginous compound nevus with abnormal architecture and cytologic features (dysplastic nevus). (D) Early or radial growth phase melanoma (large dark cells in epidermis) arising in a nevus. (E) Melanoma in vertical growth phase with metastatic potential. Note that no melanocytic nevus precursor is identified in most cases of melanoma. They are believed to arise de novo, perhaps all using the same pathway.

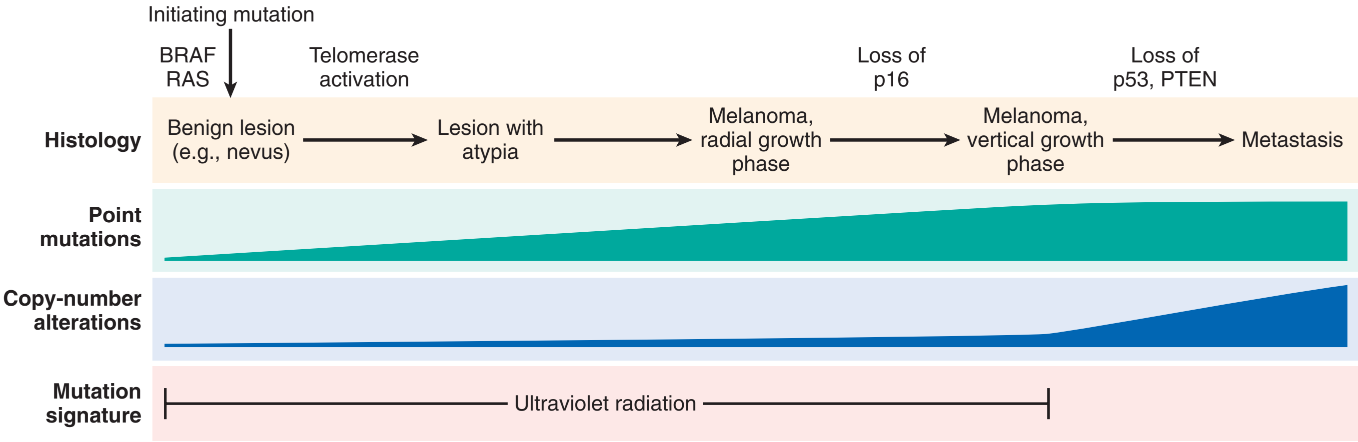

Fig. 24.22 Molecular evolution of cutaneous melanoma. The most important driver mutations and the overall mutational burden (point mutations and genomic copy-number variations) at various histologic phases of melanocytic lesion progression are indicated. Note that as the tumor metastasizes to internal sites, UV light–induced DNA damage leading to point substitutions ceases, and copy number changes related to aneuploidy increase.

CDNK2A and its encoded tumor suppressor p16, the tumor shifts to the invasive vertical phase of growth. Throughout this cutaneous phase of tumor evolution, exposure to UV light adds to the mutational burden and increases the chances of tumor progression. Finally, with additional mutations in genes such as tumor suppressors *TP53* and *PTEN*, the tumor acquires the capacity for metastasis. This phase is marked by the appearance of aneuploidy and genomic copy number alterations, which add to the genetic heterogeneity of the evolving tumor.

By contrast, the less common melanomas that arise in non–sun-exposed acral and mucosal sites follow different molecular courses. The most common initiating mutation in these tumors is a gain-of-function mutation in the KIT receptor tyrosine kinase. Similarly, melanomas arising the uvea of the eye also have a distinct set of driver gene mutations, most notably mutually exclusive mutations that activate the GTP-binding proteins GNAQ or GNA11.

In addition, it has long been speculated that melanomas express neoantigens that should be subject to recognition by the immune system. It follows that for melanoma to develop, tumor cells must acquire the ability to either suppress or evade the host immune response. **The importance of immune evasion has been proven by the response of many advanced melanomas to immune checkpoint inhibitors, agents that unleash muzzled melanoma-specific T cells, allowing them to attack the tumor** (described later).

MORPHOLOGY

Unlike benign nevi, melanomas often exhibit **striking variations in pigmentation,** including shades of black, brown, red, dark blue, and gray (Fig. 24.23A). The **borders are irregular** and often "notched." Microscopically, malignant cells grow as poorly formed nests or as individual cells at all levels of the epidermis (pagetoid spread) and in expansile dermal nodules; these constitute the radial and vertical growth phases, respectively (Fig. 24.23B-C). Of note, superficial spreading melanomas are often associated with a brisk lymphocytic infiltrate (Fig. 24.23B), a feature that may reflect a host response to tumor-specific antigens. **Increasing thickness strongly correlates with worse biologic behavior of melanomas (termed *Breslow thickness*).** By recording and using these and other variables in aggregate, accurate prognostication is possible.

Individual melanoma cells usually are considerably larger than nevus cells. They have large nuclei with irregular contours, chromatin that is characteristically clumped at the periphery of the nuclear membrane, and prominent "cherry red" eosinophilic nucleoli (Fig. 24.23D). Immunohistochemical stains can be helpful in identifying metastatic deposits (Fig. 24.23D, *inset*).

Clinical Features

Although most of these lesions arise in the skin, they also may occur in the oral and anogenital mucosal surfaces, the esophagus, the meninges, and the eye. The following discussion applies to cutaneous melanomas.

Melanoma of the skin usually is asymptomatic, although pruritus may be an early manifestation. *The most important clinical sign is a change in the color or size of a pigmented lesion.* The main clinical warning signs are as follows:

1. Rapid enlargement of a preexisting nevus
2. Itching or pain in a lesion
3. Development of a new pigmented lesion during adult life
4. Irregularity of the borders of a pigmented lesion
5. Variegation of color within a pigmented lesion

These principles are expressed in the so-called "ABCs" of melanoma: *a*symmetry, *b*order, *c*olor, *d*iameter, and *e*volution (change of an existing nevus). It is vitally important to recognize melanomas and intervene as rapidly as possible. The vast majority of superficial lesions are curable surgically, while metastatic melanoma has a very poor prognosis.

The probability of metastasis is predicted by measuring the depth of invasion in millimeters of the vertical growth phase nodule from the top of the granular cell layer of the overlying epidermis (Breslow thickness). Metastasis risk also is increased in tumors with a high mitotic rate and in those that fail to induce a local immune response. When metastases occur, they involve not only regional lymph

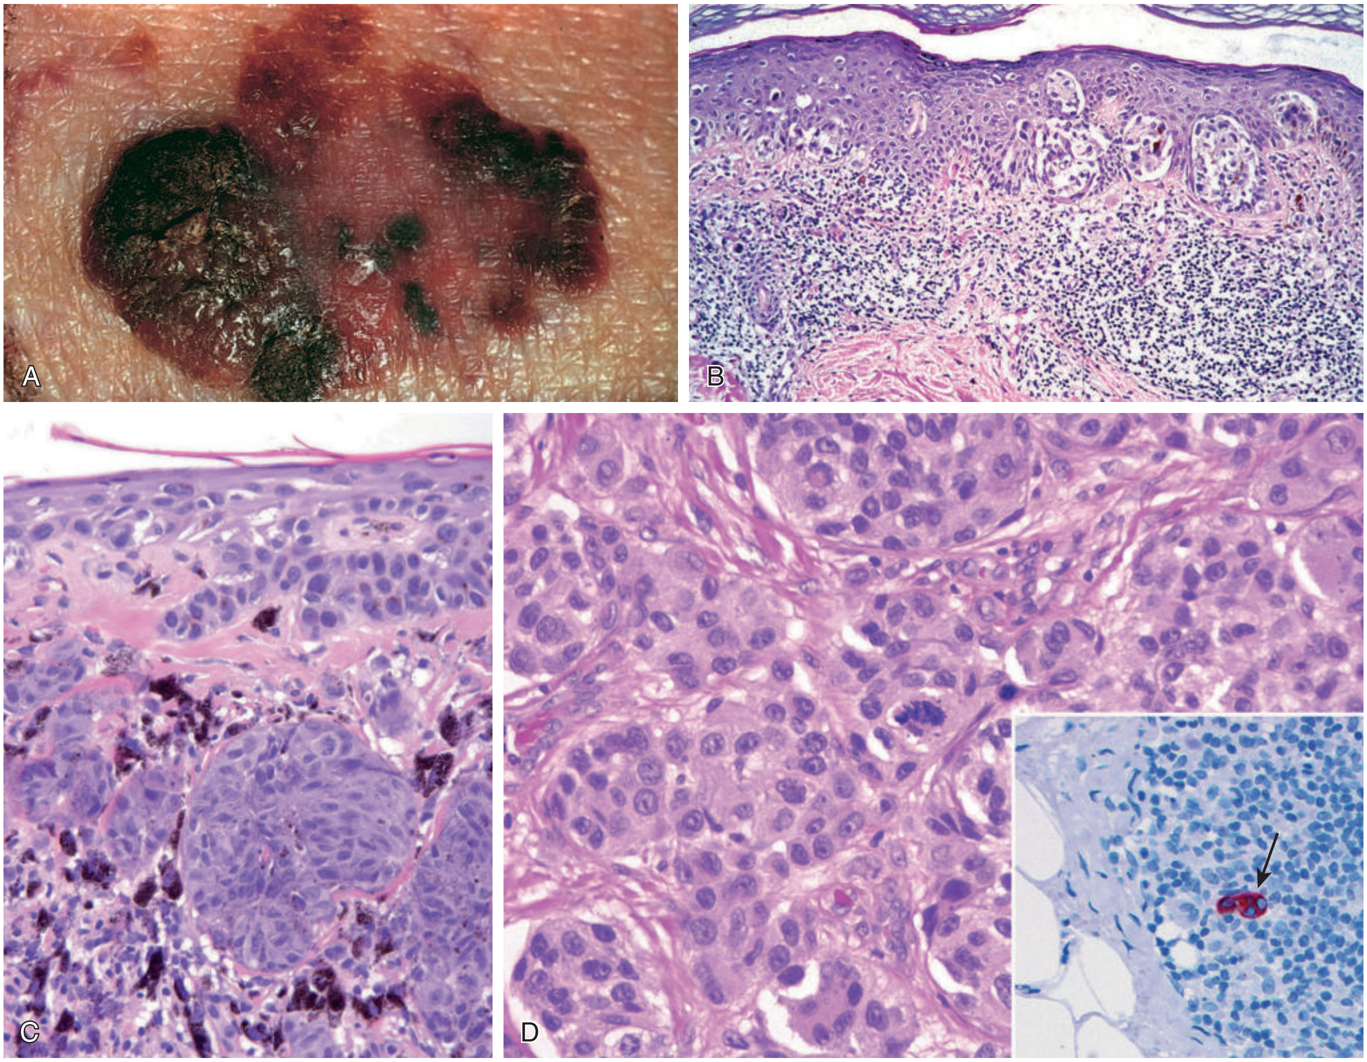

Fig. 24.23 Melanoma. (A) Lesions tend to be larger than nevi, with irregular contours and variable pigmentation. Macular areas indicate superficial (radial) growth, while elevated areas indicate dermal invasion (vertical growth). (B) Radial growth phase, with spread of nested and single melanoma cells within the epidermis. (C) Vertical growth phase, with nodular aggregates of infiltrating tumor cells within the dermis. (D) Melanoma cells with hyperchromatic irregular nuclei of varying size that have prominent nucleoli. An atypical mitotic figure is present in the center of the field). The *inset* shows a sentinel lymph node containing a tiny cluster of metastatic melanoma *(arrow)*, detected by staining for the melanocytic marker HMB-45.

nodes but also liver, lungs, brain, and virtually any other site that can be seeded hematogenously. Sentinel lymph node biopsy (of the first draining node[s] of a primary melanoma) at the time of surgery provides additional information on biologic aggressiveness.

Agents that selectively inhibit mutant BRAF and KIT have produced dramatic responses in patients with metastatic tumors with *BRAF* and *KIT* mutations, respectively, an encouraging development in a previously hopeless disease. More recently, immune checkpoint inhibitors have been shown to be effective at stabilizing metastatic disease and in some instances causing remarkable tumor regression and even clinical remissions. Immune checkpoint inhibitors are antibodies that interfere with the function of proteins found on the surface of T lymphocytes that abrogate cytotoxic T cell responsiveness. By blocking these pathways, checkpoint inhibitors reactivate the host T-cell response, which otherwise is held at bay. Current efforts are focused on building upon these successes by using combinations of different checkpoint inhibitors, as well as checkpoint inhibitors together with other targeted therapies such as BRAF inhibitors.

SUMMARY

MELANOCYTIC LESIONS, BENIGN AND MALIGNANT

- Most *melanocytic nevi* have activating mutations in *BRAF* or less often *NRAS*, but the vast majority never undergoes malignant transformation.
- Most sporadic *dysplastic nevi* are best regarded as markers of melanoma risk rather than premalignant lesions. They are characterized by architectural disorder and cytologic atypia.
- *Melanoma* is a highly aggressive malignancy; tumors only a few millimeters in thickness can give rise to deadly metastases.
- In most cases, melanoma progresses from an intraepithelial (in situ) to an invasive (dermal) form. Characteristics of the dermal tumor such as depth of invasion and mitotic activity correlate with survival.
